Participants/materials, setting, methods: Patients undergoing infertility treatment in 3 clinics were included in this study. Spent media was frozen at -20°C after collection. Metabolites were extracted from the spent media samples (20 µL) using an ultrafiltering approach to remove molecules >3KDa and then run in a UPLC-Fusion Orbitrap MS/MS system which determined the abundance of metabolites in each sample. Different statistical techniques were applied to reduce the huge number of metabolites found to the most informative ones.

Main results and the role of chance: More than 5,550 metabolites were identified and measured.

A first analysis was performed with 129 Sage media samples -30 from pregnant (P) and 99 from non-pregnant cycles (NP)-. A Sage-specific MPI (Metabolite Pregnancy Index) was built with the most informative metabolites to determine pregnancy potential. The non-supervised analysis (not telling the software which sample is pregnant and which is not) identified 100% for P and 63% of for NP. Using supervised analysis, 100% of P samples were identified and 81% of NP samples.

A second analysis was performed with 68 Vitrolife media samples from two different clinics. With the data from the first clinic samples (n=37: 20 P and 17 NP), a Vitrolife-specific MPI (Metabolite Pregnancy Index) was built with the most informative metabolites to determine pregnancy potential. For the first clinic, the analysis showed an ability to predict embryo viability of 100% for P and 88% for NP samples. A blind analysis with a third batch of Vitrolife samples from a second center (n=31: 19P+12NP) showed 78% of P samples were identified and 61% of NP samples.

Limitations, reasons for caution: The study was retrospective, but for one of the centers it was blinded and still yielded high implantation predictability. Nevertheless, a prospective clinical trial is underway. A small limitation of the test is that each culture media has a different subset of informative biomarkers. Other media are being validated.

Wider implications of the findings: This metabolomics test is non-invasive, inexpensive, does not required any change in embryology protocol, and can be combined with NI-PGT and or morphokinetics, having the potential in itself or in combination with other methods to significantly improve embryo selection without causing embryo damage.

Trial registration number: NA

P-206 Differential expression of microRNAs associated with apoptosis and implantation in human in vitro-produced blastocysts following re-vitrification

M. Daneshvar[1], M. Movahedin[1], M. Salehi[2], M. Noruzinia[3]

[1]Tarbiat Modares University, Department of Anatomical Sciences- Faculty of Medical Sciences, Tehran, Iran ;
[2]Shahid Beheshti University of Medical Sciences, Cellular and Molecular Biology Research Center, Tehran, Iran ;
[3]Tarbiat Modares University, Department of Medical Genetics- Faculty of Medical Sciences, Tehran, Iran

Study question: Does re-vitrification affect on the expression of microRNAs involved in apoptosis and implantation of human in vitro-produced blastocysts?

Summary answer: re-vitrification could change the expression of microRNAs involved in apoptosis and implantation of human in vitro-produced blastocysts

What is known already: Numerous studies have been carried out about the effect of vitrification on genetic and epigenetic changes in human embryos, and nowadays Embryo freezing is among useful and safe infertility treatment techniques. Also re-vitrification of the same embryos after thawing has both theoretical and applied cryobiological implications. sometimes, due to the embryologist's discretion, re-vitrification can be applied for good quality supernumerary thawed/warmed embryos that have not been transferred in the present cycle. However, there is almost no study about the effect of re-vitrification on genetic and epigenetics profile in human embryos.

Study design, size, duration: A total of 30 ICSI-derived human embryos were used to evaluate the effect of re-vitrification on miRNAs expression with real-time PCR and DNA fragmentation with TUNEL assay. Embryos were donated from fertile couples referring for family balancing program. Donated embryos were cultured to blastocyst stage and high quality blastocyst (AA-AB) assigned to three groups: fresh, vitrified and re-vitrified. Scoring of blastocysts were according to Gardner et al. (2012) grading system. embryos were collected from 2017-2019.

Participants/materials, setting, methods: Collected Embryos were vitrified on Cryotech carriers, with the method described by Kuwayama. After warming of blastocysts and 4 hours culturing of them, embryos were used individually for Simultaneous RNA extraction and cDNA synthesis. The relative quantification of miRna expression and their target genes expression was carried out by real-time PCR. TUNEL assessment was done using of an in situ cell death detection kit TMR red (Roche, Mannheim, Germany) based on the company's instructions

Main results and the role of chance: The results of this research showed that the re-vitrification of human blastocysts did not affect the ability of their re-expand in culture. A significant decrease in miR-16 and miR-let7a expression in re-vitrified and vitrified group was observed compared to the fresh ($p<0.05$) one. On the other hand, a significant upregulation of the target genes integrin β-3 and BCL2 in the re-vitrified and vitrified embryos was observed comparing with the fresh group ($p<0.05$). The expression of BAX as a pro-apoptotic gene gene showed a significant decrease in re-vitrification group comparing with the fresh one ($P<0.05$). In TUNEL assessment, there was no significance difference in the vitrification and re-vitrification groups compared to the fresh respect to the total number cells and also the apoptotic cell rate ($P > 0.05$)

Limitations, reasons for caution: Clinical investigations are necessary to evaluate the responses of embryos belonging to sub-fertile/infertile couples which may have less resistance potential to stressful situations and show a different response to re-vitrification.

Wider implications of the findings: This study showed that the re-vitrification of embryos changes the expression of genes involved in embryo survival and implantation. therefore, it seems the embryos with high-quality show adaptability and resistance toward stress which this response can include increased expression of anti-apoptotic proteins and genes involved in apoptosis and implantation.

Trial registration number: not applicable

P-207 Interaction of the hippo signaling pathway during bovine follicle activation and growth in vitro

N. Donfack[1], M. Devos[1], P. Vidal[1], I. Demeestere[2]

[1]Research Laboratory on Human Reproduction, Université Libre de Bruxelles, Bruxelles, Belgium ;
[2]Research Laboratory on Human Reproduction, Université Libre de Bruxelles and Obstetrics and Gynaecology- Erasme Hospital, Bruxelles, Belgium

Study question: How does biochemical inhibition of the Hippo pathway affect the activation and the growth of primordial follicles *in vitro*?

Summary answer: MAPK/ERK signaling pathway seems to promote follicles activation during *in vitro* culture independently of the hippo pathway.

What is known already: The Hippo pathway has been identified as the major suppressor of tissue overgrowth. It plays a crucial role in follicular activation in a non-physiological condition. Recent studies showed that hippo disturbance takes place during the tissue preparation and that, fragmentation-induced follicle growth is partially blocked by verteporfin.

Study design, size, duration: Bovine ovarian tissue fragments were exposed to a control medium containing 0.1% of DMSO or 3 µM of Verteporfin, a pharmacological inhibitor of YAP, *in vitro* for 3 or 24 h, and cultured for additional 3 days.

Participants/materials, setting, methods: Bovine ovaries were obtained from a slaughterhouse. The ovarian fragments were analyzed at Days 0, 3h or 3 days of culture. Cortex was either directly processed for immunohistological or western blot analysis (AKT, p-AKT, p-ERK1/2, RPS6, p-RPS6) or subjected to follicular isolation for assessment of gene expression (CCN2, BIRC1, Kit Ligand, Last 1 et 2). The follicle number and stage were evaluated to assess early follicular development. Survival was evaluated using TUNEL.

Main results and the role of chance: At least, *in vitro* culture for three days promoted follicular activation independently of treatment, triggered by the upregulation of p-ERK. However, the tissue fragments exposed to verteporfin for 3 h presented lower follicular activation than control. As observed in other species, p-AKT and p-RPS6 decreased throughout the culture period (these results will be confirmed by the ongoing PCR and immunohistochemistry). Moreover, verteporfin seems to not affect follicle survival when compared to control.
Limitations, reasons for caution: Transport and impact of *in vitro* culture may cover up the potential benefit of the Verteporfin on follicle activation.
Wider implications of the findings: Our results showed that exposure to verteporfin during fragmentation partially blocked follicular activation and suggested the contribution of MAPK/ERK signaling pathway on follicular activation during *in vitro* culture.
Trial registration number: not applicable

P-208 Extended time from second polar body extrusion to two pronuclei formation is related to aneuploid embryo formation

T.B. Hsieh[1], P. Chang[2], J. Meriano[2], R.F. Casper[2]

[1]*Wayne State University, Obstetrics & Gynaecology, Detroit, U.S.A. ;*
[2]*TRIO Fertility- University of Toronto, Obstetrics & Gynaecology, Toronto, Canada*

Study question: Can morphokinetic parameters be used to predict embryo aneuploidy?
Summary answer: An extended time period from the second polar body formation (2PB) to two pronuclei formation (PNa) is associated with an increased chance of aneuploid embryo.
What is known already: Preimplantation genetic testing for aneuploid (PGT-a) is a useful technique to enhance the implantation rate and decreases the miscarriage rate, particularly in advanced female population. Without question, PGT-a is an invasive procedure with potential harmful effects to the fetus. Time lapse microscopy (TLM) provides valuable morphokinetic parameters or morphological criteria for selecting better developed embryos to be transferred to improve implantation rate. However, current parameters still are not accurate enough to predict embryo ploidy or implantation potential.
Study design, size, duration: This is single center, retrospective cohort study conducted in a university affiliated fertility institute. A total of 1515 biopsied blastocysts were examined from 255 intracytosplasmic sperm injection (ICSI) cycles (female age, 23-48; average 37.64.1). We collected embryo records with complete TLM recording from the time of ICSI until blastocyst stage and a day 5/6 trophectoderm biopsy result for analysis. PGT-a results were obtained by using either array comparative genomic hybridization or next generation sequencing.
Participants/materials, setting, methods: Morphokinetic parameters includes tPB2(from insemination to 2PB), tPNa (from insemination to 2PN, tPNf (from insemination to pronuclei faded), T2-8 (from insemination to 2 to 8 cells), tM (from insemination to morula), tSB (from insemination to blastulation), tB (from insemination to full blastocyst), tEB (from insemination to expanded blastocyst), CC2 (from 2 to 3 cells), and CC3 (from 3 to 5 cells). Morphokinetic parameters were analyzed with Mann-Whitney-U test. *P*-values less than 0.01 were designated significant.
Main results and the role of chance: Of the total 1515 embryos, 1153 embryos were reported euploid and 362 of them were aneuploid embryos with an embryo aneuploid rate of 31.4%. 456 of the embryos also underwent TLM examination. 317 of these embryos were reported euploid and 139 of them aneuploid by PGT-a with embryo aneuploid rate of 43.8%. From the original Morphokinetic parameters, we further calculated time from 2PB to PNa (2PB-PNa), PNa to PNf, and PNf to T2 as new parameters to compare with the PGT-a results. The analysis of morphokinetic parameters and embryo ploidy status showed that PB2-PNa were correlated with an increased rate of aneuploid embryos. Aneuploid embryos have significantly longer time from 2PB to PNa (euploid 2PB-PNa: 4.2 1.8 hours, aneuploid: 5.0 2.18 hours). The other parameters didn't show any statistically significant differences.
Limitations, reasons for caution: The data variation is wide. These data are single center, sample size of this study is small and it is a retrospective study. In addition, more scientific and strict criteria to define 2PB, PNa, and PNf may be able to be established.
Wider implications of the findings: Our finding suggested that the time needed for embryos to develop from 2PB to PNf may be used as a predictor for aneuploid embryo.
Trial registration number: not applicable

P-209 Embryo morphokinetics and static morphology in the prediction of live birth: evidences that speed is more important than beauty.

A. Bartolacci[1], C. Moutier[1], D. Turchi[1], M. Lain[1], E. De Ponti[2], M. Mignini Renzini[1], J. Buratini[1,3], M. Dal Canto[1]

[1]*Biogenesi - Reproductive Medicine Centre, Istituti Clinici Zucchi, Monza, Italy ;*
[2]*ASST Monza, Department of Medical Physics, Monza, Italy ;*
[3]*Sao Paulo State University, Institute of Biosciences, Department of Physiology*

Study question: Is embryo morphokinetics more accurate than conventional embryo morphology in the prediction of live birth following day 3 fresh embryo transfer?
Summary answer: Embryo morphokinetics was more accurate than conventional embryo morphology in ranking embryos in terms of live birth potential following a day 3 fresh embryo-transfer.
What is known already: IVF/ICSI success critically depends on the accuracy of embryo selection, which has been traditionally performed with the utilization of subjective and static morphological criteria. Time-lapse technology has recently allowed a dynamic morphological evaluation, and, through the utilization of several morphokinetic parameters, the comparison of embryos'developmental performance aiming for more accurate embryo selection and higher chances of a live birth. Indeed, this technology has been already reported to increase accuracy of embryo selection, with positive impacts on pregnancy rates. Nevertheless, most IVF clinics still perform embryo selection based on static morphological criteria.
Study design, size, duration: This is a retrospective study including patients in their first ICSI cycle with embryo culture in a time-lapse system, performed from January 2015 to June 2018. 828 embryos from 461 fresh embryo transfers (SET: n= 156; DET: n=305) were included in this study, in which each individual embryo was evaluated for both morphological and morphokinetic quality. Patients giving birth to a single child after a double embryo-transfer were excluded from the analysis.
Participants/materials, setting, methods: The primary end-point was live birth. A generalized estimation equation was utilized to control for dependencies within individuals, since some patients received two embryos at transfer. The performance characteristics of the morphokinetics model and conventional embryo morphology was calculated using a ROC curve. Nine subgroups were created crossing three morphology degrees (A, B, C) with three morphokinetics degrees (A, B, C) attributed to each embryo, and live-birth rates were compared between these subgroups.
Main results and the role of chance: For each morphokinetic parameter, an optimal range was defined combining the two quartiles presenting the highest live-birth rate. The parameters to be inserted in the model were selected by logistic regression, and were: t4 [OR = 2.04 (95% CI 0.87 – 4.77)] and t2 – tPNf [OR = 1.52 (95% CI 0.99 – 2.30)]. The resulting morphokinetic model was more accurate to predict live birth than conventional embryo morphology, as measured by AUC on an external dataset not used for model development [AUC 0.658 (95% CI 0.606 – 0.681) and AUC 0.575 (95% CI 0.537 - 0.614), respectively]. Regression analysis showed a significant difference between the three subgroups in which morphokinetic quality was classified as poor (C; subgroups AC, BC, and CC) compared to the reference group AA (adjusted $p < 0.001$). Moreover, odds ratio obtained in subgroups AC (good morphology/poor morphokinetics) and CA (poor morphology/good morphokinetics) indicated that poor morphokinetics is a better marker of low embryo competence than poor morphology (OR = 0.23; 95% CI 0.09-0.60 and OR=0.55; 95% CI 0.17-1.87, respectively).
Limitations, reasons for caution: We acknowledge that our study is limited by its retrospective nature and by the utilization of data generated in a single IVF center including only day 3 transfers.
Wider implications of the findings: Our results suggest that embryo morphokinetics is a more reliable predictor of live birth potential after day 3 fresh embryo transfers than embryo static morphology, thus providing valuable references to define embryo selection strategies in IVF practice.
Trial registration number: Not applicable

P-210 The impact of synchronicity of blastomere division during dynamic human embryo monitoring by a time-lapse on blastocyst development and quality.

N. Sayme[1], M. Kljajic[2], D.H.A. Maas[1], T. Krebs[1]

[1]Team Kinderwunsch Hannover, Dept. of Ob/Gyn, Hannover, Germany ;
[2]Universitätsklinikum des Saarlandes, Reproduktionsmedizin, Homburg, Germany

Study question: Does the synchronicity of blastomere division of embryo and type of media system have an impact on blastocyst development and quality.
Summary answer: The synchronicity of the cell cycle affects blastocyst development and blastocyst quality, while the media system only affects blastocyst quality.
What is known already: The serial image capturing with time-lapse devices is a noninvasive method that offers the possibility for 24-hour continuous monitoring of embryo development, increasing the quantity and quality of information without disturbing the culture conditions. Some of the most recent publications show correlations between cleavage times until 8-cell stage and blastocyst rate, expansion, and implantation. These published data suggest that morphokinetic observations can yield valuable information to aid the selection of embryos for transfer. The impact of single versus sequential culture media systems on time-lapse data also needs to be considered since the contradictory conclusions were reached recent studies.
Study design, size, duration: The synchrony of the second cell cycle (s2) was defined as the duration of the transition from a two-blastomere embryo to a four-blastomere embryo (s2 = t4–t3), while synchrony of the third cell cycle (s3) as the duration from a five-blastomere embryo to an eight-blastomere embryo (s3 = t8–t5). The injection time of ICSI was designated as "time zero" (t0), and computer software was used to calculate the time duration of the cycle.
Participants/materials, setting, methods: A total of 87 blastocysts from 20 patients undergoing the antagonist cycle for ICSI treatment between November 2019 and December 2019 were evaluated. All blastocysts were cultured in Embryoscope™ according to the manufacturer's specifications (Vitrolife, Sweden). The Gardner and Schoolcraft scoring system was used to describe blastocyst quality. Correlations between the data were calculated using logistic regression analysis. Statistical significance was defined as $p<0.05$. All statistical analyses were performed using SAS software.
Main results and the role of chance: Morphokinetic data showed that synchrony of the second cell cycle was significantly different (s2, $p<0,05$) between embryos which reached the blastocyst stage and those embryos that did not. Although, in contrast with what was previously published, the more careful analysis revealed that blastocyst quality was not affected by synchrony of the second cell cycle as morphocinetic parameter. On the other hand, synchrony of the third cell cycle did not significantly correlate with blastocyst formation potential, but this parameter showed a significant correlation with blastocyst quality (s3, $p<0,001$).

Besides Morphokinetic observations, the impact of single versus sequential culture media systems was investigated as well. For a single media system Gynemed 501CT (Lensahn, Germany) was used and for the sequential one Sydney IVF Cleavage Medium and Sydney IVF Blastocyst Medium (Cook Medical, Ireland) were used. Obtained results showed that there was not any difference between the synchrony of the second or third cell cycle regardless on the media system. What is more, blastocyst formation potential, blastocyst quality or pregnancy rate did not differ between media system groups.
Limitations, reasons for caution: The disadvantage of the relatively small patient cohort was balanced with a wider range of patients' age. Further research should link morphokinetic parameters with pregnancy rate and live birth rate as well.
Wider implications of the findings: The potential of the present findings might be helpful for a better understanding of the association between embryo morphokinetic parameters and blastocyst development. Furthermore, the culture media system result indicates that morphokinetic benchmarks can be developed and used irrespective of a laboratory's choice of culture media.
Trial registration number: not applicable

P-211 RNAseq reveals cumulus cell transcripts associated with developmental potential of bovine oocytes

Á. Martínez Moro[1,2], I. Lamas-Toranzo[2], E. O´Callaghan[3], A. Esteve-Codina[4], P. Lonergan[3], P. Bermejo-Álvarez[2]

[1]ProcreaTec, IVF Lab, Madrid, Spain ;
[2]INIA, Animal Reproduction Department, Madrid, Spain ;
[3]University College Dublin, School of Agriculture and Food Science-, Belfield-Dublin, Ireland ;
[4]Barcelona Institute of Science and Technology, Centre for Genomic Regulation, Barcelona, Spain

Study question: Does cumulus cell transcript abundance correlate with oocyte developmental potential in the bovine model?
Summary answer: The abundance of specific transcripts in cumulus cells from oocytes developing to blastocysts following IVF differs from those arresting before that stage.
What is known already: Cumulus cells serve essential functions during folliculogenesis, being connected to the oocyte through transzonal projections. Following in vitro maturation, cumulus cells are often removed and discarded, thereby constituting an interesting biological material on which to perform molecular analysis aimed to predict oocyte developmental potential. Previous studies performed to correlate the abundance of specific transcripts in cumulus cells with their developmental potential have yielded conflicting results. These studies have been based on candidate gene qPCR or microarray analyses. RNAseq provides significant advantages over these methods as it's more sensitive and specific and it is not limited to a subset of genes.
Study design, size, duration: Bovine cumulus cells were allocated into three groups according to the developmental potential of the oocyte: 1) oocytes developing to blastocysts following IVF (Bl+Cl+), 2) oocytes cleaving following IVF but arresting their development prior to the blastocyst stage (Bl-Cl+), and 3) oocytes not cleaving following IVF (Bl-Cl-). RNAseq was performed in 4 (Bl-Cl-) or 5 samples (Bl+Cl+ and Bl-Cl+) per group. Each sample contained cumulus cells from 10 cumulus-oocyte complexes (COCs).
Participants/materials, setting, methods: Bovine cumulus-oocyte complexes were obtained from slaughtered cattle and individually matured *in vitro* (IVM). Following IVM, cumulus cells were removed by hyaluronidase treatment, pelleted, snap frozen in liquid nitrogen and stored at -80 °C until analysis. Cumulus-free oocytes were fertilized and cultured *in vitro* individually and development was recorded for each oocyte. RNAseq was performed at Illumina platform with >30 M reads/sample. Differential expression was analysed by DESeq2 software.
Main results and the role of chance: Although the abundance of most transcripts detected in cumulus cells (19335) did not vary depending on the developmental potential of their corresponding oocytes, RNAseq revealed 1609, 1466 and 1420 differentially expressed genes (DEGs) for the comparisons Bl+Cl+ vs. Bl-Cl+, Bl+Cl+ vs. Bl-Cl- and Bl-Cl+ vs. Bl-Cl-, respectively, using a raw p value <0.05. These DEGs were narrowed down to 77, 80 and 32 DEGs for the comparisons Bl+Cl+ vs. Bl-Cl+, Bl+Cl+ vs. Bl-Cl- and Bl-Cl+ vs. Bl-Cl-, respectively, when an adjusted p value <0.05 was used. From these subsets of DEGs, 49, 50 and 18 DEGs, respectively, exhibited a fold change greater than 1.5. Focussing on DEGs in cumulus cells obtained from oocytes developing to blastocysts, 10 DEGs were common to both comparisons (10/49 from Bl+Cl+ vs. Bl-Cl+, 10/50 from Bl+Cl+ vs. Bl-Cl-). These DEGs correspond to 6 genes upregulated (HBE1, ITGA1, PAPPA, AKAP12, ITGA5 and SLC1A4), and 4 genes downregulated (GSTA1, PSMB8, FMOD and SFRP4) in Bl+Cl+ compared to the other groups.
Limitations, reasons for caution: Experiments were conducted in the bovine model. Although bovine folliculogenesis, monoovulatory ovulation and early embryo development exhibit considerable similarities with that of humans, caution should be taken when extrapolating these data to humans.
Wider implications of the findings: Selecting embryos with the highest developmental potential is essential in order to achieve successful outcomes following single-embryo transfer. Our findings suggest that the abundance of specific transcripts in cumulus cells could be used as a predictor of the developmental potential of their enclosed oocyte.
Trial registration number: not applicable

P-212 Epigenetic changes with maternal age in human eggs follow an inverse U-curve shape

T. Imbar[1], G. Karavani[2], P. Pash[3], N. Shecter-safrai[2], M. Safrai[2], T. Mordechai-daniel[2], D. Bauman[2], E. Reich[3], R. Rothman[3], T. Ajiro[3], M. Klutstein[3]

[1]Hadassah-Hebrew University Medical Center, Fertility preservation center- IVF unit, Jerusalem, Israel ;
[2]Hadassah-Hebrew University Medical Center, Fertility preservation center. IVF unit, Jerusalem, Israel ;
[3]Hebrew University, Institute of Dental Sciences, Jerusalem, Israel

Study question: How do epigenetic modifications change in human MI oocytes collected from media of unstimulated ovarian pieces with aging?
Summary answer: H3K9me2 repressive epigenetic mark in human oocytes may follow an inverse U-curve with age in a similar manner to the behavior of aneuploidies.
What is known already: Natural fertility in humans follows an inverse U-curve, where young females and women of advancing maternal age show reduced fertility rates. The mechanism or mechanisms that shape the fertility curve are unclear. A recent report shows that oocyte aneuploidies also follow such a U-curve, suggesting that chromosomal errors originating in oocytes determine the behavior of natural fertility in humans. Epigenetic changes are considered as one of "hallmarks of aging". These typically cause a decline of repressive marks in repressed loci and a contaminant repression of active genes. This phenomenon, previously uninvestigated in human eggs, is termed "epigenetic aging".
Study design, size, duration: After IRB approval, all participants, undergoing fertility preservation procedures, signed informed consent. From January 2019 until October 2019, we searched and collected oocytes from media remains after ovarian cortex pieces cryopreservation. Eight women included in the study. Age ranged from nine to 30 years. Two women received chemotherapy prior to fertility preservation procedure. We used a cohort of immature oocytes stained after retrieval from fertility age IVF patients as a control.
Participants/materials, setting, methods: Medium solution obtained from handling of ovarian cortical stripes, containing oocytes of different sizes and shapes together with cumulus cells. We separated different types of oocytes in the solution using a modified Andreasen pipette technique based on Stokes law of sedimentation. Oocytes found in the media were matured in vitro to MI and immuno-stained for the histone modification H3K9me2 .
Main results and the role of chance: Using our oocyte identification method we isolated oocytes that were not seen in the routine embryology lab medium search. After maturation in vitro we identified 3 GV , 23 MI and 6 MII oocytes. MI oocytes staining for epigenetic histone modification H3K9me2 revealed a low staining intensity in the younger patients (under 10 years) with a marked increase in the more mature, post-menarche (over 14 years), patients. Staining of MI oocytes from women 30 years and older showed and even lower intensity of this marker. Staining of the few GV oocytes we retrieved corroborated this staining pattern. Thus, the intensity of the H3K9me2 repressive epigenetic marker in human oocytes follows the shape of an inverse U-curve.
Limitations, reasons for caution: Staining results are from human oocytes during fertility preservation procedures, without gonadotropin induction. Moreover, the collection of oocytes was performed following a meticulous search and isolation of oocytes in the clinical lab. Thus, the epigenetic status may not reflect only their age, but also additional factors such as cellular stress.
Wider implications of the findings: Epigenetic changes involves in human oocyte maturation and may be part of the U-curve natural fertility seen in humans. Manipulating this effect, using epigenetic drugs, might enhance and improve our ability to preserve mature oocytes from young women with urgent need of fertility preservation
Trial registration number: not applicable

P-213 Big data is not always better – prediction of live birth using machine learning on time-lapse videos of human embryos

S. Hicks[1,2], T.B. Haugen[3], M. Iliceto[3,4], H.L. Hammer[1,2], J.M. Andersen[3], O. Witczak[3], M.A. Riegler[1], M.H. Stensen[4]

[1]Simula Metropolitan Center for Digital Engineering, Holistic Systems, Oslo, Norway ;
[2]OsloMet – Oslo Metropolitan University, Faculty of Technology- Art and Design, Oslo, Norway ;
[3]OsloMet – Oslo Metropolitan University, Faculty of Health Sciences, Oslo, Norway ;
[4]Fertilitetssenteret, IVF Laboratory, Oslo, Norway

Study question: Can interpretable machine learning (ML) methods be used on small amounts of data to predict human embryo viability?
Summary answer: Traditional supervised and unsupervised ML methods can predict human embryo viability using a small number of time-lapse videos.
What is known already: There is insufficient evidence to conclude that the introduction of time-lapse technology has improved live birth outcomes after ART compared with traditional embryo assessment. ML methods have shown to have much potential in analyzing images and may have predictive value in the assessment of embryos from time-lapse videos. All recent work uses some variation of deep neural networks that are known to require a lot of training data and are not easily interpretable. Thus, we propose to use interpretable and less data-demanding ML methods to predict embryo outcome.
Study design, size, duration: We used eight time-lapse videos of embryo development, up to day five. Two labels were assigned to the videos; positive for the embryos which resulted in a live birth and negative for the non-viable embryos. The dataset was evenly balanced with an equal number of positive and negative labels. 120 frames were extracted at evenly distributed intervals throughout the entire duration of each video in the dataset.
Participants/materials, setting, methods: Global image features (GF) were extracted from each video frame. GF have the advantage of being manually engineered, which are more interpretable when compared to features extracted through deep learning. We extracted 25 different features, where the best performing features were Tamura and AutoColorCorrelogram. Due to the small number of real time-lapse videos, Synthetic Minority Over-sampling Technique (SMOTE) was used to increase the sample size. Leave-one-embryo-out cross-validation was used to demonstrate generalizability and avoid overfitting.
Main results and the role of chance: The experiments can primarily be split into two distinct groups; supervised and unsupervised ML methods. The supervised experiments used the algorithms naïve Bayes and random forests and evaluated using leave-one-embryo-out cross-validation with and without SMOTE (1000% oversampling for both classes). The unsupervised experiments were done using simple K-means clustering (using two clusters) and X-means (number of clusters chosen automatically) with and without oversampling. The motivation behind choosing more traditional algorithms over modern ones, such as deep learning, was due to their efficiency in terms of training and inference time. Furthermore, the methods used are more interpretable and allow for a higher understanding of why and how the algorithms make a prediction. The supervised methods using SMOTE performed well and classified all eight videos correctly (sensitivity and specificity of 1). Without SMOTE, specificity and sensitivity fell between 0.375 up to 0.750 depending on which feature was used. The unsupervised methods also performed well. K-means with SMOTE correctly clustered all videos into the correct clusters (live birth and not live birth). Without SMOTE, one video was wrongly clustered. X-means automatically generated two clusters and classified all instances correctly using SMOTE. Without SMOTE, X-means was able to cluster about 60% correctly.
Limitations, reasons for caution: Since the size of the dataset was minimal, leave-one-embryo-out cross-validation and SMOTE were essential in the validation of this study. For future studies, larger datasets should be used with data collected from different sources to increase generalizability and the robustness of the validation.
Wider implications of the findings: Supervised ML methods have a potential for live birth prediction. Unsupervised learning may become an essential tool for the discovery of new embryo features for use in assessments. Our results suggest that Tamura features might be visual biomarkers for embryo video analysis.
Trial registration number: not applicable

P-214 Ooplasmic DNA Repair Mechanisms of the Human Gamete Appear to Be Linked to Oocyte Maturity

D. Keating[1], A. Parrella[1], Z. Rosenwaks[1], G.D. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: Does ooplasmic maturity affect the ability of MII oocytes to repair fragmented male genome DNA?
Summary answer: If the proportion of mature oocytes retrieved is not optimal, the oocytes are unable to overcome abnormal sperm chromatin fragmentation (SCF) and generate implantable embryos.
What is known already: It is known that following sperm penetration, the ooplasm replaces the protamines of the spermatozoon with histones and runs

through the male genome, repairing DNA for accuracy and eventual repair. This is particularly relevant in cases of high SCF, known to affect implantation. The achieved nuclear maturation by extrusion of the first polar body, not concurrently, is followed by ooplasmic readiness. We have shown previously that proportional nuclear maturity of the retrieved oocyte cohort has a crucial impact on ICSI outcome in terms of fertilization, embryo implantation, and live birth.
Study design, size, duration: This study included couples treated by ICSI using ejaculated spermatozoa between 2006 and 2019. Female partners were limited to ≤37 years of age to control for female-related gamete aneuploidy. Nuclear maturity of the retrieved oocyte cohort was assessed after the removal of cumulous cells. Cycles were allocated according to the proportion of nuclear maturity of the retrieved cohort: optimal (≥80%) and suboptimal (<80%).
Participants/materials, setting, methods: Ejaculate SCF was assessed by terminal deoxynucleotidyl dUTP transferase nick-end labeling (TUNEL). Five-hundred spermatozoa were assessed with a normal threshold of ≤15%. Female patients were stimulated for ovarian superovulation by pituitary suppression utilizing either gonadotropin-releasing hormone antagonist or agonist, were treated with daily gonadotropins, and were triggered with human chorionic gonadotropin when the lead follicle reached ≥17mm. Oocyte retrieval and ICSI were performed in the standard fashion. All cycles were performed at our center.
Main results and the role of chance: A total of 126 couples underwent 220 ICSI cycles that had an optimal oocyte maturity, and 119 couples underwent 202 cycles with suboptimal oocyte maturity. The average SCF for couples with normal and abnormal levels was 9.4±3% and 24.1±10%, respectively (P<0.0001). When oocyte maturity was optimal, couples with normal and abnormal SCF had comparable fertilization (74.0% vs. 70.8%), embryo implantation (22.2% vs. 22.3%), and clinical pregnancy rates (CPR; 32.8% vs. 37.9%).
For the suboptimal maturity group, couples with normal SCF had a fertilization rate of 72.4%, an embryo implantation rate of 20.2%, and a CPR of 30.5%. Couples with abnormal SCF had a comparable fertilization rate of 72.0%; however, the implantation rate was compromised (9.8%; P<0.05). Similarly, in these couples, CPR trended lower (30.5% vs. 17.8%).
To confirm the impact that proportional oocyte maturity has on the alleviation of male genomic defects, we assessed only cycles with abnormal SCF. In cycles where the proportion of MII oocytes was optimal, the fertilization rate was 70.8%, the implantation rate was 22.3%, and the CPR was 37.9%. Cycles with suboptimal maturity had a comparable fertilization rate (72.0%); however, embryo implantation (9.8%; P<0.05) and CPRs were impaired (17.8%; P<0.05).
Limitations, reasons for caution: While we limited female age to ≤37 years to control for female-related gamete aneuploidy, it is not possible to exclude all confounding factors with certainty. This study demonstrated that not only nuclear but also cytoplasmic maturity is required for a competent MII oocyte.
Wider implications of the findings: These findings confirm the existence of DNA repair mechanisms within the human oocyte and that this function is impaired in oocytes with ooplasmic dysmaturity. This was evident in the retrieved cohort with a suboptimal number of MII oocytes. Optimization of the superovulation protocol can overcome male genomic impairment.
Trial registration number: not applicable

P-215 The role of autophagy on embryonic development at blastocyst stage

N. Adel[1], H. Elmaghraby[2], D. Ghareeb[1], M. Elmahdy[2], M. Nabil[3]

[1]Alexandria university- Faculty of science, Biochemistry, Alexandria, Egypt ;
[2]Alexandria university- Faculty of medicine, Obstetrics and Gynecology, Alexandria, Egypt ;
[3]City of scientific researches and technological applications., Pharmaceutical and fermentation industries development center, Alexandria, Egypt

Study question: Does autophagy genes and proteins expression is deifferent between preimplantation embryos that developed to blastocyst and those which are arrested on day 5?
Summary answer: From all autophagy genes and proteins, Beclin 1 and LC3 expression is important for embryonic development to blastocyst on day 5.
What is known already: Autophagy is one of the molecular mechanisms that is important for the early embryonic development. It is a massive cytoplasmic degradation pathway mediated by the lysosome.
Autophagy provides a"recycling system", As it engulfs unnecessary macromolecules proteins and organelles, degraded them to amino acids afree fatty acids which are important for the neo-synthesis of another proteins important for embryo development, It was known that autophagy is highly activated immediately after fertilization, and also found that fertilized embryos lack autophagy can not implant.
Study design, size, duration: Our study is a prospective study, 60 embryos were derived from oocytes aspirated from twelve patients undergoing ICSI between September 2019 to November 2019 at Madina fertility center.Embryos were devided on day 5 in to two groups according to its developmental stage and its ability to form blastocyst:

Group A ----> Developed embryos (blastocyst formation) n=31.
Group B ----> Arrested embryos (No blastocyst formation) n=29.

Participants/materials, setting, methods: Oocytes aspirated from twelve patients were injected with sperm by conventional ICSI , the injected oocytes were incubated till day 5.
Embryos on day 5 were scored and devided in to two groups according to its developmental stage and its ability to form blastocyst:

Group A ----> Developed embryos (blastocyst formation)
Group B ----> Arrested embryos (No blastocyst formation)

then biopsied to evaluate expression of autophagic genes (ELISA) and proteins (RT-PCR) : LC3, PI3K, E2F, mTOR.
Main results and the role of chance: Developed embryos to blastocyst stage on day 5 (Group A) shows significantly higher LC3 relative gene expression (1.12±0.51), Beclin 1 relative gene expression (1.43±0.33) and Beclin protein expression (3.8±0.028) than their expression in embryos that failed to form blastocyst on day 5 (Group B) (0.72±0.17,P=0.03), (0.35±0.12,P=0.0001),and (3.14±0.05, P=0.0001), respectively.
While mTOR and PIK3C3 proteins expression were significantly higher in Group B (arrested embryos) than their expression within developed embryos (Group A) , P=0.007 and P= 0.0001 ,respectively.As well as the expression of E2F gene which is significantly lower within group A embryos (0.32±0.07) and remarkedly higher within group B embryos (4.38±1.16), P=0.0001.

	Developed (Group A)	Arrested (group B)	P
mTOR (ng)	1.13±0.053	1.23±0.09**	0.007
Beclin (ng)	3.8±0.028	3.14±0.05***	0.0001
PIK3C3 (ng)	18.6±1.4	24.5±1.5***	0.0001
LC3 relative gene expression fold	1.12±0.51	0.72±0.17*	0.03
Beclin 1 relative gene expression fold	1.43±0.33	0.35±0.12***	0.0001
E2F relative gene expression fold	0.32±0.07	4.38±1.16***	0.0001

Limitations, reasons for caution: larger sample size is needed to support our results.
Wider implications of the findings: Investigation of autophagy function (specially evaluation of expression of Beclin 1 and LC3 genes and proteins) in embryos at late developmental stage introduce a new diagnostic tools for embryos with impaired development and those with impaired implantation potential.
Trial registration number: 0303721

P-216 The influence of post-thaw culture period on the pregnancy outcomes of poor-quality blastocyst transfer

S.H. Shin[1], J.H. Cha[1], Y.J. Kim[1], S.K. Lee[1], J.H. Kim[1], D.H. Kim[1], H.Y. Kim[1], S.H. Back[1], M.J. Choo[1], J.H. Ahn[1], H.Y. Kim[1], K.A. Pak[1], J.S. Yoon[1], S.Y. Park[1]

[1]Agaon Fertility Clinic, IVF center, Seoul, Korea- South

Study question: Does post-thaw culture period affect the pregnancy outcomes of poor-quality blastocyst in single vitrified-thawed embryo transfer?

Summary answer: In poor-quality blastocyst transfer, short post-thaw culture period was higher the pregnancy outcomes compared to long post-thaw culture period.

What is known already: During vitrification and thawing, embryo can be damaged and stressed. Stressed embryo can be particularly sensitive to environmental influences during post-thaw culture. Therefore, it raised hypothesis that the post-thaw culture period may be affect the pregnancy outcomes.

Study design, size, duration: A retrospective cohort study of 428 vitrified-thawed single embryo transfer cycles was performed from January 2014 to October 2019. Cycles with surgical retrieved sperm, genetic diagnosis, oocyte donation, and advanced maternal age (≥38 years) were excluded. We compared rates of survival, biochemical pregnancy, clinical pregnancy, ongoing pregnancy, and implantation according to post-thaw culture period.

Participants/materials, setting, methods: Cycles, that transferred single embryo of poor-quality, were divided into two groups according to post-thaw culture period; cultured overnight (21-23 h) in group A (n = 281) and short culture (3-5 h) in group B (n = 147). Blastocyst was graded according to the Gardner and Schoolcraft's classification system. Poor-quality was defined as excluding expansion grade 4-6 and ICM/trophectoderm grade A or B.

Main results and the role of chance: Cycle characteristics such as female age (33.4 ± 2.5 vs. 33.4 ± 2.4, p = 0.959), survival rate (96.6 % vs. 97.4 %, p = 0.651) were similar in the two groups. Rates of biochemical pregnancy (25.6 % vs. 44.9 %, p < 0.001), clinical pregnancy (18.1 % vs. 31.3 %, p = 0.002), and implantation (18.5 % vs. 32.0 %, p = 0.002) in Group B were higher than those of Group A. Group B tends to have a higher ongoing pregnancy rate (14.9 % vs. 22.4 %, p = 0.053) than Group A, but no significant difference.

Limitations, reasons for caution: This is a retrospective study. The quality at the time of blastocyst vitrification was not considered. Therefore, further studies are needed in order to support our results.

Wider implications of the findings: We analyzed poor-quality blastocyst, which can be assumed to be more stressed. This study suggests that poor-quality blastocyst may be sensitive to the in vitro environment. Therefore, the short post-thaw culture period of poor-quality blastocyst can improve the pregnancy outcomes.

Trial registration number: Not Applicable

P-217 The effect of inner cell mass and trophectoderm morphology on embryo ploidy, gender, and in vitro fertilization outcomes

C. Moutos[1], W. Kearns[2,3], S. Farmer[4], J. Richards[4], A. Saad[1], J.R. Crochet[1,4]

[1]University of Texas Medical Branch – Galveston, Obstetrics and Gynecology, Galveston, U.S.A. ;
[2]AdvaGenix, AdvaGenix, Rockville, U.S.A. ;
[3]Johns Hopkins University School of Medicine, Gynecology and Obstetrics, Baltimore, U.S.A. ;
[4]Center of Reproductive Medicine, Center of Reproductive Medicine, Houston, U.S.A.

Study question: Is there a relationship between inner cell mass (ICM) or trophectoderm (TE) grading and embryo gender, ploidy and *in vitro fertilization* (IVF) outcomes?

Summary answer: Higher ICM /TE grade embryos were more likely to be euploid and have better IVF outcomes. while no correlation exists between ICM/TE and embryo gender.

What is known already: Along with preimplantation genetic testing for aneuploidy (PGT-A), embryo morphology has been used in selecting which embryo to transfer during IVF/embryo transfer (ET) procedures. The relationship between embryo morphology and euploidy has been well established; the effects of ICM and TE grading separately on PGT-A and subsequent IVF outcomes remain uncertain.

Study design, size, duration: A retrospective chart review was conducted of patients age 21 to 47. Embryos that underwent PGT-A (N=3708) and subsequent elective single ET (N=539) from June 2007 to December 2018 were evaluated.

Participants/materials, setting, methods: Embryo data originated from patients receiving care at a single reproductive endocrinology practice. Primary outcomes of this study consisted of IVF outcomes among different embryo ICM and TE morphological grades. Secondary outcomes included embryo gender and ploidy. Statistical analyses were performed via Pearson's chi-squared tests.

Main results and the role of chance: ICM Grade A embryos (N=2214) were euploid in 57.1% of cases versus 45.5% and 31.2%, respectively, for ICM Grade B (N=1090) and Grade C (N=404), (P<0.0001). TE grading resulted similarly for euploidy (Grade A [N=1551] 62.0% vs. Grade B [N=1627] 48.3 % vs. Grade C [N=530] 26.2%, P<0.0001). Neither ICM (P=0.257) nor TE (P=0.079) correlated with gender.

In transferred, euploid embryos, the distribution included ICM Grade A (N=392), Grade B (N=116), Grade C (N=31) and TE Grade A (N=302), Grade B (N=209), Grade C (N=28).

Implantation rate (IR) (ICM Grade A 71.7% vs. Grade B 59.5% vs. Grade C 48.4%, P<0.0001), clinical pregnancy rate (CPR) (ICM Grade A 69.4% vs. Grade B 57.8% vs. Grade C 45.2%, P=0.0034), and ongoing pregnancy rate (OPR) (ICM Grade A 59.7% vs. Grade B 48.3% vs. Grade C 38.7%, P=0.013) are higher with better ICM grades.

TE grading resulted: IR (TE Grade A 73.8% vs. Grade B 63.2% vs. Grade C 35.7%, P<0.0001), CPR (TE Grade A 71.5% vs. Grade B 60.8% vs. Grade C 35.7%, P=0.0001), and OPR (TE Grade A 61.6% vs. Grade B 51.7% vs. Grade C 28.6%, P=0.0009). ICM and TE do not correlate with miscarriage, chemical, or ectopic pregnancy.

Limitations, reasons for caution: Limitations of this study include a patient population derived from a single facility. Additionally, the retrospective nature of this study leaves the possibility for introduction of unaccounted for confounding factors.

Wider implications of the findings: This large-scale study elaborates on the use of ICM and TE grading in predicting embryo gender, ploidy, and successful IVF outcomes. Our data suggest that both ICM and TE grading are important tools and should both be considered when selecting embryos for successful IVF outcomes.

Trial registration number: None

P-218 Human sperm selected by a direct swim-up without centrifugation is positively associated with high blastocyst formation rate in normal responders after intracytoplasmic sperm injection (ICSI)

J. Lee[1], S. Shim[1], M. Kim[1], S. Choi[1], I. Park[1], H. Sun[1], J. Kim[1]

[1]Liora Fertility Center, IVF center, Busan, Korea- South

Study question: Does human sperm selected by the direct swim-up (DU) without centrifugation affect development and quality grade of embryo and blastocyst formation rate after ICSI?

Summary answer: The human sperm selected by DU without centrifugation was significantly associated with high blastocyst formation rate, but unrelated to development and quality grade of embryo.

What is known already: Centrifugation could produce reactive oxygen species and impair sperm functions, and also induce sub-lethal damage. Therefore, we are still concerned about using centrifugation in the procedure of sperm preparation. Previous study suggested that the DU without centrifugation can minimize additional sperm preparation and should be used in assisted reproductive technology (ART) treatment as a reasonable alternative to improve the embryo development and clinical outcomes. However, there is insufficient evidence from previous studies to support this suggestion.

Study design, size, duration: A retrospective study of 76 (n = 1,365 retrieved oocytes) fresh ICSI cycles with normal responders was conducted from May 2018 to December 2019 at Liora Fertility Center. All cycles with severe oligoasthenoteratozoospermia, frozen sperm and surgically retrieved sperm were excluded. All women had undergone a GnRH antagonist protocol. Cycles were divided into two groups; DU without centrifugation (Group A, n = 49) and DU with centrifugation (Group B, n = 27).

Participants/materials, setting, methods: Sperm medium (1) was placed on the top of raw semen (1) in 5 tube. The supernatant with motile sperm was gently collected after the DU for 20 minutes, and then placed into 15 tube without the washing step using centrifugation. Then the 15 tube was stored in 6% CO_2 incubator at 35°C before ICSI. We compared the fertilization rate, embryo development, embryo quality grade and blastocyst formation rate between two groups.

Main results and the role of chance: There were no significant differences between Group A and B regarding mean female age (33.5 ± 3.9 vs. 34.6 ± 4.4, *p* = 0.257), mean male age (35.4 ± 4.5 vs. 37.1 ± 5.1, *p* = 0.137), mean number

of in *in-vitro* fertilization (IVF) attempts (0.3 ± 0.6 vs. 0.3 ± 0.8, $p = 0.864$), mean number of retrieved oocytes (18.8 ± 7.2 vs. 16.4 ± 7.2, $p = 0.156$), mean number of Metaphase II oocytes (13.2 ± 4.7 vs. 11.5 ± 5.0, $p = 0.140$), maturation rate (87.0% vs. 90.0%, $p = 0.272$), fertilization rate (76.4% vs. 75.4%, $p = 0.707$), arrested embryos rate (1.0% vs. 0.7%, $p = 0.309$). We also observed similar rates of high-quality 4-cell stage embryos on day 2 (22.1% vs. 26.9%, $p = 0.256$), high-quality cleavage stage (5- to 9-cell stages) embryos on day 3 (26.3% vs. 30.0%, $p = 0.434$), and high-quality blastocysts stage (≥BB grade, 32.8% vs. 33.5%, $p = 0.898$) in Group A and B, respectively. However, the Group A had significantly higher blastocyst formation rate (58.4% vs. 50.1%, $p = 0.036$) than Group B. Lastly, any microbial contamination during embryo culture was not discovered in two groups.

Limitations, reasons for caution: This retrospective study is based on a small sample size so that further study in a large sample is needed. We also need to investigate whether the human sperm selected by DU without centrifugation positively affect pregnancy rate in IVF cycles.

Wider implications of the findings: This method is possible to reduce the influence of impaired sperm motility and DNA damage by centrifugation. Additionally, it can help to reduce an embryologist workload as a simple sperm preparation and provide the cost effective in ART. We suggested that this method will improve safe and useful clinical application.

Trial registration number: not applicable

P-219 Can deep convolutional neural network (CNN) be used as a non-invasive method to replace Preimplantation Genetic Testing for Aneuploidy (PGT-A)?

A. Meyer[1], J. Dickinson[1], N. Kelly[1], H. Kandula[2], M. Kanakasabapathy[2], P. Thirumalaraju[2], C. Bormann[1], H. Shafiee[3]

[1]Massachusetts General Hospital, Obstetrics and Gynecology, Boston, U.S.A. ; [2]Brigham and Women's Hospital, Division of Engineering in Medicine- Department of Medicine, Boston, U.S.A. ; [3]Brigham and Women's Hospital, Department of Medicine- Harvard Medical School, Boston, U.S.A.

Study question: Can deep convolutional neural network (CNN) be used as a non-invasive method to accurately classify embryos based on their karyotype?

Summary answer: Trained CNN algorithm of cleavage and blastocyst-stage embryo images performed very well in identifying aneuploid embryos.

What is known already: Preimplantation genetic testing for aneuploidy (PGT-A) has become a widely utilized tool for screening and selecting embryos for transfer. There are limited studies showing the efficacy of this procedure in women under 35 years of age. Conversely, there are some reports demonstrating that younger patients have reduced cumulative pregnancy rates when utilizing PGT. These lower outcomes are likely due to inaccurate PGT-A results or due to the invasive procedures involved with embryo biopsy and cryopreservation. The goal of the study was to determine if deep-learning CNNs could be used as a non-invasive method to select chromosomally normal embryos for transfer.

Study design, size, duration: Using a retrospective dataset of embryos analyzed using a modified FAST-SeqS next generation sequencing method (Invitae, San Francisco, Ca) a deep neural network model was trained and tested using 3112 images to classify embryos as aneuploid or euploid. Embryo images captured on day 3 (D3) and day 5 (D5) were used to classify embryos based on karyotype.

Participants/materials, setting, methods: For D3 karyotype classification we developed a CNN with 2910 annotated images of cleavage embryos. We tested the performance using 202 D3 embryo images. For D5 karyotype classification we developed a CNN using 2906 images of annotated blastocysts. We tested the algorithm's performance using 201 blastocyst images.

Main results and the role of chance: The deep learning CNN trained to classify D3 embryos as aneuploid or euploid performed with a high specificity and thus was able to sufficiently identify 85.45% (CI: 77.46% to 91.45%) of aneuploid embryos. Similarly, the CNN used to classify embryos based on karyotype on D5 of development had a specificity of 75.23% (CI: 66.04% to 83%). These results objectively demonstrate that morphology-alone may be useful in identifying genetically abnormal embryos.

Limitations, reasons for caution: Images were obtained using a single imaging platform (EmbryoScope) at only 2 timepoints for karyotype classification.

Wider implications of the findings: These results demonstrate while networks can identify non-invasive markers for genetically-abnormal embryos, the need for markers to selecting genetically-normal embryos for transfer remains. This was the first report to our knowledge that's able to objectively determine without technician-bias or input that morphology-alone can be used to identify genetically abnormal embryos.

Trial registration number: not applicable

P-220 One step further: Prospective randomized controlled trial comparing one and two steps technique of embryo transfer.

P.E. Levi Setti[1], F. Cirillo[1], E. Morenghi[2], V. Immediata[1], V. Caccavari[3], A. Baggiani[1], E. Albani[1], P. Patrizio[4]

[1]Humanitas Research Hospital, Department og Gynecology- Division of Gynecology and Reproductive Medicine- Humanitas Fertility Center, Milano, Italy ; [2]Humanitas Research Hospital, Department of Biostatistics, Milano, Italy ; [3]Istituto Clinico Città Studi, Department of Gynecology- Division of Assisted Reproduction, Milano, Italy ; [4]Yale University- School of Medicine, Department of Obstetrics- Gynecology and Reproductive Sciences, New Haven, U.S.A.

Study question: To determine if there are differences in ease of use between two different embryo transfer's techniques: preload single step and post load double step approach.

Summary answer: Two step technique seems to reduce the difficult embryo transfer rate.

What is known already: Numerous published trials now document that the embryo transfer (ET) procedure has a huge impact on pregnancy and delivery rates after IVF. Difficult transfers should be avoided, as they are likely to reduce the chances of implantation and subsequent pregnancy rates. Free hand embryo transfers with soft catheters under ultrasound guidance is currently considered the best option in transferring embryos. However, in technically difficult ET the use of harder catheters is needed and this could impact in uterine contraction. Among soft catheters, it is not known which technique is preferable.

Study design, size, duration: prospective randomized unblinded controlled clinical trial, including 352 ecoguided ETs assigned to single step ET with Cook k-soft-5000 soft catheter or double step ET with Cook K-JETS-551910-S bulb tip catheter, from September 2017 to September 2019. The sample size was calculated on the basis of historical difficult ET rate encountered between 2014 and 2015. The randomization to one of the study branches was done by the operator just before the procedure, with a closed envelope.

Participants/materials, setting, methods: Inclusion criteria: 18 - 38 years old, BMI between 18 and 28, one thawed blastocyst transfers. Exclusion criteria: ICSI-TESE and pregestational test cycles. The primary outcome was difficult transfer rate, defined as presence of blood, required manipulation, need for instrumentation, stylet or tenaculum, multiple attempts, force and dilatation, for both groups. For the single step approach, the need for the outer sheath was considered as a difficult ET. The secondary outcome was clinical pregnancy rate.

Main results and the role of chance: A total of 352 ET's were performed. The two arms were homogeneous for age at ET and at freezing, endometrial preparation protocols, BMI, and duration of infertility. Among the entire population, 24.15% of the ET was defined as difficult. In the two branches, difficult transfer rate was significantly higher in the single step group than in the double step's one: 38.76% versus 9.20% respectively ($p<0.001$); the OR of difficult transfer with the double step was 0.16 (IC 95% 0.09 – 0.29). Clinical pregnancy rate was lower, however not significantly, in the single step group (42.13% versus 48.28%).

Limitations, reasons for caution: 18 different experienced operators participated in the trial, using a fixed distance transfer protocol. The differences in difficult transfer rate between operators were not analyzed. Conclusions about the pregnancy rate should not be generalized, since the sample analysis was not performed on this outcome.

Wider implications of the findings: Difficult transfer rate was significantly higher in the single step group. Further study about the correlation with ART outcomes are required.

Trial registration number: NCT03161119

P-221 Euploidy rates between either oral dydrogesterone (DYG) primed ovarian stimulation protocol or the GnRH antagonist (GnRH-ant) protocol in 780 patients in the first PGT-A cycle

L. Yang[1], K. Luo[1], G. Lu[1,2,3], G. Lin[1,2,3], F. Gong[1,3]

[1]Reproductive and Genetic Hospital of CITIC-XIANGYA, Reproductive and Genetic Hospital of CITIC-XIANGYA, Changsha, China ;
[2]Key Laboratory of Reproductive and Stem Cell Engineering- National Health and Family Planning Commission, Key Laboratory of Reproductive and Stem Cell Engineering, Changsha, China ;
[3]Institute of Reproducitve and Stem Cell Engineering- Basic Medicine College-Central South University, Institute of Reproducitve and Stem Cell Engineering-, Changsha, China

Study question: whether differences in euploidy rates between oral dydrogesterone (DYG) primed ovarian stimulation protocol and the GnRH-ant protocol in the first PGT-A cycle.
Summary answer: DYG is comparable to GnRH-ant protocol in terms of euploidy rates at OPU in the first PGT-A cycle.
What is known already: It is well known that successful meiosis in the IVF laboratory is inversely correlated with maternal age. However, it is unclear whether other factors, particularly the IVF process, can interfere with normal oocyte physiology. Oral treatment with DYG inhibits the pituitary LH surge during ovarian stimulation. Previous reports indicated that both the number of MII retrieved and pregnancy rates from these oocytes are comparable to short protocol of GnRH agonists during IVF cycles. It is worth investigating whether ovarian stimulation protocol in the first PGT-A cycle affects euploidy status in DYG protocol and the GnRH-ant protocol.
Study design, size, duration: This single-center, retrospective cohort study included patient who underwent the dydrogesterone (DYG, study group) or the GnRH-ant protocol (control group) in the first PGT-A cycle from November 2017 to May 2019 in Reproductive and Genetic Hospital of CITIC-XIANGYA. The study group and control group both included 390 cycles, obtained from 408 and 534 cycles respectively by propensity matching.
Participants/materials, setting, methods: We retrospectively evaluated in the first PGT-A cycle patients who underwent the dydrogesterone (DYG, study group) or the GnRH-ant protocol (control group). Propensity matching was used to identify a propensity matched control group from a cohort of 534 cycles, based on age, BMI, and AMH with a 1:1 ratio. Patient's demographic, baseline, and cycle characteristics were obtained for each cycle from our electronic medical record. The main outcome was euploidy rate.
Main results and the role of chance: 780 cycles were included in the study. The study group and control group both included 390 cycles. There was no difference in patient baseline and cycle characteristics between the two groups. The number of oocytes retrieved (6.08±5.02 vs. 6.41±4.68, P =0.34), MII (4.97±4.09 vs. 5.15±3.78, P = 0.42), embryos biopsied (1.88±2.57 vs. 1.79±2.01, P = 0.59), and embryos testing (1.88±2.57 vs. 1.79±2.01, P = 0.59) were no statistic difference between study and control groups. Due to some cycles did not form biopsy blastocysts. Therefore, cycles using NGS testing were 262 in study group and 263 in the control group respectively. The main outcome was that the euploid rate per embryo biopsied was not significantly different between study and control groups (DYG vs. GnRH-ant: 34.9%±2.4% vs.40.2%±3.97%, P = 0.116).
Limitations, reasons for caution: It is a retrospective study and subject to bias from confounding factors.
Wider implications of the findings: DYG and GnRH-ant protocol result in comparable euploid rates. Therefore, ovarian stimulation protocol with DYG should be considered a valid option in freeze-all PGT-A cycles, in view of its demonstrated effectiveness and known safety enhancement.
Trial registration number: not applicable

P-222 Prediction of blastocyst formation based on very early-cleavage embryos parameters by time-lapse monitoring

H. De Martin[1,2], G. Alecsandra[1], M. Fujii[1], M. Conatti[1], M. Nakano[2], T. Bonetti[3,4], P. Monteleone[2,5]

Study question: Is very early-cleavage embryos parameters, as soon as the second cell cycle (CC2), based on time-lapse monitoring (TLM) useful to predict blastocyst formation?
Summary answer: The time to embryos progress from two to three-cell (CC2) predict blastocyst formation. Optimal CC2 time-range is 8 to 13 hours, leading to 78.2% blastocysts
What is known already: Assisted reproductive technologies success is dependent of a number of factors, but embryo selection is a crucial step. The cell number during cleavage has been described as a key factor for selecting embryos, as slow or fast cleavage embryos shows reduced implantation potential. The introduction of TLM allowed additional noninvasive criteria to best embryo selection and markers of embryonic kinetic from the first-cleavage onwards has been studied and applied in algorithms for best embryo choice. Although early cleavage parameters may be predictive of blastocyst development and even implantation, this approach has gathered little attention and a consensus is not stablished.
Study design, size, duration: Retrospective cohort study used prospectively collected data from 671 ICSI cycles from 486 patients (37.7±4.2 years) between April/2018 and September/2019 in a private reproductive medicine center. A total of 4724 mature (MII) oocytes were fertilized by ICSI and cultured in a time-lapse monitoring system (Embryoscope®). Embryos were recorded since fertilization until the blastocyst formation. The time for pronuclei fading (tPNf), two-cell (t2), three-cell (t3), four-cell (t4), five-cell (t5), eight-cell (t8), nine-cell (t9) were evaluated.
Participants/materials, setting, methods: The early-cleavage characteristics were analyzed and correlated to blastocyst formation. The periods between t2-t3 (cell cycle two – CC2), between t3-t5 (CC3) and between t5-t9 (CC4) were calculated. The blastocysts were also classified according to morphology by Gardner's classification and those with trophoectoderm grade ≥3 and inner cell mass A or B were considered top-quality. The blastocyst rate (BlastR) was calculated by the number of blastocysts formed per number of 2PN in each category.
Main results and the role of chance: From the 4724 MII oocytes injected, 3622 were normally fertilized (2PN). From those, 3552 cleaved into two-cells (t2=28.5±6.7 hours), 3500 attained three-cell (t3=38.6±7.3 hours), 3399 got five-cell (t5=51.0±10.0 hours) and 3077 attained nine-cell (t9=73.7±12.2 hours). The mean time of CC2 was 10.2±4.7, CC3 was 12.6±6.7 and CC4 was 23.3±9.1 hours. A total of 2341 embryos developed to blastocyst stage (64.6%) on days 5 (n=2108, 90.0%) or 6 (n=233, 10.0%). We evaluated the blastocyst rate (BlastR) according to CC2 varying from zero (for embryos who had tripolar mitosis and did not had two cells observed) to ≥20 hours. For CC2<1.0 hour the mean BlastR was 20.4%, for CC2 between 1 and 7 hours the mean BlastR was 46.2%. The highest BlastR (78.2%) occurred for embryos presenting CC2 between 8 and 13 hours. After that, the BlastR progressively decreased for embryos with CC2≥14 hours (38.9%), attaining a mean of 12.2% for CC2≥20 hours. Among the blastocysts developed, we assessed the top-quality blastocyst rate (TQ-BlastR) and the same pattern was observed: CC2<1.0 hour: TQ-BlastR=17.0%; CC2 between 1 and 7 hours: TQ-BlastR=20.0%; CC2 between 8 and 13 hours: TQ-BlastR=55.5%; CC2≥14 hours: 42.7%. There was no TQ-Blast formed when the CC2 was ≥18 hours.
Limitations, reasons for caution: This is a retrospective study evaluating the association of CC2 and blastocyst formation. The choice of blastocysts for transfer was based on blastocyst morphology on day 5 or 6 and did not take into account the CC2. Then, we could not evaluate the impact of CC2 on pregnancy success.
Wider implications of the findings: Based on our findings, we can underline that time of CC2 predict blastocyst formation and can be used for selecting day-3 embryos for transfer and contribute to embryo development prognostic. The CC2 is an auspicious candidate to be included in the time-lapse algorithm and should be further validated for that.
Trial registration number: not applicable

P-223 Comparison between two oil layer thickness covering on human embryo culture: a prospective study

H. Bahri[1], M. Benkhalifa[2], W. Zidi[3], Z. Mhamdi[4], H. Garai[4], O. Triki[4], K. Ben Rhouma[4], G. Merdassi[4]

[1]Alyssa Fertility Group, Alyssa Clinic / HB laboratory, tunis, Tunisia ;

[2]Alyssa Fertility Group / Faculty of sciences of Bizert, Alyssa Clinic / Biochemistry department of La Rabta Hospital, tunis, Tunisia ;
[3]Faculty of sciences of Bizert, Biochemistry department of La Rabta Hospital, tunis, Tunisia ;
[4]Alyssa Fertility Group, Alyssa Clinic, tunis, Tunisia

Study question: Does the light paraffin oil layer thickness used for in vitro embryo culture improve in vitro development of human embryos and pregnancy rate?
Summary answer: The success rate of embryo implantation and biochemical pregnancy (BP) was significantly higher with *in vitro* embryo culture (EC) using a thicker cover of light-paraffin-oil.
What is known already: The oil overlay in embryo culture systems prevents medium evaporation helps to maintain appropriate pH and osmotic conditions and protects from volatile organic compounds and microbial contamination. In classic procedures, once microinjected, the oocytes are transferred into a culture dish of separated embryo culture medium drops (1 – 3 oocytes per drop of 25µl) covered with approximately 1 mm of paraffin oil (from the top of the drops). The risk of the infiltration of contaminating agent becomes higher after 3 days of culture.
Study design, size, duration: 168 patients (20-40years) undergoing in-vitro fertilization (IVF) treatment by intracytoplasmic-sperm-injection (ICSI) were enrolled in our prospective study between October 14 – December 23, 2019. After ICSI, 833 oocytes were allocated into 2 groups according to the thickness of oil covering the embryo culture medium (ECM): 1mm or 4mm. Statistical-analyses by SPSS 20.0 (SPSS Inc., Chicago-IL-USA) with Kolmogorov-Smirnov test for normality, Student-t test for parametric comparisons and Mann-Whitney test for non-parametric comparisons with $p<0.05$ as statistically-significant.
Participants/materials, setting, methods: Group-1: Protected culture (PC+): 520 matured oocytes with EC in dishes containing single layer of 400µl ECM covered by ~200µl of light-paraffin-oil (Ovoil, Vitrolife-Sweden) (~4mm from the ECM surface). Group-2 (PC-) 313 matured oocytes with EC in dishes covered by light-paraffin-oil (1mm of thickness from the top of the drops). Sage1-step (Origio-Denmark) was used as ECM. EC was into trigaz incubators. BP was defined as a positive βHCG-test after 2 weeks from the embryo transfer.
Main results and the role of chance: Embryo morphology was recorded on days 3 and 5. A total of 139 PC+ and 97 PC- day3 embryos and 59 PC+ and 46 PC- day5 embryos were analyzed.
There were no differences between the two groups in terms of mean of age, number of collected oocytes, and number of matured oocytes, cleavage rate, top quality day3 embryo rate and the number of transferred embryos. The proportion of top quality day3 embryos was 66.66% [0% – 100%] vs 75.00% [0% – 100%] in PC+ and PC- groups respectively. However, Blastulation rate was significantly higher in PC+ group than in PC- with 61.55% ±2.77% vs 57.73% ±2.54%; (p=0.001) respectively. Pregnancy rate per transfer was evaluated in 69% of the total patients. When the unknown βHCG test results were eliminated, the biochemical pregnancy rate was higher in the PC+ group compared to PC- group with 41.2% vs 35.4%; (p< 0.001) respectively.
Limitations, reasons for caution: The design in this study is not a randomized controlled trial, although it is prospective. Moreover, different origin of sperm (Ejaculated and testicular) were used to fertilize corresponding oocytes.
Wider implications of the findings: These results should interest embryologists who want to improve embryo culture conditions. More studies must be done with a larger cohort of oocytes.
Trial registration number: Not applicable

P-224 Reducing oxygen concentration from 5% to 3% after embryo compaction decreases the aneuploidy rate of the derived blastocysts. Analysis of 119 sibling zygotes

A. Ruberti[1], M.G. Minasi[1], E. Cursio[1], A. Colasante[1], S. Muzzì[1], G. Pirastu[1], D. Paccagnini[1], S. Gatti[1], A. Caragia[1], P. Greco[1], E. Iovine[1], A. Greco[1], M.T. Varricchio[1], E. Greco[1]

[1]European Hospital, Medicina della Riproduzione, Rome, Italy

Study question: Does a reduction in incubation oxygen concentration from 5% to 3%, from day-3 of culture in advance, affect blastocyst's quality?
Summary answer: Reducing oxygen concentration from day-3 of culture allows to obtain a higher blastocyst number available for the transfer compared to fixed 5% oxygen concentration.
What is known already: It is well established that culturing embryos in an oxygen concentration lower than the atmospheric one will increase clinical and live birth rates. The oxygen tension most widely employed is 5%. Based on the observation that the levels of oxygen in the uterus are lower than in the oviduct, it has been postulated that a further reduction in oxygen tension after embryo compaction could more closely mimics the natural environment, better supporting the embryo's physiology. Few studies comparing different oxygen values have been published with conflicting results and the optimal range of oxygen concentration has still to be determined.
Study design, size, duration: From September to December 2018, 12 patients undergoing to preimplantation genetic testing for aneuploidy cycles were enrolled in the study. The mean female age was 36.7±4.1 years old. Inclusion criteria were at least 6 normal fertilized oocytes. Exclusion criteria were: genetic diseases, severe male factors and egg donation cycles.
Participants/materials, setting, methods: Sibling zygotes were divided in 1:1 ratio in two groups. All cultures were performed in sequential media with a change-over on day-3. In the standard oxygen (SO) group, zygotes were maintained at 5% of oxygen tension for the whole culture. In the low oxygen (LO) group, zygotes were maintained at 5% until day-3 of culture and then moved to 3% of oxygen tension for the remaining days.
Main results and the role of chance: A total of 119 normal fertilized zygotes were obtained, 62 and 57 of them were cultured in SO and LO groups, respectively. The good/excellent day-3 embryo quality was comparable in the two groups: 80.6% (N=50) and 87.7% (N=50) in SO and LO groups, respectively (NS). The blastocyst formation rate was similar in the two groups: 56.5% (N=35) and 52.6% (N=30) in SO and LO groups, respectively (NS). In SO group, 15 blastocysts were obtained on day-5, 15 on day-6 and 5 on day-7. In LO group, 14 blastocysts were obtained on day-5, 16 on day-6 and none on day-7. A total of 30 and 27 blastocysts were biopsied in SO and LO groups, respectively. The percentage of blastocyst available for the transfer was statistically higher in LO group (81.5%, N=22) compared to SO group (46.7%, N=14; p=0.0124). In 3 and 1 blastocysts it was not possible to obtain the genetic result, in the SO and LO groups, respectively.
Limitations, reasons for caution: This is a pilot study enrolling few patients with a high oocyte's number. Data on clinical outcomes, such as implantation, clinical pregnancy, live birth and miscarriage rates as well as follow-up data on babies born, are still missing. These preliminary results need to be confirmed on an increased sample size.
Wider implications of the findings: It has been reported that euploidy rate can greatly vary among different infertility centers demonstrating that chromosomal abnormalities can be partially iatrogenic. To set-up the optimal culture conditions in order to obtain the highest number of transferable blastocysts could enhance the efficiency of infertility treatments.

P-225 The effect of women's age on timing, morphology and implantation of the competent blastocyst – a multicenter cohort study

M. Buhl Borgstrøm[1], M.L. Grøndahl[1], T. Wirenfeldt Klausen[2], A. Kjærgard Danielsen[3], T. Thomsen[4], U. Schiøler Kesmodel[5], I.T.C.B.P.G. Inclusive: The Competent Blastocyst Project Group[1]

[1]Herlev University Hospital, The fertility clinic, Herlev, Denmark ;
[2]Herlev University Hospital, Department of hematology, Herlev, Denmark ;
[3]Herlev University Hospital, Department of gastroenterology, Herlev, Denmark ;
[4]Herlev University Hospital, Department of Anaesthesiology, Herlev, Denmark ;
[5]Aalborg University Hospital, Department og Obstetrics and Gynecology, Aalborg, Denmark

Study question: Is the age of women undergoing assisted reproductive technology (ART) associated with timing, morphology and implantation of the competent blastocyst?
Summary answer: The effect of age on timing and morphology was modest, while initial hCG rise was lower for the youngest women.
What is known already: Within ART, the age of a woman is the most prognostic parameter for her chance to conceive. Both women's age and ploidy fail to be reflected in routine embryo assessment. We have previously shown that initial hCG rise in singleton pregnancies after single cleavage stage embryo transfer is higher with increasing age in both in vitro fertilization (IVF) and

intracytoplasmic sperm injection (ICSI) suggesting that age may influence trophoblast differentiation and placentation. Hence, the question remains whether the competent blastocyst develops in the same way regardless of women's age or if age imposes an alteration in timing, morphology and implantation?

Study design, size, duration: This is a multicenter historical cohort study based on exposure and outcome data from 7246 women, who between 2014 and 2018 underwent controlled ovarian stimulation (COS) or Frozen Embryo Transfer (FET) followed by single blastocyst transfer and hCG measurement, resulting in singleton pregnancy. These data were linked to the Danish Medical Birth Registry using the women's unique personal identification number (CPR). Resulting in a total of 5466 women with a live birth being included.

Participants/materials, setting, methods: Exposure (age) and outcome (Gardner's score (1-6), inner cell mass (ICM)(A,B,C), trophectoderm (TE) (A,B,C) and hCG) data were collected from the fertility database, Danish Medical Data Center, used by the 16 participating private and public fertility clinics. All COS cycles (IVF and ICSI) and FET cycles (natural and substituted), were included. Exclusion criteria were cycles with pre-implantation genetic testing and donated oocytes. The analysis was adjusted for male age, female smoking, female BMI, diagnosis and clinic.

Main results and the role of chance: The women's mean age for COS/FET was 32.4/32.6 years. Adjusted analysis of age and stage in COS treatments showed that for every one-year increase in age there was a 5% reduced probability of the competent blastocyst assessed as being in a high stage at transfer (OR 0.95, 95% CI (0.93;0.98)). Adjusted analysis of age and TE (A,B,C; A being the highest category) in FET treatments showed that for every one-year there was a 3% increased probability of the competent blastocyst assessed as being in a high TE category. Other comparisons related to the effect of age on timing and morphology did not reach statistical significance.

HCG values followed an identical pattern in COS and FET, with the lowest hCG values in the youngest age group for both treatments, 95.3 (IU/L) for COS and 130.9 (IU/L) for FET. Comparison between hCG values in women 18-24 years and 25-29 years in those receiving respectively COS and FET treatment, showed a significantly lower levels in the youngest women, with a significant mean difference in the adjusted analyses COS: -20.9, 95% CI (-35.7;-6.1)); FET: -21.8, 95% CI (-42.1;-1.5). Other comparisons did not reach statistical significance.

Limitations, reasons for caution: The blastocyst morphology was subjectively assessed and inter observer differences may have influenced the results. However, adjusting for clinic takes the potential inter clinic variation in embryo scoring into consideration.

Wider implications of the findings: Our study supports an association between young age and lower initial hCG-values after ART-treatment irrespective of mode of treatment, which should be born in mind when evaluating hCG-measurements.

Whether these findings correlate to the embryo or the endometrium need further clarification.

Trial registration number: not relevant

P-226 Paternal influence on mitochondrial DNA levels in day 3 euploid embryos: a retrospective pilot study.

Y. Mourad[1], M. Bazzi[1], V. Massaad[2], C. Afeich[2], G. Raad[1], J. Mortada[3], F. Fakih[4], R. Yazbeck[5], M. Chartouny[5], R. Zahwe[1], C. Fakih[1]

[1]Al Hadi Laboratory and Medical Center, Ivf, Beirut, Lebanon ;
[2]Lebanese University, Master in Reproduction and Development, Fanar, Lebanon ;
[3]Al Hadi Laboratory and Medical Center, Molecular Biology, Beirut, Lebanon ;
[4]Al Hadi aboratory and Medical Center, Ivf, Beirut, Lebanon ;
[5]Lebanese University, Faculty of Medicine, Hadath, Lebanon

Study question: Is there any paternal influence on the mitochondrial DNA levels in day 3 euploid embryos?

Summary answer: Higher mitochondrial DNA (mtDNA) levels were detected in day 3 euploid embryos of non-normozoospermic men compared to normozoospermic.

What is known already: Early paternal influence on pre-implantation embryo development was considered to be related to sperm cytoplasmic factors such as centrioles. Recently, double-stranded sperm DNA damage was shown to be associated with a delay in cleavage embryo kinetics. Furthermore, altered cleavage divisions may lead to an abnormal distribution of mitochondria between blastomeres. In parallel, oocyte may have the capacity to modulate and repair, to certain extent, the sperm genome. In this study, we hypothesize that poor sperm quality may modify the oocyte's mtDNA levels as a part of the repair mechanism.

Study design, size, duration: A retrospective pilot study was conducted at AL Hadi Laboratory and Medical Center, between January 2019 and January 2020.The study included the data analysis of 170 embryos obtained from 28 infertile couples undergoing pre-implantation genetic screening (PGS) for aneuploidy. Couples were categorized based on sperm indices into: normozoospermic (n= 13) and non-normozoospermic (n= 15) groups. Non-normozoospermia was defined by the presence of at least one abnormal sperm parameter according to the World Health Organization 2010.

Participants/materials, setting, methods: PGS data collected from couples with maternal age <38 years, a history of unsuccessful IVF treatments, and/or previous spontaneous miscarriages were included. Evaluation of embryo quality was carried out in accordance with Alpha-ESHRE consensus. Fresh embryos derived from fresh gametes were biopsied on day 3. Genomic and mitochondrial DNA levels were quantified using next generation sequencing (Ion Torrent, ThermoFisher Scientific, Lebanon). Implantation rates per transferred fresh embryo were analyzed.

Main results and the role of chance: From the total of 170 assessed embryos, 73 were identified as euploid. No statistical significant trend was observed in the percentage of euploid embryos between the normozoospermic and non-normozoospermic groups (49% and 38% respectively). In contrast, a higher mtDNA levels were detected in the non- normozoospermic group compared to the normozoospermic ($p = 0.0232$). Implantation and fertilization rates showed no significant difference between the two comparable groups ($p > 0.05$).

Limitations, reasons for caution: This study provided a possible effect caused by paternal factors on embryonic mtDNA levels. However, to determine the true extent of this clinical outcome, a prospective design with a larger sample size is necessary to corroborate the current findings.

Wider implications of the findings: The biological mechanism(s) underlying the association between paternal factors, oocyte repair system, and mitochondrial DNA are unknown. Hence, this topic is of considerable importance in future assessment of the role of mitochondria in oocyte ability to repair any sperm defect that could alter embryo development.

Trial registration number: Not applicable

P-227 Clinical factors affecting meiotic spindle imaging of oocytes by PolScope before ICSI

S.J. Kim[1], J. Jeong[1], S. Kim[1], T.H. Kim[1], J.H. Eum[1], W.S. Lee[1], S.W. Lyu[1]

[1]Fertility Center of CHA Gangnam Medical Center- CHA University School of Medicine, Department of Obstetrics and Gynecology, Seoul, Korea- South

Study question: Are there clinical factors associated with the visibility of meiotic spindle of oocytes when performing intracytoplasmic sperm injection (ICSI)?

Summary answer: Longer gonadotropin stimulation was associated with oocytes of no visible spindle, but not the ovarian reserve and female age.

What is known already: In the laboratory, Polarized light microscopy (PolScope) has been used to locate the meiotic spindle and inject oocytes without damaging spindle. Meiotic spindle imaging by PolScope has been studied to predict oocyte quality. Moreover, some studies analyzed various environmental conditions affecting meiotic spindle. However, there are few papers on the relationship between clinical factors and oocyte meiotic spindle.

Study design, size, duration: This retrospective study was conducted at a single fertility center. A total of 717 mature oocytes of 140 patients were selected for spindle analysis. Fertilization and embryo development of each oocyte were analyzed with respect to the observed spindle pattern. We evaluated multiple clinical factors as a predictor of oocytes with no visible spindle.

Participants/materials, setting, methods: From October 2017 to April 2019, patients who underwent ICSI in previous in vitro fertilization treatment but have failed pregnancy more than 2 times were recruited. The meiotic spindle angle of oocytes was defined as the angle of spindle deviation to the first polar body and graded as the follows: a, 0-5°; b, 6°-15°; c, 16°-30°; d, 31°-45°; e, >46°; non-visible spindle. Statistical analysis was carried out using the Chi-square test and multivariate regression analysis.

Main results and the role of chance: The mean age, anti-Mullerian hormone (AMH), and duration of stimulation were 39.6 ± 3.6 years, 2.25 ± 3.04 ng/ml,

and 9.0 ± 2.5 days, respectively. The number of oocytes retrieved and the number of mature oocytes retrieved were 7.8 ± 6.6 and 5.3 ± 4.8, respectively. The distribution of the oocytes according to grade were as follows: a (32.6%), b (31.7%), c (18.0%), d (7.1%), e (6.0%), and non-visible (4.6%). Fertilization rates were similar except non-visible grade: a (73.9%), b (74.0%), c (72.9%), d (72.5%), e (76.7%), and non-visible (51.5%). However, the cleavage rate and good quality of cleavage embryo formation rate were not different among the grades. When evaluating for factors predicting oocyte of non-visible spindle, the duration of gonadotropin stimulation was the only relevant factor (adjusted Odds Ratio (aOR) 1.218, 95% CI (1.005-1.477)). However, Female age (aOR 1.064 (0.929-1.220)), body mass index (aOR 1.092 (0.901-1.323)), AMH (aOR 0.976 (0.806-1.182)), and the number of oocytes retrieved (aOR 1.124 (0.948-1.333) were not associated with spindle nondetection.

Limitations, reasons for caution: The retrospective study design and the small number of study subjects are limitations. We only focused on clinical factors; therefore, further studies are needed to evaluate the laboratory factors such as temperature and pH.

Wider implications of the findings: Oocytes with non-visible spindle showed significantly lower fertilization rates. Meiotic spindle angle does not affect the oocyte quality represented by fertilization rate, cleavage rate, and good quality of cleavage embryo formation rate. The duration of gonadotropin stimulation was the only clinical factor related to oocytes of no visible spindle.

Trial registration number: Not Applicable

P-228 Laser assisted hatching at cleavage stage before the subsequent trophectoderm biopsy: to perform or not to perform?

M.G. Minasi[1], E. Cursio[1], A. Colasante[1], S. Muzzì[1], G. Pirastu[1], D. Paccagnini[1], S. Gatti[1], C. Arrivi[1], A. Greco[1], P. Greco[1], M.C. Greco[1], M.T. Varricchio[1], A. Ruberti[1], E. Greco[1]

[1]European Hospital, Center for Reproductive Medicine, Rome, Italy

Study question: Is the laser assisted hatching (LAH) day-3 zona pellucida (ZP) opening, performed in order to facilitate the subsequent biopsy at blastocyst level, safe?

Summary answer: To perform LAH at cleavage stage is safe and does not impair the ploidy nor the implantation rate in the deriving blastocysts

What is known already: Preimplantation genetic testing (PGT) is widespread used to select the embryo with the highest implantation potential. Currently, the blastocyst is the preferred developmental stage to be biopsied. A strategy is open the ZP with laser at embryo level in order to favorite the subsequent blastocyst hatching, simplifying the biopsy procedure. This method, however, has been suggested to negatively interfere with embryo development. Another possibility, hypothesized to be safer, consist of let the embryos undisturbed during the whole culture performing the ZP opening directly during the biopsy. A complete evaluation of the risks associated with these methods is still missing.

Study design, size, duration: Retrospective analysis of 491 PGT cycles. According to our laboratory procedure, when a cycle was allocated in sequential culture media all the developing day-3 embryos underwent to LAH during the media change-over (LAH group). When single-step media was employed, all embryos were maintained undisturbed in culture and LAH was performed directly during the biopsy at blastocyst stage (NO-LAH group). The allocation in the two culture media is randomly based on weekly rotation

Participants/materials, setting, methods: All cycles were performed from June 2015 to December 2019: 393 were allocated in LAH and 98 in NO-LAH groups, respectively. All culture were carried out in the same time-lapse incubator at 37°C, 5%O_2 and 6%CO_2. Mean female ages were 38.8±4.1 and 37.4±3.9 year old in LAH and NO-LAH groups, respectively (p=0.002). Monogenic diseases, structural rearrangements and egg donation cycles were excluded from the analysis. All embryo transfers were performed on a subsequent cryopreserved cycle

Main results and the role of chance: In LAH group, 3706 oocytes were collected, 2747 of them were mature and were injected. In NO-LAH group 720 out of 1013 retrieved oocytes were mature and injected. The fertilization rates were 76.2% (N=2093) and 80.0% (N=576) in LAH and NO-LAH groups, respectively (p=0.0324). A total of 2081 and 576 day-3 embryos were obtained in LAH and NO-LAH groups, respectively. The blastocyst formation rates were 54.2% (N=1127) and 65.3% (N=376) in LAH and NO-LAH groups, respectively (p<0.0001). Overall, 1123 and 374 blastocysts were biopsied and for 1072 and 363 of them it was obtained the genetic result (95.5% and 97.1%, NS) in LAH and NO-LAH groups, respectively. The percentages of transfereable blastocysts were comparable between the two groups: 40.2% (N=452) and 41.2% (N=154) in LAH and NO-LAH groups (NS), respectively. In total, 275 and 47 frozen embryo transfer were performed in LAH and NO-LAH groups, respectively. In LAH group, 281 blastocysts were transferred and 139 of them implanted (49.5%). In NO-LAH group, 48 blastocysts were transferred and 22 of them implanted (45.8%, NS). The miscarriage rate was the same in two groups (19.0%). Statistical analysis was performed using Sudent's t-test and Chi-squared test at the level of p<0.05

Limitations, reasons for caution: Although the incubator employed for the culture was the same in all analyzed embryos, the use of different culture media in the two groups could have introduced a bias in the study. The study has a retrospective design

Wider implications of the findings: Despite NO-LAH group includes younger women and higher fertilization and blastocyst formation rates compared to LAH group, the percentage of blastocyst available for transfer and the implantation rate were comparable. This outcome should reassure the operators about the LAH day-3 ZP opening in order to simplify the blastocyst biopsy procedure

Trial registration number: Not applicable

P-229 Can we predict aneuploidy or mosaicism considering blastocyst morphology?

A. Rodríguez-Arnedo[1], L. Herrero[2], L. Cascales[2], J.A. Ortiz[3], A. Bernabeu[4], J. Llácer[4], A. Llaneza[5], J. Ten[1], R. Bernabeu[4]

[1]Instituto Bernabeu, Embryology Dept., Alicante, Spain ;
[2]Instituto Bernabeu, Embryology Dept., Madrid, Spain ;
[3]Instituto Bernabeu, Molecular Biology, Alicante, Spain ;
[4]Instituto Bernabeu, Reproductive Medicine, Alicante, Spain ;
[5]Instituto Bernabeu, Reproductive Medicine, Madrid, Spain

Study question: Can we correlate blastocyst morphology with aneuploidy or mosaicism rates?

Summary answer: Blastocyst morphology: quality and expansion (percentage of trophectoderm (TE) hatching out of the zona) as well as maternal age are associated with aneuploidy and mosaicism.

What is known already: Preimplantation genetic testing of aneuploidies (PGT-A) has significantly grown in assisted reproduction treatments in the last decade. PGT-A aims to find the best euploid embryo, improving birth rates and allowing single embryo transfer. Embryo morphology is considered a predictor of implantation potential and several publications support a correlation between embryo development parameters with the chromosomic status of the embryo. Nonetheless, many "top-quality" embryos still turn out to be aneuploid after PGT-A. The aim of this study is to identify which embryo features are correlated with higher aneuploidy or mosaicism rates, and if it is possible to predict them.

Study design, size, duration: Retrospective database study performed between August 2017 and December 2018 including 162 PGT-A cycles and 499 biopsied embryos. Cycles with severe male factor (sperm samples concentrations under one million/mL) were excluded.

Participants/materials, setting, methods: Blastocyst quality was assessed according to Gardner and Schoolcraft score. Expansion was classified according to the percentage of Trophectoderm (TE) hatching out of the zona. Mosaic embryos with ≤25% aneuploid cells were considered euploid, and those with >50% were considered aneuploid.

Student's t, Pearson's chi-square and multivariate analysis (linear and binary logistic regressions) were used. Maternal age, embryo quality and expansion, day of biopsy and oocyte origin were introduced as confounding variables.

Main results and the role of chance: A total number of 310 blastocysts were biopsied on day-5 (62.1% out of 499). Three-hundred and twenty-eight blastocysts came from donor eggs cycles (65.7%) and 183 from frozen/thawed oocytes (36.7%). The diagnosed blastocysts (4.6% amplification failure) were classified in: 57.7% euploid, 13.7% euploid mosaic and 42.4% aneuploidy blastocysts. A tendency of lower aneuploidy rates as the blastocyst expansion increases was observed: 5-25% extruded TE: 47.7% aneuploidy, 25-50% extruded TE: 44.0% aneuploidy, >50% extruded TE: 32.6% aneuploidy, 100% extruded TE: 28.6% aneuploidy (p=0.052). Maternal average age also decreased as the blastocyst expansion increased (p=0.089). TE quality was found to be significative in predicting aneuploidy rate: 40.8% aneuploidy (TE A/B), 93.3% (TE C/D;

p=0.004). Maternal average age of blastocyst with A/B TE was lower than those blastocysts with C/D TE (29.8±9.8 vs 31.8±6.8 years), and also predictive for aneuploidy: p<0.001. TE quality (p=0.016) and maternal age (p=0.012) were found to be the most important variables predicting mosaicism. Logistic regression and multivariate aneuploidy risk score were performed. AUC was used to assess the predictive performance of the aneuploidy risk score: AUC=0.719 (95% CI 0.672-0.767). The same multivariate analysis was performed to predict euploid mosaic presence, and the AUC was 0.672 (95% CI 0.595-0.748).

Limitations, reasons for caution: Expansion and quality assessment is operator dependent and a potential source of subjective bias. Further studies focused on non-invasive embryo biomarkers for implantation potential to improve selection are warranted. PGT-A cannot yet be replaced by a genetic status statistical estimation, but it will be helpful in patient counselling.

Wider implications of the findings: Our results suggest a correlation between aneuploidy and blastocyst expansion/TE quality. This information might be helpful for patient counselling especially when PGT-A is not considered. Based on our findings, poor morphology and slow blastocysts from older patients carry a high risk for aneuploidies.

Trial registration number: no trial rnumber

P-230 Comparison of ploidy outcomes between grouped and single embryo culture in preimplantation genetic testing for aneuploidy (PGT-A) cycles.

S. Makieva[1], L. Pagliardini[1], L. Corti[1], A. Alteri[1], E. Papaleo[1], G. Cermisoni[1], A. Biricik[2], F. Spinella[2], F. Fiorentino[2], P. Viganò[1]

[1]IRCCS San Raffaele Scientific Institute, Obstetrics and Gynecology Unit, Milan, Italy ;
[2]Genoma, Molecular Genetics Laboratory, Rome, Italy

Study question: Does grouped embryo culture influence ploidy outcomes in PGT-A cycles?

Summary answer: PGT-A cycles performed using grouped embryo culture had 7.1% (p=0.02) higher euploidy rate compared to single embryo culture.

What is known already: Animal and human studies have shown that single embryos in culture lack the benefits of embryotrophic factors of group culture. In mice, single culture is associated with suboptimal neonatal outcomes while in humans grouped culture reduces embryo development rates, blastocyst quality and pregnancy rates. Thus, single culture may be detrimental to human embryos compared to grouped culture plausibly due to deprivation of paracrine signaling occurring between neighboring embryos. To date no study has assessed whether grouping embryos can influence their genetic composition and, hence, PGT-A outcomes.

Study design, size, duration: A retrospective analysis of 342 PGT-A cycles involving 1265 biopsied blastocysts performed between December 2014 and July 2019. The blastocysts were cultured either in groups of 1-6 (grouped culture; n=616) between December 2014 and March 2017 or individually (single culture; n=649) between May 2017 and July 2019, under similar conditions. The biopsy was performed between day 5 and 7 of development. The PGT-A diagnosis and other IVF outcomes were compared between the two groups.

Participants/materials, setting, methods: PGT-A cycles were performed at the IVF center of San Raffaele Hospital and included patients with an indication for advanced maternal age, recurrent implantation failure or a risk for a genetic disease. Grouped and single embryo culture involved a sequential system using culture media supplemented with SSS. All procedures were performed according to standard clinical practice. The PGT-A diagnosis was based on WGA+aCGH or NGS, which was predominantly performed at the genetics laboratory GENOMA.

Main results and the role of chance: The analysis of 1265 blastocysts revealed that grouped culture had a higher number of euploid (176/616; 28.5%; p=0.027) and lower number of mosaic (72/616;11.6%; p=0.025) blastocysts when compared to single culture (150/649;23.1% and 104/649;16% respectively). The number of grouped blastocysts biopsied on day 5 (261/616; 42.3%) was higher (p<0.0001) when compared to single blastocysts (166/649;26.9%). Moreover, single cultured blastocysts were more likely to be biopsied on day 6 (414/649;67.2%; p<0.0001) and day 7 (69/649;11.2%; p=0.0015) compared to grouped (366/616;49.6% and 49/616;7.9% respectively). Overall, the rate of euploidy in the 159 cycles in the grouped culture group was significantly higher compared to that in the 183 cycles of single group (28.66 ±29.19% vs 20.95 ±28.45%; p=0.002). No difference was observed in the rate of mosaicism. In the grouped culture cycles, the rate of day 5 biopsy was higher (38.73 ±18.89% vs 24.76 ±19.28%; p<0.0001) and of day 6 lower (52.39±29.07% vs 63.69 ±33.75%; p=0.0012) compared to single culture cycles. A generalised linear estimation corrected for variables known to be associated with ploidy according to the literature. Single embryo culture had 7.1% (13.2-1.1 %CI) lower euploidy rate compared to grouped embryo culture (p=0.02).

Limitations, reasons for caution: The study is limited by its retrospective design. The grouped embryo culture contained embryos cultured individually when the cycle had 1 embryo in excess. Cycles including at least 1 blastocyst with inconclusive diagnosis were included. The methodology used for assessment of chromosomal constitution may have introduced a bias.

Wider implications of the findings: Our findings suggest that grouped embryo culture may benefit PGT-A cycles by increasing the number of blastocysts diagnosed as euploid. This phenomenon could be attributed to the paracrine communication that may aid cell correction and free the blastocyst from aneuploid cells, which if persist may result in a mosaic diagnosis.

Trial registration number: non applicable

P-231 Suitability of 3D culture system with GrowDex for long-term culture of granulosa cells

E. Chmelíková[1], M. Sedmíková[1], M. Ješeta[2], P. Postlerová[1], R. Krejčířová[1], T. Krejčová[1], K. Havlíková[1], J. Žáková[2], P. Ventruba[2]

[1]Czech University of Life Sciences Prague, Department of Veterinary Sciences, Prague, Czech Republic ;
[2]Faculty of Medicine- Masaryk University Brno and University Hospital Brno, Department of Obstetrics and Gynecology, Brno, Czech Republic

Study question: Is it possible to increase the suitability of *in vitro* culture system for long-term granulosa cells cultivation using three dimensional (3D) culture with hydrocellulose GrowDex?

Summary answer: Using of 3D long-term culture system with GrowDex resulted in increasing of anti-apoptotic Bcl-2 and decreasing of pro-apoptotic Bax factors in porcine granulosa cells.

What is known already: Granulosa cells (GC) play important role in meiotic maturation of oocytes: by steroidogenesis, hormone activity regulation and prevention apoptosis. Apoptosis is regulated by pro- and anti-apoptotic factors; well-known of them are Bcl-2 and Bax. GC represent suitable model for *in vitro* culture, however when GC are cultured in monolayers they gradually lose their functions. 3D culture systems more closely mimic cell physiology environment and preserve interactions between cells. GrowDex hydrogel could be used as a matrix for 3D cultivation. GrowDex is a nanofibrillar cellulose hydrogel that forms fibres with length of several micrometres while their diameter is only 4-100 nanometres.

Study design, size, duration: In this study, porcine cumulus oocyte complexes (COCs) were matured in culture medium with GrowDex hydrogel as a matrix for 3D culture system (20 COCs; 4-well NUNC dish; 38°C; 5% CO_2). Conventional (2D) culture system was used as a control. After 48-hour culture matured oocytes were removed from COCs and GC were further cultured for 16 days. After pro-long culture, apoptotic factors (Bcl-2 and Bax) were determined in GC samples. Experiment was four times repeated.

Participants/materials, setting, methods: BCl-2 and Bax proteins were detected by blot immunodetection. The antigen-response signal to antibody was expressed on the basis of integrated optical density (IOD), which is equal to the average optical density and the area at the antigen-antibody response. In order to assess the amount of detected proteins, the IOD values were compared to the integrated optical density of non-cultured GC (RIOD=1). Statistical evaluation was performed using one-way ANOVA.

Main results and the role of chance: 3D culture system with GrowDex was shown to be more suitable for long-term culture of porcine granulosa cells as compared with conventional 2D culture system. Granulosa cells cultured in 3D culture system expressed pro-apoptotic factor Bax in significantly lower manner than those in 2D conventional system (RIOD = 0.3 vs. 0.73). On the contrary, the expression of the anti-apoptotic factor Bcl-2 was significantly higher in GrowDex culture system (RIOD = 2.31 vs. 1.61).

Limitations, reasons for caution: A limitation is the number of samples included and analysed in this study, which slightly reduced the power of statistical analysis.

Wider implications of the findings: 3D culture system with GrowDex could be tested for human granulosa cells when the long-term culture is required.
Trial registration number: Not applicable

P-232 Blastocyst re-expansion after warming is not predictive of implantation after euploid blastocyst transfer.

S. Mateo cuadros[1], M. Parriego[1], M. Solé[1], L. Coll[1], M. Tresanchez[1], F. Martínez[1], M. Boada[1], A. Veiga[1]

[1]Dexeus Mujer, Reproductive Medicine Service- Department of Obstetrics- Gynecology and Reproduction, Barcelona, Spain

Study question: Is blastocoel re-expansion a predictor of implantation in euploid blastocyst transfer?
Summary answer: Blastocoel re-expansion degree before embryo transfer does not correlate with implantation potential in warmed euploid blastocysts.
What is known already: Vitrification has improved the efficiency of embryo cryopreservation allowing the achievement of similar results after frozen/warmed embryo transfer compared to the fresh ones. In PGT cycles where a freeze-all strategy is needed, vitrification results have enabled the transition to blastocyst biopsy. Nonetheless, little is known about embryo characteristics after warming that can impact on implantation after euploid embryo transfer. Time between biopsy and vitrification, as well as time between warming and transfer, have been matter of study without conclusive results. Similarly, blastocyst re-expansion after warming has been proposed as a good prognosis parameter but without consensus in the literature.
Study design, size, duration: Prospective observational study of 113 euploid blastocysts replaced in single frozen-thawed embryo transfers performed from June to December 2019. Characteristics of the implanted and non-implanted blastocysts were compared. Blastocyst re-expansion index was the main variable analysed. Secondary variables were blastocyst morphology before biopsy, elapsed time between biopsy and vitrification and between warming and transfer.
Participants/materials, setting, methods: Blastocyst morphology included: inner cell mass (ICM) and trophectoderm (TE) grade (A, B or C, according to ASEBIR classification). Biopsied blastocysts were vitrified/warmed as described by manufacturer (Kitazato®). In order to assess the degree of blastocoel re-expansion, two pictures of the blastocysts were obtained: one taken immediately after warming (AW) and the second before transfer (BT). Re-expansion index was calculated as follows: diameter BT/diameter AW. Presence or absence of degenerated cells was also evaluated.
Main results and the role of chance: The mean maternal age was 35.5±6.1. Sixty-three of 113 blastocysts implanted (IR=55.8%). Implanted blastocysts exhibited significantly better ICM and TE quality than those that failed to implant (ICM A: 78.6% vs 21.4%, p=0.018; TE A: 80% vs 20%, p=0.012). Blastocoel re-expansion index ranged from 0.2 to 2.4 without differences between implanted and non-implanted blastocysts (1.3±0.3 vs 1.2±0.3 respectively; p=0.096). Degenerated cells after warming were detected in 39 blastocysts (34.5%). This feature was associated with an impaired implantation ability after embryo transfer (64.9% vs 38.5%; p=0.007). Elapsed time between biopsy and vitrification ranged from 0.2h to 7.2h with no differences between implanted and non-implanted blastocysts (1.9h vs 2.0h; p=0.938). Elapsed time between warming and embryo transfer ranged between 0.2h and 5.2h with no differences between implanted and non-implanted blastocysts (3h vs 3.2h; p=0.412).
Limitations, reasons for caution: These are preliminary results. For a deeper analysis controlling for potential confounding factors more data are needed. As unique SOPs were applied in a single IVF setting the time ranges included were limited.
Wider implications of the findings: Time to vitrification after biopsy, as well as time to transfer after warming can be adjusted according laboratory needs. When dealing with poor morphology blastocysts before vitrification and degenerated cells arise after warming, double embryo transfer might be proposed to selected couples.
Trial registration number: Not applicable

P-233 Expression of genes related to lipid metabolism in cells of the cumulus oophorus retrieved from patients undergoing assisted reproductive treatments.

S. Pizzasegale[1], A. Stendardi[1], T. Ruocco[2], F.L. Vellucci[1], F. Ietta[2], B. Fineschi[1], L. Gambera[1]

[1]A.G.I. Medica, Reproductive Medicine, Siena, Italy ;
[2]Università degli studi di Siena, Dipartimento di Scienze della Vita, Siena, Italy

Study question: is there a difference in the expression of some genes involved in lipid metabolism, between different categories of patients?
Summary answer: Some genes involved in lipid metabolism are differently expressed overall in patients with reduced ovarian reserve.
What is known already: Successful reproduction is dependent on the ovulation of competent oocyte, capable of undergoing fertilization and subsequent embryo and fetal development, and requires the co-ordinated growth and maturation of the oocyte and its somatic cells. Oocytes, but also cumulus cells are well known to contain lipid droplets, but not yet much is known about their role play during the maturation of the oocyte. Further studies are needed to understand the expression profile of those genes that regulate folliculogenesis especially during the last stages of follicular maturation that could be useful in identifying the lipids most involved during oocyte development.
Study design, size, duration: Present study included 16 IVF patients referred to our fertility Center A.G.I. Medica. Patients were subdivided into 3 groups according to the type of infertility: male infertility (control Group, n=7), Group 1 (G1, n=5) idiophatic infertility and Group 2 (G2, n=4) reduced ovarian reserve. The study was performed in cumulus cells obtained from cycles of intra-cytoplasmatic injection between March and October 2019.
Participants/materials, setting, methods: Following oocytes denudation, cumulus cells (CC) were collected and cumulated for each patient. CC were then washed and centrifuged and their number and viability was evaluated with Trypan Blue dye. In addition, mRNA extraction and retrotranscription was performed and through the Real Time Quantitative PCR were analyzed and quantified following genes: 11β-HSD 1, 11β-HSD 2, NR3C1 FASN, PNPLA2.
Main results and the role of chance: our data reported low viability of CC in the G2, which is also the group with the highest average age (39.5-2). These results suggest that the incidence of CC viability could predict the age-related decline in fertility. Molecular studies indicate that the expression of 11β-HSD-1 or 2 in the ovary depends on the prevailing hormonal environment and/or functional phenotype of cells. Compared to the control group our results indicate reduced levels of 11β-HSD-1 in G1 and G2 whereas 11β-HSD-2 is down regulated in G2 only. Considering the 11β-HSD-1/11β-HSD-2 ratio, which should increase physiologically during the ovulatory phase, this appears to have a clearly decrease especially in G2: this could mean that in this group an adequate conversion to cortisol does not take place. In addition in G2 the NR3C1 (glucocorticoid receptor) expression increase significantly compared to control; this could indicate a greater presence of receptor for low hormone levels as physiological feedback. PNPLA2 (involved in lipolysis) is significantly increased in G2, this could indicate a greater presence of free fatty acids. The FASN expression (involved in the synthesis of fatty acids) significantly increases in G1 and G2, compared to the control group and this could indicate an increased cellular metabolism.
Limitations, reasons for caution: Additional studies with an increased sample size in different clinical group will help to validate present results. In addition, it would be appropriate to evaluate the viability and expression of the lipid metabolism genes in CC of individual oocytes and not by cumulating them as we did in this study.
Wider implications of the findings: none
Trial registration number: None

P-234 Intracytoplasmic sperm injection versus conventional in vitro fertilization in non-male factor infertility. Interim analysis of a prospective randomized study

P. Fancsovits[1], Z. Kaszas[1], A. Nemes[1], K. Szedlak[1], A. Murber[1], D. Pocsi[1], A. Arokszallasi[1], J. Urbancsek[1]

[1]Semmelweis University, Division of Assisited Reproduction- Department of Obstetrics and Gynecology, Budapest, Hungary

Study question: Does intracytoplasmic sperm injection (ICSI) superior to conventional in vitro fertilization (IVF) as a method of fertilization in non-male factor infertility?
Summary answer: Conventional IVF resulted in higher fertilization rate while pregnancy and implantation rate was similar in IVF and ICSI cycles.

What is known already: ICSI is the most effective assisted reproductive technique to treat male infertility. However, it is also used for non-male factor indications, such as low number of oocytes or advanced maternal age. Thus, the incidence of ICSI fertilization method in fresh IVF cycles exceeds 70 % worldwide. However, data on the superiority of ICSI over conventional IVF in case of non-male factor infertility are still lacking.
Study design, size, duration: Data of interim analysis from an ongoing prospective randomized study performed in a university setting are presented here. Two hundred thirty two IVF cycles were randomized into ICSI or conventional IVF group between January 2018 and November 2019.
Participants/materials, setting, methods: Inclusion criteria: semen parameters suitable for conventional IVF fertilization, number of oocytes ≤4 and/or female age ≥40 years. Primary outcome was fertilization rate, secondary outcome was clinical pregnancy and implantation rates. Embryo development and quality (cell number, fragmentation, morphology score, rate of good quality embryos) on day 2 were also compared. Cycles with low oocyte number (A), advanced maternal age (B) and both factor together (C) were also investigated in a subgroup analysis.
Main results and the role of chance: Oocytes were fertilized by conventional IVF in 118 and by ICSI in 114 cycles. Fertilization rate was significantly higher in IVF group (IVF:62,7%, ICSI:50,8%; P<0,001). Clinical pregnancy rate was 24,5% (25/102) in IVF group and 18,8% (18/96) in ICSI group. The difference was not significant (P=0,326). Implantation rate was also similar in the two group (IVF:13,0%, ICSI:9,6%; P=0,270). Number of blastomeres (IVF:3,79±1,34, ICSI:3,85±1,14; P=0,596), embryo score (IVF:2,17±0,87, ICSI:2,21±0,78; P=0,495) and frequency of good quality embryos (IVF:29,4%, ICSI:26,9%; P=0,510) was comparable in the two group.

In cycles with ≤4 oocytes (Subgroup A) the fertilization rate, clinical pregnancy rate and implantation rate was similar in the two group. In case of advanced maternal age (≥40 years; Subgroup B) the fertilization rate was significantly higher in IVF group (IVF:64,1%, ICSI: 49,5%; P<0,001), but clinical pregnancy rate and implantation rate did not differ between the two fertilization method. In cycles where advanced maternal age was associated with low number of oocytes (Subgroup C), the fertilization rate (IVF:60,9%, ICSI:47,1%; P=0,043), clinical pregnancy rate (IVF:23,7%, ICSI:3,0%; P=0,013) and implantation rate (IVF:14,3%, ICSI:2,0%; P=0,018) was significantly higher in case of conventional IVF compared to ICSI.
Limitations, reasons for caution: This is an interim analysis of a prospective randomized study. Number of cases are low to draw a powerful conclusion on the effect of fertilization method on pregnancy an implantation rates.
Wider implications of the findings: Our data show a clear evidence that ICSI is not superior over conventional IVF in non-male factor infertility as conventional IVF resulted in higher fertilization rate. Furthermore, in case of advanced maternal age combined with low oocyte number, conventional IVF could be the most effective method of fertilization.
Trial registration number: ClinicalTrial: NCT03513913

P-235 Germline nuclear transfer to overcome mitochondrial disease and female infertility

M. Tang[1], A. Boel[1], R.R. Guggilla[1], B. Bekaert[1], P. De Sutter[1], B. Menten[2], F. Vanden Meerschaut[1], D. Stoop[1], P. Coucke[2], B. Heindryckx[1]

[1]Ghent University Hospital Ghent Fertility and Stem cell Team, Department for Reproductive Medicine, Gent, Belgium ;
[2]Ghent University Hospital, Center for Medical Genetics, Ghent, Belgium

Study question: Can germline nuclear transfer (NT) technique serve as a novel reproductive approach to overcome mitochondrial DNA (mtDNA) diseases as well as female infertility?
Summary answer: The NT technique has a high potential to overcome mitochondrial disease transmission and certain forms of female infertility in human.
What is known already: Mitochondrial disease prevention may currently be possible using NT, such as spindle transfer (ST) and pronuclear transfer (PNT). These techniques involve transferring nuclear genome from an oocyte/zygote carrying mtDNA mutations to an enucleated donor counterpart with unaffected mtDNA. Besides, NT has also been considered for certain infertility indications, such as infertile women experiencing poor embryo development. This is mainly based on the rationale that replacing a low-quality cytoplasm with a competent one using NT, will improve oocyte competence, resulting in better IVF outcomes. Nevertheless, there are limited data on applying NT in human for overcoming mitochondrial diseases and female infertility.
Study design, size, duration: ST and recently proposed early (e)PNT were performed in the first patient using *in vivo* matured (n=5) and an *in vitro* matured (IVM) oocyte, respectively. Donated enucleated frozen-thawed *in vivo* matured oocytes with smooth endoplasmic reticulum aggregates (SERa) and a healthy fresh IVM oocyte (after ICSI and enucleation) served as cytoplast recipients, respectively. The second patient's spindles were transferred from fresh IVM oocytes (n=5) into enucleated frozen-thawed SERa oocytes from other patients, followed by ICSI.
Participants/materials, setting, methods: The first patient was a 30-year-old woman carrying a homoplasmic mtDNA mutation m.11778G>A, which is known to cause Leber's hereditary optic neuropathy (LHON) syndrome. The second patient was a 26-year-old woman experiencing two failed ICSI cycles characterized by almost all oocytes having fertilization failure. Finally, using B6D2F1 mice, we conducted RNA sequencing (RNA-seq) on PNT-blastocysts (n=3). Blastocysts from ICSI-oocytes (n=3) and unmanipulated oocyte pools (n=2) served as controls to assess safety concerns of NT technology.
Main results and the role of chance: For the patient harboring m.11778G>A mutation, PGD confirmed almost 100% homoplasmic mutation load in all embryos analyzed, which could not be used for embryo transfer. After ICSI, 5/5 of ST-oocytes were normally fertilized, 5/5 cleaved, and 1/5 progressed to the blastocyst stage (scored as 4AA); while 1/1 reconstructed ePNT-zygote reached morula stage. NGS data revealed that mtDNA carry-over in two trophectoderm biopsy samples from the ST-blastocyst and the ePNT-morula was 3.2%, 2.9% and 3.1%, respectively, Carry-over of remaining arrested ST-embryos was 2.9%. For the patient displaying fertilization failure, we first applied the mouse oocyte activation test to evaluate sperm activation potential of patient's partner. After injecting human sperm into mouse oocytes, more than 85% of mouse oocytes were activated (suspected oocyte-related problem). The application of assisted oocyte activation (AOA) resulted in only one oocyte fertilized (1/12), showing vague 2PN and no division further. Following ST and routine ICSI without AOA, 2/4 reconstituted oocytes were normally fertilized with 2PN, one showed 1PN, and the last one underwent immediate cleavage, and 3/4 subsequently cleaved further but did not progress to blastocysts. RNA-seq data showed that mouse PNT-blastocysts clustered very closely with ICSI controls, indicating that NT did not significantly change global gene expression.
Limitations, reasons for caution: The scarce availability of human oocytes donated for research purposes is a limiting factor to obtain more pre-clinical evidence of this new NT technology. In addition, molecular analysis of reconstructed embryos following NT is still required to verify the safety concerns.
Wider implications of the findings: Both ST and ePNT show the capacity to prevent the transmission of pathogenic mtDNA mutations of human, with minimal carry-over in the reconstructed embryos. Moreover, as a proof-of-concept, ST might be able to overcome fertilization failure in case of an oocyte-related activation deficiency causing failed fertilization after ICSI and AOA.
Trial registration number: Not applicable

P-236 Performance variability among Spanish oocyte cryobanks

G. Terzuoli[1], M.C. Magli[1], L. Maresca[1], D. Visone[1], A.P. Ferraretti[1], L. Gianaroli[1]

[1]S.I.S.Me.R., Reproductive Medicine Unit, Bologna, Italy

Study question: Do vitrified oocytes coming from different cryobanks have a different performance in the same oocyte donation program?
Summary answer: In our oocyte donation program using vitrified oocytes, there are significant, cryobank-dependent differences in the clinical performance of the thawed oocytes.
What is known already: Several studies show that the use of vitrified oocytes does not negatively affect the clinical pregnancy rate compared to fresh oocytes. Therefore, the import of vitrified oocytes from cryobanks has been adopted in many oocyte donation programs as a practical solution to the major problems related to the realization of this program. These include the difficulty of recruiting local donors, and the need to perform the screen tests requested by the European Directives on Tissues and Cells.
Study design, size, duration: This retrospective study includes 275 oocyte donation cycles from January 2016 to December 2019. We used vitrified oocytes

from four different cryobanks that were selected on the basis of their oocytes' availability. Laboratory data and clinical outcome were analyzed and compared among the four cryobanks, including oocyte survival rate, clinical pregnancy rate at the first transfer, and ongoing cumulative pregnancy rate. We also calculated the number of oocytes needed to have a baby born.

Participants/materials, setting, methods: The oocytes from the four cryobanks were used as follows. Cryobank bank 1, 67 cycles; cryobank 2, 22 cycles; cryobank 3, 116 cycles; and cryobank 4, 70 cycles. A minimum of 6 oocytes were allotted to each cycle and the same transfer policy was applied to all cycles. All thawing procedures were performed by experienced embryologists that strictly followed the given protocol and after a specific training provided in loco by each cryobank.

Main results and the role of chance: The characteristics of the recipients in the four groups were similar. No relevant differences among the four cryobanks were found in the survival rate (mean value 82.7%, range 79.08-89.4%). Conversely, the clinical outcome showed significant disparities with cryobank 1 having the lowest clinical pregnancy rate per thawing cycle at the first transfer (24.1%) in comparison with cryobank 3 (40.5%, P<0.025) and 4 (40%, P<0.05). The same trend was registered in the cumulative pregnancy rate (29.8% vs. 55.1%, P<0.005; and 51.4%, P<0.025 respectively). Clinical and cumulative pregnancy rates in oocytes from cryobank 2 were 22.7% and 36.3% respectively, but due to the low number of treated cycles, these data were not used in the statistical examination. To calculate the number of oocytes needed to have a baby born, the analysis of the data was restricted until December 2018. In all, the number of oocytes to be thawed to have a birth were 23.1 in cryobank 1, 21.2 in cryobank 2, 15.7 in cryobank 3 and 14.6 in cryobank 4.

Limitations, reasons for caution: The number of cycles in the four cryobanks was not homogenous.

Wider implications of the findings: The different quality of thawed oocytes from different cryobanks is not necessarily reflected by their survival, but by their developmental potential. Considering a tight control of thawing conditions, possible causes could be the donors' ovarian stimulation and/or the operator of the vitrification procedure, suggesting that oocyte viability is cryobank-dependent.

Trial registration number: not applicable

P-237 Cytoplasmic strings, who would say that they are not as bad as we thought?

M. Palma Rodríguez[1], C. Olmedo-Illueca[1], V.M. Chapero-Ciurana[1], D. Domingo-Fernandez-Vermejo[1], M. Barea-Gomez[1], L. Abad-De-Velasco[1], S. Royo-Bolea[1], I. Cuevas-Saiz[1]

[1]Hospital General de Valencia, Unidad de Medicina Reproductiva, Valenca, Spain

Study question: Is there any relation between cytoplasmic strings and embryo quality as well as implantation outcomes?

Summary answer: In this study correlation was found between presence or absence of cytoplasmic strings and implantation outcomes in addition to blastocyst quality.

What is known already: It has been described that, during *in-vitro* embryo development, trophectoderm (TE) cells project cytoplasmic extensions to the inner cell mass (ICM), known as cytoplasmic strings or filopodia. Cytoplasmic strings are mainly classified into two groups: Short strings, which are extended from the ICM to the mural TE and long strings, which are extended from the ICM, trough the blastocoelic cavity, to the polar ICM. According to bibliography, cytoplasmic strings are still present during expansion in poor quality blastocysts and related to poor media conditions.

Study design, size, duration: Presence/absence of cytoplasmic strings, type and the moment of development when were expressed (before/after or during blastocyst expansion) were retrospectively analyzed in 154 blastocyst that underwent fresh or frozen embryo transfer with known implantation data (KID). All data were collected from 2015 until 2019. Two groups were defined regarding KID+ or -. Furthermore, presence or absence of cytoplasmic string was also related to embryo quality. ASEBIR's embryo selection criteria was used to assess embryo quality.

Participants/materials, setting, methods: 131 patients underwent elective embryo transfer. 154 embryos were cultured at MIRI-TL® (Esco, Denmark) incubator using Continuous Single Culture Media (Irvine Scientific, EEUU). To set correlation between presence/absence of cytoplasmic strings and KID+/-, *Chi-Squared* test was performed. To determine correlation between type and when strings were expressed with KID+/-, ANOVA test was used. Correlation between presence/absence and embryo quality was studied using *Kruskal-Wallis* test. All statistics were performed using SPSS© v22.0 (IBM, EEUU) software (p<0,05).

Main results and the role of chance: Out of 154 embryos, 123 showed cytoplasmic strings. 66,3% of them were KID+ and 56,7% were KID-. 31 embryos did not show any cytoplasmic strings; in this case 16,7% were KID+ and 14,3% were KID-. Significant differences were found (p=0,021) between presence or absence of cytoplasmic strings groups. Regarding type and moment when strings were expressed, no correlation was found between those two variables and implantation outcomes (p=0 ,742 and p=0,585, respectively). According to embryo quality and presence of cytoplasmic strings: 62,3% of embryos were A quality, 25,5% B quality, 10,2% C quality and 2% D embryos. However, in the absence of cytoplasmic strings: 38,5% were A quality, 53,8% B quality and 7,7% C quality. Significant differences were registered between these two groups (p=0,049).

Limitations, reasons for caution: To confirm if presence of strings in the expanded blastocyst is not related with a poor embryo quality (C and D classification in ASEBIR's embryo selection criteria) and that could be a good embryo implantation predictor, further studies should be carried out.

Wider implications of the findings: According to these findings and conversely to previous bibliography, the presence of cytoplasmic strings could have positive implication on embryo development and implantation outcomes. This filopodia could provide cells from ICM, which is mitotically active, to TE, which is mitotically less active and more differentiated.

Trial registration number: Not applicable

P-238 Clinical pregnancy in euploid blastocyst transfer is correlated to early cleavage and blastulation morphokinetic parameters

C. Jacobs[1], M. Nicolielo[2], L. Cremonesi[2], E.L.A. Motta[3], J.R. Alegretti[2], A. Lorenzon[4]

[1]Huntington Medicina Reprodutiva, Embryology, Sao Paulo, Brazil ;
[2]Huntington Medicina Reprodutiva, Embryology, São Paulo, Brazil ;
[3]Huntington Medicina Reprodutiva / Federal University of São Paulo, Clinical Director / Associate Professor, São Paulo, Brazil ;
[4]Huntington Medicina Reprodutiva, Research & Development, São Paulo, Brazil

Study question: What are the differences to achieve clinical pregnancy correlated to morphokinetic parameters with euploid embryos?

Summary answer: Euploid blastocysts that results in clinical pregnancy achieved time to 5 (t5), to 8 cells (t8) and blastulation (tB) at an earlier point in time.

What is known already: Embryo aneuploidy is known as the main cause of embryo implantation failure. The next-generation sequencing analysis (NGS) of blastocysts biopsied cells is the current most advanced technique to diagnose embryo genetic constitution allowing the selection of an euploid embryo for transfer. Beside the ploidy status, the morphokinetic evaluation for embryo selection can enhance the chance to achieve an ongoing pregnancy. The rapid spread of the time-lapse technology increased the demand of algorithms to predict embryo potential. However, intrinsic differences in each laboratory should be taken into consideration before applying global algorithms in routine before validation.

Study design, size, duration: Retrospective cohort study analyzing the morphokinetic parameters of 227 euploid biopsied embryos (NGS) from autologous cycles (n= 132 patients) with known implantation outcome (single embryo transfer: positive or negative gestational sac (GS) and fetal heartbeat (FHB), double embryo transfer: negative or two GS and FHB). Data was collected between December 2017 and December 2019 in a private IVF center.

Participants/materials, setting, methods: Blastocyst biopsied embryos from patients undergoing IVF with clinical indication for PGT-A were included. All oocytes were fertilized by ICSI and cultured in time-lapse system incubator (Embryoscope Plus, Vitrolife). Embryos were analyzed for the following morphokinetic parameters: time of pronucleous fading (tPNf), time to 2-cell(t2), time to 3-cell (t3), time to 4-cell (t4), time to 5-cell (t5), time to 8-cell (t8) and time to blastulation (tB). Embryos were graded according to Gardner's morphology parameters.

Main results and the role of chance: Two-hundred twenty-seven blastocysts were analyzed: 165 single embryo transfers (sET) and 62 embryos from 31 double embryo transfers (dET). From those, 119 blastocysts resulted in positive clinical pregnancy (49%, 81 from sET and 38 from dET) and 108 in negative (51%, 84 from sET and 24 from dET). Maternal age was similar between positive and negative clinical pregnancy (38,43 ± 3,15 versus 38,31 ± 4,07, p=0.9090). Morphokinetics parameters were earlier in euploid embryos that achieved clinical pregnancy in three time-points: t5, t8 and tB (t5: 48,55 ± 6,42 versus 50,46 ± 6,63, p=0.028; t8: 56,93 ± 8,43 versus 60,81 ± 9,57, p=0.001 and tB: 106,58 ± 9,71 versus 109,64 ± 11,05, p=0.023). Regarding other parameters analyzed, all earlier time-points were similar between positive and negative clinical pregnancy (tPNf: 23,11±3,76 versus 23,43±3,62, p=0.278, t2: 26,32±3,56 versus 26,66±2,99, p=0.239; t3: 36,84±4,29 versus 37,16±3,73, p=0.180; t4: 38,11±4,92 versus 38,56±3,50, p=0.162). Morphology grades for positive and negative clinical pregnancy were different between good quality embryos (grades A and B – 86% versus 73%) and poor quality embryos (at least one grade C – 14% versus 27%, p=0.021). Statistical significances were calculated using chi square or t-test as appropriate.

Limitations, reasons for caution: This is an observational study based on a retrospective database analysis, limited to biopsied embryos, generated by a population with PGT-A indication.

Wider implications of the findings: Our study highlights differences in morphokinetic parameters in euploid blastocysts that achieved clinical pregnancy. Since the differences in these parameters were independent from aneuploidy status, they represent potential time-points to be better analyzed in laboratory algorithms, reinforcing the potential use of morphokinetics as a tool for non-invasive embryo selection.

Trial registration number: Not applicable

P-239 The effectiveness of two cycles with single embryo transfer (fresh + frozen) versus one fresh double embryo transfer in women treated in egg donation program

S. Herzberg[1], S. Kraus[1], N. Schachter-Safarai[1], G. Karavani[1], A. Simon[1], A. Ben-Meir[1]

[1]Hadassah Ein Cerem- Jerusalem, Obstetrics and Gynecology, Jerusalem, Israel

Study question: What is the effectiveness of two cycles of Single Embryo Transfer (SET) versus Double Embryo Transfer (DET) in egg donation IVF treatment.

Summary answer: Implantation rate in two cycles of SET is similar to DET in egg donation IVF treatment. Multiple pregnancy rate is significantly higher in DET.

What is known already: The practice of transferring multiple embryos results in a high incidence of multiple births. Several studies on autologous IVF treatment have shown that two cycles of SET compared to DET result in a significant decrease of multiple pregnancy with similar pregnancy rates. Several factors can influence the results, including: the freezing and thawing process and an endometrial receptivity impairment secondary to the ovarian hyperstimulation. In egg donation we effectively neutralize the possible effect of exposing the endometrium to high levels of estrogen. This allows us to examine more clearly whether differences between fresh embryo and frozen-thawed transfers are present.

Study design, size, duration: A retrospective cohort study conducted at two IVF units in the years 2010-2019.

The patients were divided into 2 groups: Group A - DET - transferring of two fresh embryos in one cycle, Group B - SET - transferring of a single fresh embryo and later a second single frozen thawed embryo transfer in another cycle. Implantation rate, multiple pregnancy rate and obstetrical outcomes were compared between the two groups.

Participants/materials, setting, methods: Women treated with oocyte donation and who had at least two A-grade embryos were included in the study. The donors were healthy women 25-32 years. The endometrial preparation of the recipient women included estradiol for two weeks. On the oocyte retrieval day, the recipient began treatment with progesterone. The recipients were treated with Long-acting GnRH agonist, to prevent unplanned ovulation.

Main results and the role of chance: 251 women met the criteria set for the study. 168 women were included in the DET group and 81 women were included in the SET group. The two groups were similar in the demographic and clinical characteristics. Implantation rate was 32.3% in the SET group and 39.3% in the DET group, without significant difference (OR of 0.74, 95%CI: 0.48-1.13; p=0.16). However, multiple pregnancy rate was significantly higher in the DET group compared to the SET group (37.5% Vs 0%; p= 0.006), Moreover, preterm birth rate was 32.3% in the DET group compare to 13.9% in the SET group with OR of 2.94 (95%CI: 1.12-7.7; P value=0.03). Other obstetrical parameters were without significant difference between the two groups.

The similar implantation rate following two cycles of SET compared to DET in egg donation treatment means that the impaired endometrial receptivity following the ovarian hyperstimulation in autologous IVF treatment is not the main factor to explain this finding. It may support the existing information that the transfer of frozen-thawed embryo has similar success rates as the transfer of fresh embryo.

Limitations, reasons for caution: The retrospective design of our study makes it more prone to bias.

Wider implications of the findings: This study can give us an insight on the factors that contribute SET, DET outcomes in autologous and egg donation treatments. In addition, the study results support the use of elective SET in egg donation program in order to decrease the risk of multiple pregnancy without decreasing implantation rate.

Trial registration number: Not applicable

P-240 A novel microfluidic-based organoid mimicking the oviduct environment in vivo promote the embryo development via reducing cellular reactive oxygen species (ROS) level

M. Wang[1], B. Zhang[1], L. Jin[1]

[1]Tongji Hospital- Tongji Medical College- Huazhong University of Science and Technology, Reproductive Medicine Center, Wuhan, China

Study question: Could a microfluidic-based oviduct organoid promote the embryo development?

Summary answer: A microfluidic-based organoid mimicking both anatomical and biochemical environment of oviduct in vivo could promote the embryo development via reducing cellular ROS level.

What is known already: In current methods, embryos were cultured in petri-dish under substantially static conditions, conversely during the most of time, in vivo pre-implantation embryos experience dynamic micro-environments. In addition, the processes of fertilization and development from zygote to cleavage embryo were completed in the oviduct. Consequently, oviduct is extremely significant for pre-implantation embryo. However, due to the intra-abdominal anatomical location, it is difficult to access an available oviduct model for embryo development at present. Microfluidic chips are widely applied in various walks of life due to the extraordinary characteristics. Therefore, a microfluidic-based oviduct organoid was designed for embryo culturing.

Study design, size, duration: The microfluidic devices were fabricated following standard rapid prototyping methods. Mouse primary oviduct epithelial cells and embryos were obtained from ICR, and then identified by anti-Keratin immunofluorescence staining. Mouse embryos were cultured in chip and in dish separately and cellular ROS level were measured.

Participants/materials, setting, methods: The PDMS-PDMS devices were fabricated by multi-layer soft lithography technology. Oviduct epithelial cells and embryos were obtained from ICR. Mouse embryos were separated into two groups for further development. In microfluidic group, embryos were co-cultured with oviduct epithelial cells in the microfluidic-based organoid, and in control groups were cultured in traditional dish. The numbers of embryos in different stages were recorded, and then retrieved and exposed in H2DCFDA to measure cellular ROS level.

Main results and the role of chance: The novel microfluidic-based organoid in this study was able to mimic oviduct environment in terms of both anatomy and biochemistry of fallopian tubes. The oviduct-on-chip models were with a length of 2 cm and a diameter of 1 cm, which were in accordance with the anatomical characteristics of the oviduct in vivo. When the microfluidic chips were connected to the computer control system, the liquid can flow into the micro-channels through the inlets to outlets at a slow speed. Mouse primary oviduct epithelial cells were obtained and identified by immunofluorescence staining, and then loaded into the chip to provide a suitable biochemical environment. The levels of embryo ROS in microfluidic groups were statistically significant lower than that in control group ($P < 0.001$). In order to explore the effect of different conditions on the development of embryos, fertilization rate,

4-cell embryo rate, 8-cell embryo rate and high quality embryo rate were calculated. Compared with control group, the rates of different stages embryos in microfluidic group were higher, although there were no significant differences (P=0.159, 0.246, 0.823, 0.258 respectively).
Limitations, reasons for caution: The reduction of ROS concentration can definitely benefit to the embryo quality. However, the gold standard of embryo quality is DNA integrity of euploid embryo. In addition, mouse oocytes and sperms were used instead of human due to ethical requirements. More experiments are needed using human tissue.
Wider implications of the findings: This organ-on-chip device allows the probability of mammalian embryo culture in a microfluidic-based manner. Further development might promote the combination of this novel embryo development methods and clinical IVF practice, and enhance the cumulative clinical pregnancy rate.
Trial registration number: not applicable

P-241 Universal warming protocol for vitrified blastocysts: The "coming-out" of "off-label" use of warming kit brands

L. Parmegiani[1], C. Garello[2], S. Canosa[2], F. Granella[2], F. Evangelista[2], G. Monelli[2], D. Guidetti[2], F. Bongioanni[2], M. Filicori[3]

[1]GynePro Medical, Reproductive Medicine Unit, Bologna, Italy ;
[2]LIVET Srl, LIVET Srl, Torino, Italy ;
[3]GynePro Medical NextClinics International, Reproductive Medicine Unit, Bologna, Italy

Study question: Is it possible to use warming kit brands "off-label" to efficiently warm vitrified blastocysts?
Summary answer: Different vitrification and warming kits can be combined without affecting survival and implantation rates.
What is known already: Embryos are routinely vitirified using different commercial brands of ready-to-use vitrification solutions which differ only slightly in their composition. Every brand of vitrification kit requires the use of its own warming kit. However, it is useful for Assisted Reproduction centres to have alternative options for carrying out any procedure. The application of "Universal Warming" through the combination of different vitrification/warming kits can offer this flexibility, but this action may have potential legal consequences for AR centers. This study aims to give scientific validation to this common but "off-label" and thus often covert usage.
Study design, size, duration: Prospective randomized study. Vitrified blastocysts were randomized at warming. Group randomization 1:1:1 via www.random.org. Total number of vitrified/warmed blastocysts: 231. Duration: January – October 2018.
Participants/materials, setting, methods: 107 blastocysts from patients' own oocytes, 124 blastocysts form donors. Each patient's/ donor's embryos were vitrified with Kitazato Vitrification Kit (Japan) and warmed with three different warming kits: i) Kitazato, ii) Sage - Coopersurgical, Denmark, iii) Irvine -Fujifilm USA . Group names: KK, KS, KI, (patient's blastocysts); eKK, eKS, eKI (donor's blastocysts). Primary outcome measure: cryo-survival rate (embryos surviving/embryos warmed). Secondary outcome measure: embryo implantation rate (gestational sacs/embryos transferred).
Main results and the role of chance: Cryo-survival rate was statistically comparable between the study groups: KK 97.9% (47/48), KS 96.5% (53/55), KI 100% (47/47), eKK 97.5% (39/40), eKS 100% (37/37), eKI 95.7% (45/47). Embryo implantation rate was comparable between groups: KK 40.4% (19/47), KS 43.4% (23/53), KI 48.9% (23/47), eKK 46.1% (18/39), eKS 35.1% (11/37), eKI 46.7% (21/45).
Limitations, reasons for caution: These results need to be confirmed with larger studies investigating different "off-label" combinations of vitrification and warming kits.
Wider implications of the findings: This study confirms that the combination of different kits for vitrification/warming permits efficient survival and implantation, irrespective of brand, cryoprotectants and basic medium in the kits. This result supports the "off-label" use of different combinations of vitrification and warming kits, allowing practitioners worldwide to "come-out" of the closet.
Trial registration number: Not Applicable

P-242 Embryonic development and cytogenetic evaluation of apronuclear zygotes after 18 to 20 hours of in vitro fertilization

D. Freitas[1], C. Teixeira[1], A. Almeida[1], L. Queiroz[1], R. Carvalho[2], T. Oliveira[2], C. Santos[2], T. Abreu[2], M. Niag[2], G. Coelho[3]

[1]IVIRMA Brazil- Clinic IVI Salvador, IVF LAB, Salvador, Brazil ;
[2]Universidade Federal do Recôncavo da Bahia., Medicine, Santo Antonio de Jesus, Brazil ;
[3]IVIRMA Brazil- Clinic IVI Salvador, Clinical director, Salvador, Brazil

Study question: How is the embryonic development, cytogenetic constitution and blastocyst rates of apronuclear zygotes presenting two polar bodies ("0PN- pronuclei / 2CP- polar body")?
Summary answer: Apronuclear zygotes with two polar bodies ("0PN / 2CP") can be euploid and have appropriate embryonic development.
What is known already: The fertilization process involves ordered morphological changes that affect the gametes, cellularity, allowing to identify failures or changes in the zygote. A fertilization assessment comprises complex and dynamic classification systems for embryo morphology at various stages of development, which impact on embryo selection. The average observation time for fertilization is 16 to 22 hours. The interpretation of the absence of pro-nuclei (0PN) in zygotes with 2 polar body and the use of these zygotes in IVF has been a topic of debate. Cytogenetic analyzes reveal that a significant subset of these zygotes is diploid and with competent development.
Study design, size, duration: This is a descriptive retrospective, cross-sectional study. A convenience sample was used, covering the analysis of medical records of couples diagnosed with infertility, who underwent treatment at an assisted reproduction clinic in Salvador, Bahia, Brazil. This work was developed during the period from January to December 2019.
Participants/materials, setting, methods: This study was carried out through the analysis of medical records of couples submitted to assisted reproduction techniques for conjugal infertility. The analysis included 309 cycles of couples submitted to in-vitro fertilization and who had at least one apronuclear zygote. These analyzed embryos were cultured using sequential media until blastocyst (D5 / D6). Fertilization was evaluated between 18 and 20 hours after ICSI (Intracytoplasmic Sperm Injection) of 2642 MII oocytes (in metaphase II).
Main results and the role of chance: 2129 oocytes fertilized from 2642 oocytes MII injected, performing a fertilization rate of 80.58%. From these fertilized eggs, 295 were apronuclear, with the presence of 2 polar bodies (0PN / 2CP), representing 13.85% of the total number of zygotes. Among the 295 0PN / 2CP zygotes, a group of 36 embryos, belonging to 15 cycles of patients with an average age of 36.72 years, had their development monitored, since they would be submitted to cytogenetic study. 24 blastocysts were generated, with a blastocyst rate of 66.67%, being submitted to PGT (Preimplantation Genetic Testing) by NGS (New Generation Sequencing). Among the 24 embryos analyzed, 13 embryos (54.17%) had a normal karyotype, and 11 embryos (45.83%) had an abnormal result. Of the 13 euploid blastocysts, only 9 embryos have already been transferred and 3 of these embryos have implanted, which gives an implantation rate of 33.33%.
Limitations, reasons for caution: The reduced number of embryos analyzed in this study does not allow the establishment of more precise correlations between analyzed variables. This study will be complemented with new cycles to increase the investigation of the apronuclear zygotes (0PN / 2CP).
Wider implications of the findings: Embryos from apronuclear zygotes tend to be discarded due to erroneous attribution of ploidy based on numbers of pronuclei. Studies that evaluate the development in blastocysts and the genetic evaluation, demonstrate that many apronuclear zygotes present diploid, resulting in pregnancies with the birth of healthy babies.
Trial registration number: not applicable

P-243 Is the embryo utilization rate different after conventional IVF or ICSI in sibling oocytes?

I. Mateizel[1], P. Drakopoulos[1], H. Tournaye[1], G. Verheyen[1]

[1]UZ Brussel, Centre for Reproductive Medicine, Jette- Brussels, Belgium

Study question: Is the embryo utilization rate affected by the insemination procedure (conventional IVF or ICSI) in patients with split insemination of sibling oocytes?
Summary answer: Embryo utilization rates are similar after IVF and ICSI in sibling oocytes cycles.

What is known already: The use of ICSI in assisted reproduction has increased exponentially since its clinical introduction in 1991. Initially developed for severe male factor infertility, it is now offered for all causes of infertility, despite lack of data to justify this approach. Few studies have addressed the issue of the optimal insemination technique, with conflicting results and possible biased by the inclusion of women with poorer prognosis in the ICSI group. Hence, the ideal population to study the effectiveness of each insemination method, considering also the ovarian response, would be patients undergoing IVF and ICSI within the same cycle.
Study design, size, duration: The aim of our retrospective study was to compare the embryological outcome between IVF or ICSI insemination. All consecutive patients undergoing IVF versus ICSI procedure in their first ovarian stimulation cycle (only antagonist protocol) between 2009 and 2014 were included. Only patients with fresh semen samples fulfilling the minimum criteria for IVF were considered.
Participants/materials, setting, methods: Following ovarian puncture, the sibling cumulus–oocyte-complexes (COCs) were randomly allocated to either IVF or ICSI procedure. In cases of an uneven COC number, the extra COC was included in the ICSI arm. The embryos were cultured in sequential media until day 3 or day 5/6. The main outcome was the embryo utilization rate per fertilized oocyte (total number of embryos transferred and cryopreserved divided by the number of 2PN).
Main results and the role of chance: A number of 418 patients were included and divided according to their ovarian response in: poor (≤ 3 COC retrieved, suboptimal (4-9 COC), normal (10-15 COC) and high (>15 COC) responders.The median age [interquartile range (IQR)] was 32 (29-36), while the number of oocytes retrieved per insemination method was 5 (3-7). Fertilization rates defined as the ratio of 2PN per number of COCs were significantly higher in ICSI (67.5 vs. 54.1, p<0.001). However, embryo utilization rates per 2PN were similar between oocytes inseminated with IVF and those inseminated with ICSI (53.8% vs. 57.4%, p value =0.3). In order to assess the effect of the insemination technique on embryo utilization rates after accounting for several confounders (age, BMI, cause of infertility, initial stimulation dose, number of COCs), a regression model with estimation by generalized estimating equations (GEE) was used. According to GEE, the insemination method was not significantly associated with embryo utilization rate (coefficient 3.8, 95% CI -1.3 to 9, p=0.14). Also when considering subpopulations according to ovarian response, embryo utilization rate after IVF and ICSI were comparable (coefficient 3.4, 95% CI -1.8 to 8.5, p=0.2).
Limitations, reasons for caution: The retrospective nature of the present study can be considered as a limitation.
Wider implications of the findings: The robust design of our study, allowing each patient to serve as its own control, provides reassuring evidence that embryo quality is not impaired by the insemination method used.
Trial registration number: B.U.N.143201939166

P-244 A comparison of live birth and multiple pregnancy rates when 1 or 2 low quality blastocysts are transferred in a frozen cycle, stratified for age

S. Aldhaheri[1], S. Arab[2], A. Baeghiesh[1], M.H. Dahan[1]

[1]McGill University, Obstetrics and Gynecology, Montreal, Canada ;
[2]McGill University, Gyncecologic and Reproductive Endocrinology and Infertility - Obstetrics and Gynecology Department, Montreal, Canada

Study question: What are the in-vitro fertilization (IVF) outcomes in patient with Gardner's grade BB or lower frozen blastocysts transfers and the effect on multiple pregnancy rates?
Summary answer: If age was <40 but not ≥40, the multiple pregnancy rates were significantly higher in double embryo transfer (DET) than single embryo transfer (SET) cycles.
What is known already: Most studies have investigated outcomes based on high quality blastocyst transfer or a combination of good and poor quality blastocysts. Outcomes among women with only Gardner's grade BB, BC, CB and CC frozen embryos transferred (FET) are not well known. The outcomes stratified for age with low quality frozen blastocysts has also not been investigated, nor has the role of transferring two poor grade blastocysts on multiple pregnancy rates. Our study will be the first one to look at the multiple pregnancy and live-birth rates after transferring one or two Gardner's grade BB or lower quality frozen blastocysts.
Study design, size, duration: A retrospective cohort study including 1104 FET cycles was performed. All frozen Day 5 or 6 blastocyst of Gardner's grade BB or lower quality blastocysts transferred between January-2008 to December-2019 at an Academic Fertility center were included. 189 cycles were egg donor. Data was stratified for age, autologous or donor embryo and embryo quality. In the case of a double embryo transfer quality was based on the best grade of the two embryos.
Participants/materials, setting, methods: 96 cycles were in patients >40-years of age and 819 cycles in women <40 years of age, at collection. Clinical pregnancy (CP), multiple pregnancy (MP) and live birth rates (LBR) per cycle were compared between SET (n=969) and DET (n=135) in each group. Clinical pregnancy and multiple pregnancy rates were compared between SET and DET per cycle in grade BB (n=894), BC (n=86), CB (n=52) and CC (n=72) groups individually.
Main results and the role of chance: In SET group, Gardner's grade BB blastocysts had higher pregnancy 48% (P=0.000), CP 34% (P=0.000) and LBR 19% (P=0.059) in comparison to Gardner's grade BC, CB and CC single embryo transfers. Within BB FET cycles, MP rate was significantly higher when transferring two vs. one (5.9 vs. 1.9, P =0.009). Transferring two Gardner's grade CB, BC or CC embryos did not increase the multiple pregnancy rate **(**P=0.78)**.** If age at egg collection was ≥40 no difference was found in CP (11.1 vs. 11.7, P =0.9), MP (0 vs. 0) and LBR (6.3% vs. 0%, P=0.13) when SET or DET was performed. If age at egg collection was <40(N=819) the MP rate was significantly higher in DET than SET (6.75% vs 1.63%, P=0.004) even though, age at collection (37 vs. 33years, P=0.001) and transfer (39 vs. 35years, P=0.001) were significantly older, respectively. However, no difference was found in CP and LBR, overall. Among egg donors (N=189), there were no difference in CP (25.9% vs. 29.62%, P=0.68), MP (3.12% vs.7.4%, P=0.28) and LBR (11.72% vs. 22.2%, P=0.137) between SET and DET. Among egg donors the LBR for Gardner's grade BB, BC, CB and CC were (8.2%, 6.3% 9% and 0%), respectively (P=0.74).
Limitations, reasons for caution: This is a retrospective cohort study with the inherent risk of undetected bias. The small number of cycles in women ≥40 years of age at collection should be considered.
Wider implications of the findings: Among women with grade BB or lower blastocyst at ≥40 years-of-age transferring 2 did not increase the MP rates. In women <40 years-of-age transferring 2 BB blastocysts increased the MP rate, but may fall into acceptable limits. MP rates did not increase when transferring two CB, BC or CC blastocysts.
Trial registration number: MUHC REB arsu6002/2020-6228

P-245 Assessment of molecular determinants underlying recurrent embryo developmental arrest and value of assisted oocyte activation as a treatment option

A. Boel[1], D. Bonte[1], A. Cardona Barberan[1], V. Thys[1], D. Stoop[1], P. De Sutter[1], P. Coucke[2], F. Vanden Meerschaut[1], B. Heindryckx[1]

[1]Ghent University Hospital, Ghent-Fertility And Stem cell Team- Department for Reproductive Medicine, Ghent, Belgium ;
[2]Ghent University, Center for Medical Genetics Ghent- Department of Biomolecular Medicine, Ghent, Belgium

Study question: Can recurrent embryo developmental arrest be linked to specific molecular defects and be overcome by assisted oocyte activation (AOA)?
Summary answer: Applying stringent inclusion criteria, AOA did not show beneficial effects in our patient cohort, for which the molecular cause of embryo arrest remains mainly unexplained.
What is known already: Recurrent embryo developmental arrest has recently been linked to genetic defects in maternal effect genes. Treatment options for these patients are limited, however, assisted oocyte activation (AOA) has been proposed. AOA is routinely used to overcome fertilization failure after ICSI and involves the artificial induction of Ca^{2+} rises in the oocyte. The lack of Ca^{2+} oscillations, normally evoked by the sperm factor phospholipase C zeta (PLCζ), has been suggested to both contribute to failed fertilization, as well as to post-fertilization processes, such as embryo arrest or inferior blastocyst formation.
Study design, size, duration: A prospective study was performed between January 2018 and August 2019, including 11 couples, presenting with embryo

arrest or inferior blastocyst formation. Patients were only included when they underwent at least two fresh ICSI cycles. Furthermore, high fertilization rates (≥60% 2PN or zygote) with a minimum of 10 zygotes but low blastocyst rates (≤15% of at least early blastocyst quality on day 5) were required.

Participants/materials, setting, methods: All couples underwent a fresh AOA cycle ($CaCl_2$ injection and ionomycin exposure (2x)). Both partners donated a saliva sample for genetic screening of six MEGs (female) and *PLCZ1* (male). Except for one lesbian couple, the Ca^{2+} oscillatory patterns induced by the male patient's spermatozoa were examined through mouse oocyte Ca^{2+} analysis (MOCA). The mean maternal age was 33.4 years ± 3.4 years. Most couples suffered from male factor infertility (n=3) or unexplained female infertility (n=3).

Main results and the role of chance: In total, 11 AOA cycles were performed and compared to 31 previous routine ICSI cycles. The overall fertilization rate after AOA application was 70.1% (96/137) which was similar to the fertilization rate of 74.8% (237/317) after conventional ICSI. Blastocyst rates did not significantly increase after AOA (9.4%, 9/96) compared to the rates obtained in previous ICSI attempts (9.3%, 22/237). Furthermore, pregnancy rates were not significantly different between AOA (28.6%, 2/7) and conventional ICSI (36.8%, 7/19). Previous conventional ICSI cycles resulted in one miscarriage, two biochemical pregnancies, and four healthy singletons. Regarding the 11 AOA cycles, one embryo transfer resulted in an ectopic pregnancy, while the other pregnancy is still ongoing.

For all male patients, MOCA displayed Ca^{2+} oscillatory patterns with high Ca^{2+} spike frequencies, comparable to controls, confirming a normal oocyte activating capacity. Sequencing of the selected MEGs (*NLRP2, NLRP5, NLRP7, TLE6, PADI6, KHDC3L*) in female and *PLCZ1* in male patients revealed several variants, most of which were categorized as benign and likely benign. No *PLCZ1* pathogenic mutations were identified in the ten assessed male individuals. However, amongst the eleven tested female individuals who underwent AOA, we identified three unique heterozygous variants of uncertain significance.

Limitations, reasons for caution: Our study, showing that AOA is not able to overcome embryo developmental problems, which is in contrast with earlier findings, is limited by its small sample size and displays therefore only preliminary results. Genetic screening targets are too restricted to identify a genetic cause underlying the phenotype for all patients.

Wider implications of the findings: Strong evidence for AOA to overcome impaired embryonic development is still lacking, therefore, embryo arrest should not be an indication for AOA application. Genetic screening on a routine basis might be valuable to improve clinical management.

Trial registration number: NA

P-246 Is mosaicism and its characteristics influenced by the method of trophectoderm-biopsy technique employed in PGT-A cycles? Genetic and reproductive outcomes after pulling versus flicking.

L. Herrero Grassa[1], M. Aparicio Gonzalez[1], L. Cascales Romero[1], J.A. Ortiz[2], J.C. Castillo[3], C. García-Ajofrin[4], J. Ten[5], R. Bernabéu[3]

[1]Instituto Bernabéu Madrid, IVF Laboratory, Madrid, Spain ;
[2]Instituto Bernabéu Biotech, Molecular Genetics Laboratory, Alicante, Spain ;
[3]Instituto Bernabéu Alicante, Ginaecology, Alicante, Spain ;
[4]Instituto Bernabéu Madrid, Gynaecology, Madrid, Spain ;
[5]Instituto Bernabéu Alicante, IVF Laboratory, Alicante, Spain

Study question: Are pulling and laser (over)exposure influencing a (over) diagnose of euploid mosaic embryos in PGT-A cycles?

Summary answer: Pulling and number of laser shots employed might influence the genetic condition of the biopsied fragment leading to an over-diagnosis of normal embryos as mosaic.

What is known already: Preimplantation genetic testing for aneuploidies (PGT-A) and blastocyst biopsy is a fashion trend in assisted reproduction, but it must be performed without damaging the embryo or disrupting its genetic condition. Laser technology is commonly used to manipulate embryos in the IVF laboratory, optimizing the efficacy and reducing the exposure to suboptimal conditions.

Blastocyst stage biopsy is associated to high resolution and sensitive genetics technologies that enable mosaicism detection, increasing the reproductive chances per PGT cycle.

The main objective of this study is to find out how the biopsy technique influences the subsequent genetic results and clinical outcomes.

Study design, size, duration: Retrospective database study including 499 embryos belonging to 162 PGT-A cycles performed between August 2017 and December 2018. Cycles with semen sample concentrations under 1 million/mL were excluded. Blastocyst were biopsied by two expert embryologists using the same micromanipulation equipment. They performed two different biopsy techniques: pulling (292 embryos) and flicking (207 embryos).

Participants/materials, setting, methods: In pulling, cells were suctioned, while laser pulses were applied (4-9). In flicking, cells were aspirated and after 3-4 laser pulses they were removed by a quick movement of the biopsy needle against the holding.

Mosaic embryos with ≤25% aneuploidy were considered euploid. Euploid embryo fragments with 25-40% of aneuploidy were classified as low-grade mosaics, and those with 40-50%, were sorted as high-grade mosaics.

Student's t and Pearson's chi-square were used.

Main results and the role of chance: Pulling and flicking techniques achieved significant differences in average number of laser shots needed (6.7±2.7 vs. 3.2±0.8, respectively; p<0.0001) to obtain similar number of trophectoderm cells biopsied (5.4±1.4 vs. 5.6±1.6, respectively). No differences in amplification failure between techniques were reported (4.8% vs. 4.3%, respectively).

Similar aneuploidy rate was observed between pulling and flicking (43.0% vs. 41.3%, respectively; p=0.812) but a tendency of higher euploid mosaicism rate in the pulling group was noticed (16.1% vs. 10.2%; p=0.061). Furthermore, flicking mosaics resulted to be more complex than pulling ones: more high-grade mosaics (35.6% vs. 60.0%; p=0.066), higher number of chromosomes involved in the mosaicism (1.6±1.0 vs. 2.5±2.1; p=0.025), and higher number of segmentary alterations (1.0±1.0 vs. 1.9±2.1; p=0.029).

Until December 2018, 139 euploid single embryo transfers (SET) were performed (78 from pulling group and 61 from flicking group) and no differences in clinical pregnancy rate (34.7% vs. 32.8%) or live birth rate (32.1% vs. 27.8%) were observed, respectively. Nevertheless, it seems to be a tendency of lower implantation rate and delivery rates when flicking euploid mosaics were transferred: 45.5% implantation and live birth rate in the pulling group (11 SET) vs. 20% in the flicking group (5 SET).

Limitations, reasons for caution: This is a retrospective study, based on observation of current practice and its impact on subsequent results. Biopsy techniques were carried out by different embryologists, with the implicit bias on it. The sample size exploring reproductive outcome is small. More data must be compiled, and prospective studies carried out.

Wider implications of the findings: Even though laser used had been proved safe, more than 4 shots employed in the pulling method could modify the genetic result of the biopsy, increasing the euploid mosaicism rate.

Mosaics derived from pulling are less-complex and may implant as euploid embryos, suggesting a plausible over-diagnosis of mosaics.

Trial registration number: None

P-247 Association between IL-17A levels, oocyte fertilisation and embryo development in unexplained infertility

F. Reidy[1], R. Kavanagh[2], L. Glover[1], C. O'Farrelly[2], M. Wingfield[1]

[1]Merrion Fertility Clinic- National Maternity Hospital, Obstetrics and Gynaecology, Dublin, Ireland ;
[2]Trinity College Dublin, Trinity Biomedical Sciences Institute, Dublin, Ireland

Study question: Does dysregulation of the IL-17 pathway impact on fertilisation and embryo development?

Summary answer: Raised IL-17A levels prior to an ART cycle are associated with a reduced fertilisation rate.

What is known already: The inflammatory cytokine IL-17A plays a multifaceted role in modulating the immune response, and is thought to contribute to successful embryo implantation. We recently showed that dysregulation of the IL-17 pathway influences the outcome of ART cycles, such that elevated levels of endometrial and serum IL-17 were associated with a reduced live birth rate. In the current study, we analysed the impact of IL17 on ovarian innate immune responses, and investigated whether elevated circulating IL-17A is associated with impaired oocyte fertilisation and subsequent embryo development.

Study design, size, duration: Our aim was to investigate if serum IL-17A levels impact on embryo fertilisation and embryo development in women undergoing ART cycles. Peripheral blood samples were taken at mid-luteal cycle phase, timed with luteinising hormone testing. Serum IL-17 levels were correlated with oocyte fertilisation rates, embryo quality and pregnancy outcomes. This study also examined the effect of IL-17A, a potent proinflammatory cytokine, on the regulation of three antimicrobial peptides, Human b Defensin 1, Psoriasin and Elafin.

Participants/materials, setting, methods: 20 patients undergoing IVF/ICSI were recruited. Patients were ≤38 years, with no previous pregnancy and BMI<30kg/m². Serum IL-17A levels were measured using ELISA. An in vitro study was also performed utilizing a commercially available model of ovarian epithelia. Ovcar-3 epithelial cells were treated with recombinant human IL-17A and expression levels of the antimicrobial peptide (AMP) genes beta-defensin-1, PI3 and S100A7 were assessed by qPCR.

Main results and the role of chance: Mean fertilisation rate for oocytes retrieved from women with a serum IL-17A level of <50pg/ml (0.7283; n=9) is significantly increased compared to that of women with a serum IL17A level of >50pg/ml (0.5857; n=11); p= 0.0193. With lower circulating IL-17A there is also a trend towards improved embryo quality, but does not reach statistical significance.

IL-17A stimulation of female reproductive tract epithelial cells in vitro increased antimicrobial peptide expression. This further connects this cytokine to the mediation of the innate immune response in the ovary.

Limitations, reasons for caution: This study suggests that IL-17A can modulate innate immune responses in the female reproductive tract, including the ovarian microenvironment, in successful pregnancy. Our study is limited by the small sample size, and further study is ongoing to elaborate on these findings.

Wider implications of the findings: Our previous work has found that dysregulation of IL-17A impacts on success of ART. This further analysis suggests an effect on egg quality and subsequent embryo development. We have also shown that IL-17A induces expression of antimicrobial peptides,highlighting the role it may have in activation of the innate immune response.

Trial registration number: n/a

P-248 Soluble human leucocyte antigen-G (sHLA-G) in embryo-spent medium is a potential embryo viability biomarker and a positive predictor of live-births: a retrospective Indian study

V. Venkatappa[1], S.S. Vasan[2], S.K. Adiga[3], V. Samson Roy[4], G. Sachdeva[5], P.B. Seshagiri[6]

[1]Indian Institute of Science, Molecular Reproduction and Developmental Genetics, Bangalore, India ;
[2]Manipal Ankur Andrology & Reproductive Services-, IVF Clinic, Bangalore, India ;
[3]Kasturba Medical College-, Department of Clinical Embryology-, Manipal, India ;
[4]Advanced Fertility Clinic, IVF Clinic, Bangalore, India ;
[5]National Institute for Research in Reproductive Health-, Department of Primate Biology, Mumbai, India ;
[6]Indian Institute of Science, Department of Molecular Reproduction- Development and Genetics-, Bangalore, India

Study question: Can embryo-secreted soluble human leucocyte antigen-G (sHLA-G) serve as a predictive biomarker for embryo viability with successful pregnancy outcome?

Summary answer: Embryo-secreted sHLA-G concentrations showed positive correlations with (i) developing embryo stages and (ii) live-births. Their altered concentrations were associated with pregnancy loss or miscarriages.

What is known already: Human infertility is treated in IVF clinics with the live-birth rate being only <15%. Poor embryo viability contributes to pregnancy loss. Current embryo-grading approach has limitations in terms of identifying biologically-viable embryos that are capable of producing live-births. Several reports have indicated that sHLA-G could act as a biomarker for elective-embryo transfer, with positive IVF outcomes. But, there were controversies in terms of correlative analyses, lack of cross-clinics comparisons and to predict live-births. Hence, there is a need for a cross-clinics comparison on the embryo viability biomarker *i.e.*, sHLA-G with embryo quality assessment and correlative analysis with live-births.

Study design, size, duration: This was a three-IVF clinics retrospective study performed between Oct 2017 and May 2019, using 539 embryo-spent media (E-SMs) obtained from 539 transferred embryos from 300 sub/infertile women. Following ICSI and embryo cultures, E-SMs were stored frozen (-80° C) until subjecting them to sandwich ELISA for sHLA-G (Mybiosource, USA). Measured sHLA-G in E-SMs was correlated with embryo stages and their morphology and clinical outcomes, in terms live-births.

Participants/materials, setting, methods: We analysed E-SMs, for sHLA-G (ng/ml), from three embryonic stages *i.e.*, 4-8-cells (cleavage-stage; n = 247), morulae (n = 112) and blastocysts (n = 180). Obtained values for statistical differences were analysed between/among embryo-groups using the Student's *t-test*/ANOVA (P ≤0.05), followed by *Tukey posthoc test*. Levels of sHLA-G and embryo morphology were correlated using Pearson correlation analysis. We compared sHLA-G positive embryos with their pregnancy outcomes in terms of live-births.

Main results and the role of chance: Concentrations of sHLA-G were significantly different (P<0.05) in E-SMs of cleavage-stage (0.89 ± 0.12; n = 23) embryos *vs* blastocysts (1.81 ± 0.21; n = 11; fresh-ETs). Similarly, sHLA-G concentrations between E-SMs of cleavage-stage embryos (1.58 ± 0.17, n = 63) *vs* blastocysts (3.06 ± 0.28; n = 46; frozen-ETs) were different (P<0.05). Within and across clinic comparisons showed that concentrations of sHLA-G in E-SMs of cleavage-stage embryos, morulae and blastocysts were variable. A significant difference (P<0.001) was observed in sHLA-G concentrations only with cleavage-stage embryos but not with morulae or blastocysts, indicating embryo development stage-wise correlations, albeit, with variability within and across clinics. Furthermore, there was a moderate relationship between cleavage-stage embryo morphology and sHLA-G levels and, a positive correlation of the blastocyst grades with sHLA-G concentrations. Interestingly, sHLA-G levels were higher in live-births cases *vis-à-vis* no-birth cases; the sHLA-G concentration was higher in live-births out of blastocyst-ETs (1.79 ± 0.28, n = 22) *vs* those out of cleavage-ETs (1.44 ± 0.24; n = 42). Live-births were observed only when at least one sHLA-G positive embryo was a part in twin- or triple- ETs. These results show a clear association of embryo-secreted sHLA-G levels with pregnancy outcome with live-births.

Limitations, reasons for caution: Variations of sHLA-G contents in E-SMs between different IVF clinics could be attributed to protocol-practices differences of clinics. More multi-centric larger-cohort studies and a large scale meta-analysis are required to establish the diagnostic accuracy power of the sHLA-G for predicting the IVF outcomes in term of child-birth.

Wider implications of the findings: For the first time, our multi-centric Indian study, show that the sHLA-G could be an embryo viability biomarker to predict child-birth. The sHLA-G could potentially be an immunodiagnostic point-of-care diagnostic test, a valuable adjunct to other criteria practiced for selection of potentially 'top-quality' embryo(s) for ET.

P-249 The removal of a quarter of the Zona Pellucida improves pregnancy and implantation rates in vitrified blastocysts that underwent Artificial Shrinkage

A. Volpes[1], F. Sammartano[1], M. Modica[1], S. Gullo[2], A. Marino[1], A. Allegra[1]

[1]ANDROS Day Surgery Clinic, Reproductive Medicine Unit, Palermo, Italy ;
[2]University of Palermo, Department of Psychology- Educational Science and Human Movement- Statistics Unit-, Palermo, Italy

Study question: Is the partial removal of the Zona Pellucida (ZP) effective in improving pregnancy and implantation rates in vitrified blastocysts undergoing Artificial Shrinkage (AS)?

Summary answer: Partial removal of the ZP significantly improves pregnancy and implantation rates in blastocysts that underwent AS either before vitrification or after thawing.

What is known already: The hatching process is an essential mechanism enabling blastocyst implantation. It is well known that vitrification may cause hardening of the ZP and this event could explain implantation failure after blastocyst thawing and transfer.

However, due to the thinness of the ZP in the expanded blastocysts, Laser Assisted Hatching (LAH) is almost impossible to perform.

Moreover, published articles state that the blastocoelic fluid may cause inadequate vitrification resulting in lower pregnancy and implantation rates.

To overcome this problem, a reduction in the volume of the blastocyst has been proposed, by using pre-vitrification AS to allow the blastocoelic fluid leak.
Study design, size, duration: Retrospective observational study. All procedures were performed at Andros Day Surgery Clinic, Reproductive Medicine Unit, Palermo, Italy.

We included 409 warming cycles (January 2017-October 2019) (625 blastocysts; 397 embryo transfer).
Participants/materials, setting, methods: We compared outcomes in cycles with blastocysts cryopreserved performing AS and LAH (group A) and blastocysts transferred without performing AS nor LAH (group B).

Moreover, group A was divided in A1 (where AS was performed before vitrification; after thawing, LAH was applied to partially remove ZP) and A2 (where blastocysts were vitrified without AS; after thawing, in the expanded blastocysts, AS and LAH were performed; if blastocysts were still spontaneously collapsed, only LAH was conducted).
Main results and the role of chance: Significant differences were determined using chi-square with Yates' correction and Fisher's exact tests. Independent t-test was computed for continuous variable (age). A P-value < 0.05 was considered significant.

Group A included 248 blastocysts transferred in 162 cycles. Group B included 345 blastocysts transferred in 235 cycles.

There is no significant difference in maternal age between two groups (33.1±5.4 vs 32.05±5.5 p=0.06).

Survival rate is the same in both groups (group A: 96.9% and group B: 93.5% p=0.07).

Both pregnancy and implantation rates are significantly higher in group A than group B (pregnancy rate=47.5% vs 35.3% p=0.019; implantation rate=38.3% vs 28.7% p=0.018).

No differences are shown regarding multiple pregnancy rates (22.1% vs 19.3% p=0.81) or miscarriage rates (26.0% vs 25.3% p=0.93).

We also compared group A1 and group A2.

Group A1 included 200 blastocysts transferred in 127 cycles.

Group A2 included 48 blastocysts transferred in 35 cycles.

Survival (97.6% vs 94.1% p=0.20), pregnancy (48.8% vs 42.9% p=0.53), implantation (38,0% vs 39.6% p=0.84), multiple pregnancies (26.7% vs 21,0% p=0.89) and miscarriage (24.2% vs 33.3% p=0.69) rates are not statistically different.
Limitations, reasons for caution: The study, being retrospective, limits its value. Furthermore, group A2 is less numerous than the others.
Wider implications of the findings: Our results seem to indicate that the increased outcomes are not correlated to the AS. The removal of a quarter of the ZP before embryo transfer (as in blastocysts collapsed before vitrification and blastocysts collapsed after thawing) could be the key to the improved outcomes.
Trial registration number: Non applicable

P-250 Maternal age alters morphokinetics of embryos competent to provide a live birth

M.C. Guglielmo[1], A. Bartolacci[1], E. De Ponti[2], F. Brambillasca[1], M. Mignini Renzini[1], J. Buratini[1,3], D.C. Mariabeatrice[1]

[1]Biogenesi - Reproductive Medicine Centre, Istituti Clinici Zucchi, Monza, Italy ; [2]ASST Monza, Dept Medical Physics, Monza, Italy ; [3]Sao Paulo University - Institute of Biosciences, Department of Physiology, Botucatu, Brazil

Study question: Do morphokinetic parameters until the eight-cells stage differ between embryos competent and noncompetent to provide a live birth, and are they influenced by maternal age?
Summary answer: Embryos competent to provide a live birth display faster early developmental kinetics than those noncompetent. Maternal age reduces kinetic differences between competent and noncompetent embryos.
What is known already: Time-lapse microscopy (TLM) has been increasingly applied to improve accuracy in embryo selection. However, the lack of studies assessing the association of morphokinetic markers in embryos with their competence to provide a live birth (LB) represents a significant knowledge gap. The performance of TLM-based algorithms has varied among different clinical settings, and patient profile, particularly maternal age, has been suggested as a significant driver of this variation. Nevertheless, to our knowledge, no study so far has assessed the impact of maternal age on the morphokinetics of embryos competent to provide a LB.
Study design, size, duration: Retrospective study including 816 ICSI first cycles, from 2014 to 2018. 4915 embryos were produced, from which 2093 were morphologically selected to be transferred in SET or DET 3 days after ICSI, resulting in 168 LB and 1176 non-implanted (NI) embryos with trackable morphokinetics. Morphokinetic parameters were compared between LB and NI embryos, and within each embryo type, between patients <37 or ≥37 years. The correlation between morphokinetic parameters and LB rates was tested.
Participants/materials, setting, methods: After ICSI, embryo culture was performed in a TLM incubator. The morphokinetic parameters assessed were tPNf, t2, t3, t4, t5 and t8, which were compared between groups with different embryo performance (LB *vs.* NI), and between LB embryos from patients < 37 and ≥ 37 years by Wilcoxon test. The association between morphokinetic parameters and LB rates was assessed by multivariate regression analysis including maternal age and BMI as continuous variables in the model.
Main results and the role of chance: All morphokinetic parameters were reached significantly earlier by LB embryos compared to NI embryos [means(hours)±SD; tPNf: 22.5±2.7 *vs.* 24±3.4; t2: 25±2.7 *vs.* 26.8±3.7; t3: 36.1±3.3 *vs.* 37.7±4.5; t4: 36.8±3.6 *vs.* 39.1±5.1; t5: 48.8±4.9 *vs.* 50.1±6.4; t8: 52.7±6.1 *vs.* 55.1±6.6; (p<0.0001)]. LB embryos from patients < 37 years reached all morphokinetic endpoints faster than LB embryos from patients ≥ 37 years [tPNf: 22.3±2.7 *vs.* 23.2±2.4; t2: 24.8±2.8 *vs.* 25.7±2.5; t3: 35.7±3.1 *vs.* 37.4±3.4; t4: 36.4±3.5 *vs.* 37.9±3.6; t5: 48.1±4.7 *vs.* 50.8±5; t8: 52.2±6 *vs.* 54.2±6.2; (p<0.05)]. There were no differences between morphokinetic parameters from NI embryos obtained from patients < 37 and ≥ 37 years. Consequently, differences between LB and NI morphokinetics were more evident in patients < 37 years, compared to those ≥ 37 years. Multivariate regression analysis revealed that, independently of maternal age and BMI, tPNf, t2, t5 and t8 are significantly associated with LB rate in the overall patient population [tPNf: 0.7 OR, (0.4-1.0) 95% IC, p=0.048; t2: 0.7 OR, (0.4-1.0) 95% IC, p=0.048; t5: 1.1 (0.6-1.0), p=0.01; t8: 0.9 (0.9-1.0, p=0.047)].
Limitations, reasons for caution: Our study is subjected to the intrinsic limitations of a retrospective analysis, the results presented could have been affected by variables that are uncontrolled for.
Wider implications of the findings: The present data indicate that early morphokinetics can be used to predict embryo developmental competence, but its predictive power decreases with maternal age. Therefore, our study provides valuable references for the design and application of embryo selection strategies utilizing TLM-derived information.
Trial registration number: Not Applicable.

P-251 How many donor eggs are needed in an IVF-DO cycle?

B. Marqués López-Teijón[1], A. Garcia-Faura[1], S. Novo[1], F. Garcia[1], C. Castello[1], M. Lopez-Teijon[1]

[1]Institut Marques, Reproductive Medicine Service, Barcelona, Spain

Study question: Is the largest number of donor eggs always associated with better results?
Summary answer: Good results can be obtained with an adjusted number of mature oocytes and a greatly increasing the number of ovules provides a limited value.
What is known already: There is much literature on the number of eggs necessary to obtain success in an IVF of their own, but scarce about how many mature eggs are necessary for an optimal result in case of IVF with donor eggs. Fertility clinics suffer the pressure of patients who need donor eggs because they believe that the greater the number, the more likely they are to succeed.
Study design, size, duration: We have conducted a single center retrospective observational study. The result of IVF cycles with egg donation is compared according to the number of mature oocytes assigned. 1,648 consecutive IVF with donor eggs cycles were analyzed over a period of two years (2017-2019). Three groups were created according to the number of mature oocytes assigned: A. 4 mature oocytes in metaphase II (396 cycles), B. 5-7 oocytes (620 cycles) and C. 8-10 oocytes (632 cycles).
Participants/materials, setting, methods: The groups are comparable in mean age of donors (26.2 years) and recipients (43.0 years), in percentage of fresh (91-94%) and vitrified (6-9%) oocytes, and in percentage of fresh embryo

transfers (35-37%) and frozen (63-65%). All embryo transfers were of single blastocyst of superior or equal quality to 3BB (Gardner).
Main results and the role of chance: Statistically significant differences ($p < 0.05$) have been found in the average of good quality blastocysts obtained per cycle: 2.1 in group A, compared to 3.1 and 3.2 in groups B and C. There are also statistically significant differences in the pregnancy rate per cycle: 85% in group A, compared to 91% and 90% in groups B and C. No statistically significant differences were found between the groups in the pregnancy rate per transfer (61,5% to 65,2%) or in the newborn rate per transfer (44,2% to 47,2%).
Limitations, reasons for caution: It's a retrospective single center study, these results will vary depending on the success rates of each laboratory.
Wider implications of the findings: Increasing the number of eggs up to a 250%, the pregnancy rate per cycle rises just a 5%. These data suggest that good results can be obtained with an adjusted number of mature oocytes and that greatly increasing the number of eggs provides limited value.
Trial registration number: not applicable

P-252 Reproductive potential of conventional IVF and ICSI on sibling oocytes in the case of isolated teratozoospermia.

N. Thondehal Math[1], G. Devika[1], G. Deepanjali[1], R. Sajana[1], R. Anjana[1], B. Vidhya[1], W.Y. Son[2]

[1]Gunasheela Surgical & Maternity Hospital, embryology, Bangalore, India ; [2]McGill University Health Centre, Embryology, Montreal, Canada

Study question: Does ICSI have any embryological and clinical benefits for the couple who have isolated teratozoospermia compared to conventional IVF insemination?
Summary answer: Reproductive potential is similar between both insemination methods and so, couples with isolated teratozoospermia need not be subjected to ICSI.
What is known already: In many studies, semen samples with teratozoospermia produced lower fertilization rates when conventional IVF was used. On the other hand, in some studies, patients with teratozoospermia achieved good fertilization in conventional IVF as long as the sperm concentration and motility were within the normal range (isolated teratozoospermia) according to WHO standards. Few studies observed the difference in embryo quality and further clinical outcomes of patients with isolated teratozoospermia between conventional IVF and ICSI. This study compares reproductive potential between conventional IVF and ICSI from the same patients with isolated teratozoospermia.
Study design, size, duration: These prospective studies were conducted in a private hospital between April 2015 and December 2019. In each case, sibling oocyte cumulus complexes were randomized to be inseminated either by ICSI (n=1555) or IVF (n=471) (4: 1 ratio) to prevent completely failed fertilization. Fertilization, good blastocyst rates (≥ 4BB) and clinical outcomes in ICSI group were compared to IVF group.
Participants/materials, setting, methods: This study was conducted in patients (n= 102, age= 34.7 ± 4.6 years old) for whom at least 10 oocytes were retrieved and partner had isolated teratozoospermia. In the ICSI group, 1159 oocytes out of total 1555 oocytes were mature and underwent ICSI, and the rest underwent conventional IVF. All fertilized embryos were cultured to blastocyst stage. The best blastocysts produced were transferred in either fresh or frozen cycles.
Main results and the role of chance: Fertilization and blastocyst utilization rates were similar between ICSI group (75.8%, 878/1159; 67.8%, 595/878) and IVF group (74.5%, 351/471; 71.5%, 251/351) ($P > 0.05$). Failure of fertilization after IVF insemination occurred in 5 of the 102 couples (4.9%) and in none with ICSI. After transferring the embryos either in fresh or frozen cycles (n=94) there was no statistically significant difference in clinical pregnancy and ongoing/live birth rates among cycles transferred from ICSI (58.13%, 25/43; 53.4%, 23/43), IVF (64.7%, 22/34; 47.1%, 16/34) and combined groups (61.7%, 11/17; 58.8%).
Limitations, reasons for caution: The sample size is low. Although number of sibling oocytes should have been put into IVF group, the design was intended to prevent total fertilization failure.
Wider implications of the findings: Since failed fertilization rate in IVF insemination on normospermic infertility factor patients is also over 5%, our study implies that IVF insemination is an option to avoid unnecessary use of ICSI which is time-consuming, costly and has potential risks for the couples with isolated teratozoospermia.
Trial registration number: not applicable

P-253 Oocyte incubation time prior to ICSI and its impact on assisted reproduction results. A randomized controlled trial

R. Pesce[1], A. Piazza[1], R. Rolando[1], C. Elizondo[2], G. Perman[3]

[1]Hospital Italiano de Buenos Aires, Gyneacologucal Department, Buenos Aires, Argentina ; [2]Hospital Italiano de Buenos Aires, Epidemiology Department, Buenos Aires, Argentina ; [3]Hospital Italiano de Buenos Aires, Public Health Department, Buenos Aires, Argentina

Study question: Are there differences in oocyte maturity, fertilization rate and early embryo evolution (cleaving embryo) between early and late oocyte denudation immediately prior to ICSI?
Summary answer: Early oocyte denudation is better than late denudation in percentage of: MII oocytes (OR 2.38; p 0.013) and cleaving embryos (OR 2.30; p 0.028).
What is known already: The time of contact between cumulus cells and the oocyte play an important role in the achievement of oocyte competence, oocyte aging process and early embryo development. In addition, the time from trigger administration to retrieval, and the time in culture before insemination affect oocyte maturation and ovarian ageing in vitro.

There is controversy in international scientific literature regarding oocyte incubation time. Studies thus far were done in women with fertility issues, or in donor women but with retrospective designs.

The best timing of incubation prior to ICSI is yet to be determined.
Study design, size, duration: Design: randomized controlled trial. Oocytes were randomized to early or late denudation time (two arms). They were the unit of analysis. Since oocytes coming from each donor woman were considered to have a cluster effect, we adjusted for this with a random-effects multilevel model.

Sample size: 184 oocytes per treatment arm (accounting for the design effect) to have 80% power and 5% alpha error to detect a 20% difference in results.

Duration: January 2016-December 2018.
Participants/materials, setting, methods: Setting: Oocyte donation programme in a university hospital.

Participants: Randomized oocytes came from healthy women (donors).
Methods: Treatment arms: Early denudation: thirty minutes after oocyte pick-up (OPU), oocytes were denudated from its cumulus. Late denudation: four hours later than OPU. All oocytes were subject to ICSI immediately after denudation.

All participants, professionals and researchers were blinded to treatment allocation except for the biologist that performed the process (who did not participate in other activities).
Main results and the role of chance: Out of a total of 375 included oocytes, 191 were randomly assigned to early denudation (ED) arm, and 184 to late denudation (LD). The mean time to denudation was: ED, 0.5 hours (95% CI 0.42 – 0.58); LD, 4 hours (4 – 4.5); p <0.001.

The crude percentage of MII oocytes was 91.6% and 83.7% (ED vs LD, respectively), p 0.033. The crude percentage of fertilized oocytes was 55.3% vs 44.7%, p 0.642. The crude percentage of cleaving embryos was 56.9% vs 43.1%, p 0.012.

The adjusted odds ratio (OR) for MII oocytes (comparing early vs late denudation) was 2.38 (95% CI 1.20 – 4.72); p 0.013. The adjusted OR for fertilization was 1.30 (0.68 – 2.48); 0.423. The adjusted OR for cleaving embryo was 2.30 (1.10 – 4.85); p 0.028**Limitations, reasons for caution:** This is the first randomized controlled trial that evaluates early vs late denudation in oocytes from healthy women. Its results can encourage the production of new studies that confirm findings and assess its potential impact in clinical outcomes (pregnancy rate and live birth rate).
Wider implications of the findings: These findings suggest that early denudation could improve the odds of having cleaving embryos at third day after ICSI. This could mean a need for change in usual embryology laboratory processes.
Trial registration number: ClinicalTrials.gov Identifier: NCT03121924

P-254 Make hey while sun shines! Hormone 25 OH D (vitamin D3) in follicular fluid: a determinant factor for top grade blastocyst formation?

N.M. Chimote[1], B. Chimote[2]

[1]Vaunshdhara Fertility Centre, Embryology & Reproductive Endocrinology, Nagpur, India ; [2]Vaunshdhara Fertility Centre, Embryology- Endocrinology, Nagpur, India

Study question: To investigate relationship of 25(OH) D (vitamin D3) in follicular fluid (FF) with oocyte competence to fertilize, cleave and for top quality blastocysts.
Summary answer: Follicular-fluid level of 25(OH)D (Vitamin D3) is a potentially predictive marker for oocyte competence to fertilize, cleave and form top-grade blastocysts in women undergoing IVF.
What is known already: There is growing evidence that [25(OH)D has very important role in human reproduction. Vitamin D3 contributes to restoration of the menstrual cycle and endometrial proliferation, growth of follicles, improves primary dysmenorrhea, and reduce occurrence of uterine fibroids. However, owing to conflicting results, the relationship of serum levels of Vitamin D3 with ovarian stimulation characteristics or with embryo quality has been rather obscure. IVF provides a unique opportunity to explore such a relationship as measurement of vitamin D3 in follicular-fluid can help trace the fate of individual oocytes, their fertilization and embryonic development.
Study design, size, duration: This non-randomized prospective study included women (n=300, 22-42 years) undergoing IVF during January2017-December2019. None of the patients received vitamin D3 supplementation before Controlled Ovarian Hyperstimulation (COH). Follicular-fluid collected from first aspirate of individual follicle was pooled, for each patient, to measure Vitamin D3 levels using RIA kits. Embryonic development from fertilization to blastocyst formation was recorded. Embryo gradation was done as per conventional criteria. All blastocysts were vitrified for next natural cycle embryo transfer.
Participants/materials, setting, methods: Women with endometriosis, tuberculosis and hydrosalpynx and their male partners with severe or moderate male factor were excluded from this study. Women with Poor ovarian response (≤ 3 retrieved oocytes) to recombinat FSH / gonadotropin stimulation were also excluded. FF Vitamin D3 levels were divided into Low and High groups as per their median value. Fertilization, cleavage and blastocyst formation rates were recorded in low and high FF vitamin D3 groups.
Main results and the role of chance: Age, number of eggs retrieved and MII oocytes were comparable between Low FF Vitamin D3 Group (< 41 ng/ml, n=152) and High FF Vitamin D3 groups (> 41 ng/ml, n= 148). % fertilization, % cleavage was significantly higher in low group than high vit D3 group (93.3 ± 22.6 vs 86.1 ± 29.5% P: 0.0205). Overall Blastocyst formation remained similar (50.3 ±37.9 vs. 54.1 ± 35.4% : P value 0.3740). However, top and good grade blastocysts were significantly higher in low FF/vit. D3 group than in high FF/vit. D3 group (Top: 34.4 ±0.4 vs 24.2 ±0.8%, P= 0.0183 and Good: 37.8 ± 0.69 vs 21.4 ± 0.72, p= 0.0002).

Interestingly, poor quality blastocysts were significantly high in high FF/ vit. D3 compared to FF/low vit. D3 group (45.0 ± 38.5 vs 26.3 ± 33.0 %, P value: < 0.0001). Thus, measurement of vit. D3 in follicular fluid has tremendous potential to identify the embryonic development to blastocyst stage with top or good quality so as to select the best embryo for transfer. It also helps enhance the chances of getting a viable pregnancy resulting in live birth.
Limitations, reasons for caution: Since this study has very limited number of cases, more multicentric studies should be carried out to endorse impact of vit. D3 on embryonic development. Hence, pre treatment of supplementation of Vit D3 also should be contemplated according to variability of sunlight all over the world.
Wider implications of the findings: With changes in weather and carbon emission with problems in ozone layers all over the world, it seems that natural synthesis of vit. D3 is disturbed. Hence, proper evaluation of this hormone should be judiciously done to improve excellent embryo development and a viable pregnancy.
Trial registration number: not applicable

P-255 A freeze-all strategy in a donor egg program

A.M. Quinteiro Retamar[1], M. Miguens[2], A. Coscia[2], N. Allende[2], G. Vega Balbuena[2], D. Acosta[2], G. Fiszbajn[1]

[1]CEGYR, EGG DONATION, caba, Argentina ;
[2]CEGYR, clinical, caba, Argentina

Study question: To compare ongoing pregnancy and miscarriage rate after blastocyst transfer in an oocyte donation program in patients with synchronization of donor-recipient cycle versus freeze-thawed strategy.
Summary answer: A freeze-all strategy may be an advantage allowing to schedule treatments without cancellation or delays, but the reproductive results have not shown statistical difference.
What is known already: Theoretically, freeze-thawed embryo-transfer (ET) may have better ongoing pregnancy rate than fresh ET due to a more favorable intrauterine environment by avoiding the condition after ovarian stimulation. It is although thought that the pregnancy potential of blastocyst frozen on day 5 and slow developing day 6 blastocysts, after a freeze-thawed strategy, are comparable. Synchronization of the donor-recipient cycle may have some difficulties such as cancellation of the treatment, either of the donor stimulation or the recipient endometrial preparation or the possibility of the absence of blastocyst. These challenges may disappear with a freeze-all strategy.
Study design, size, duration: This was a retrospective cohort study conducted at CEGyR, Buenos Aires, Argentina. A total of 650 women who were recipients having her first single embryo transfer from March 2016 and November 2019 were included.
Participants/materials, setting, methods: A total of 650 recipients between 28-51 years who were having her first single ET were included. All ET were performed at blastocyst stage. The patients were separated in two groups: (1) ET was made with a synchronization of donor-recipient cycle (2) ET was made after a freeze-all strategy. The analyzed variables were ongoing pregnancy rate and miscarriage rate by chi square test. (The ongoing pregnancy rate determined by transvaginal ultrasonography at gestational weeks 8-10).
Main results and the role of chance: A total of 392 patients were included in group 1 and 258 patients in group 2. The average age in group one was 41.5 years old and in group two 42.1 years old. In the former group the ongoing pregnancy rate was 47,70% (n=187) vs 43,41% (n=112) in the latter group (IC95 0,76-1,08 p=0.14). The miscarriage rate in the first group was 11,48% (n=45) vs 14,34% (n=37) in the second group (IC95 0,86-1,86 p=0.11). Both groups have similar results and they were not statistical significance.
Limitations, reasons for caution: The main limitation of this study was its retrospective design based on data from a single center which may be subject of bias.
Wider implications of the findings: While the freeze-all strategy is a more practical way to schedule treatments, it has not shown better clinical results. However, prospective randomized studies are needed to confirm the hypothesis and a cost-effectiveness analysis to determine its applicability.
Trial registration number: NOT APPLICABLE

P-256 The association of early-cleavage embryo morphokinetics and blastocyst formation rate does not vary by women age: a time-lapse monitoring study

A. Gomes[1], H. De Martin[1,2], M. Fujji[1], M. Conatti[1], M. Nakano[2,3], T. Bonetti[4,5], P. Monteleone[2,6]

[1]Monteleone - Human reproduction center, Embryology, São Paulo, Brazil ;
[2]Universidade de São Paulo - USP, Gynecology Discipline - Obstetrics and Gynecology Department, São Paulo, Brazil ;
[3]Monteleone - Human reproduction center, Clinical, São Paulo, Brazil ;
[4]Monteleone - Human reproduction center, Scientific, São Paulo, Brazil ;
[5]Universidade Federal de São Paulo, Gynecology Department, São Paulo, Brazil ;
[6]Monteleone - Human reproduction center, Clinical director, São Paulo, Brazil

Study question: Does the embryo morphokinetics, from early cleavage until blastocyst formation based on time-lapse monitoring (TLM), vary according to women age?
Summary answer: The time-range of embryos progressing from two to three-cell (CC2) is associated to blastocyst formation and does not vary by women age
What is known already: ART success depends on a number of factors and one of the most significant is the women age. Reproductive capacity in women declines with ageing, associated with a decrease in oocyte quantity and quality, which correlates with lower fertilization rates and poorer embryo development. Embryo selection is a crucial step in ART and the introduction of TLM provided additional noninvasive criteria for better embryo selection and embryonic kinetics markers starting from the first cleavage. Early cleavage has been described as a key factor for embryo selection, however, there is studies evaluating the variation in these parameters according to maternal age.
Study design, size, duration: This retrospective cohort study used prospectively collected data from 671 ICSI cycles from 486 patients between April/2018 and September/2019 in a private reproductive medicine center. A total of 4724 mature (MII) oocytes were fertilized by ICSI and cultured in a time-lapse monitoring system (Embryoscope®). The time-lapse monitoring parameters and

blastocyst formation rate (BlastR) were compared in groups according to women age (<38 years or ≥38 years).

Participants/materials, setting, methods: Early-cleavage parameters were analyzed and correlated to blastocyst formation in each group. The time between two-cell and three-cell (cell cycle two – CC2), three-cell and five-cell (CC3), five-cell and nine-cell (CC4) were calculated. The blastocysts were classified according to morphology by Gardner's classification and those with trophoectoderm grade ≥3 and inner-cell mass A or B were considered top-quality. The blastocyst rate (BlastR) was calculated by dividing the number of blastocysts obtained by number of 2PN.

Main results and the role of chance: From the 4724 MII oocytes injected, 3622 were normally fertilized (2PN). From those, 1635 came from women <38 years (48.8%) and 1716 from women ≥38 years (51.2%). 271 2PN oocytes were excluded from analysis due to missing data. The mean time of CC2 (<38-years: 10.0±4.7 vs ≥38-years: 10.5±4.8; p=0.005), CC3 (<38-years: 12.4±6.6 vs ≥38-years: 12.7±6.8; p=0.212) and CC4 (<38-years: 23.1±8.9 vs ≥38-years: 23.4±9.0; p=0.300) did not clinically differed between age groups. A total of 2159 embryos developed to blastocyst stage (64.5%) and the BlastR did not clinically differed between <38-years group (66.4%) and >=38-years group (62.6%, p=0.023) as well. The BlastR varied according to CC2 and the higher BlastR occurred when embryos presented CC2 between 8 and 13 hours for both groups (<38-years: 80.5% vs ≥38-years: 75.9%; p=0.007). For the top-quality blastocyst rate (TQ-BlastR) the same pattern was observed and TQ-BlastR when CC2 was between 8 and 13 hours were (<38-years: 59.9% vs ≥38-years: 49.5%; p<0.001). Despite of statistically significance observed in some parameters compared between groups <38-years vs ≥38-years, those did not have clinical impact as the means are very close and the statistical differences occurred possibly by the high number of embryos included in the analysis.

Limitations, reasons for caution: This retrospective study evaluated the association of CC2 and blastocyst formation according to women ages. The blastocyst choosing criteria was based on blastocyst morphology and did not take CC2 into account. Then, we could not evaluate the impact of CC2 on pregnancy success.

Wider implications of the findings: We can underline that time of CC2 predict blastocyst formation and it does not vary according to women age. Although the pregnancy rate decreases in older women, our findings support the hypothesis that the morphokinetics of embryos from the first cleavage to the blastocyst formation does not vary with age.

Trial registration number: not applicable

P-257 Two Labs-Two countries: five-years' report with cumulative live birth rate of the ovum donation program in an Italian University Hospital

R. Picone[1], F. Bertocci[1], R. Fucci[1], P. Falcone[1], C. Giachini[1], E. Borrani[1], M.E. Coccia[1], G.M. Cito[1], L. Badolato[1], P. Evangelisti[1], F. Rizzello[1], D. De Angelis[1], C. Cozzi[1]

[1]Careggi University Hospital, assisted reproduction technology, Florence, Italy

Study question: Two labs-two countries' for the egg donation program: how is it efficient in terms of cumulative life birth rate (CLBR)?

Summary answer: Combining fresh/frozen embryo transfer in the same couple, deriving from donor vitrified and travelling oocytes is an efficient way to improve significantly the CLBR.

What is known already: Vitrification of oocytes and embryos is the golden standard used worldwide for the cryopreservation in IVF and fertility preservation programs. The IVF outcome, in terms of pregnancy and implantation rate, are comparable with those obtained with fresh oocytes/embryos. Advances in reproductive techniques, i.e. the introduction of oocytes vitrification, has allowed simplifying the donation process by the formation of egg banks. The extremely low rate of egg donation by Italian women does not satisfy the current level of demand and over 90% of the IVF cycles with egg donation originated from foreign (mainly Spanish) gamete bank.

Study design, size, duration: Retro-prospective study on our couples from 2015 to 2019. In our five-years' experience we have been used the so-called 'two country-two lab' model meaning that the oocytes retrieval and the subsequent vitrification is performed in foreign banks while their fertilization after warming by ICSI and embryo transfer is made in our laboratory. Thanks to collaboration between our laboratory and the foreign banks we were able to optimize the entire procedure.

Participants/materials, setting, methods: For each egg donation cycle we receive six oocytes. The kitazato protocol was utilized for oocytes warming. Banks can be asked to send 3 more oocytes if the survival rate was less than 50%. Rates of oocytes survival, fertilization, cleavage, clinical pregnancy and life birth were reported, including CLBR. Embryo transfer and cryopreservation were performed on day 3 or 5.

Main results and the role of chance: From 2015 to 2019 a total of 900 egg donation cycles were performed. The oocyte survival rate is 81,0±19,3%. The fertilization rate is 70,0±25%. The cleavage rate is 91,0±14,2%. The percentage of pregnancy rate in the fresh transfer is 36% with a life birth rate of 26%.

30.5% of patients underwent ET also have cryopreserved embryos, thus they have the chance to have subsequent ETs.

Considering the cumulative percentage, i.e. including ET with warmed embryos, the pregnancy and the life birth rates increase significantly, up to 40% and 32% respectively (p <0.05 for both parameters).

These results indicate that cryopreserved embryo transfers contribute substantially to the total success rate of an IVF cycle with egg donation.

Limitations, reasons for caution: Cumulative life birth rate has been calculated on concluded IVF cycles, i.e. if life birth was achieved or when no more vitrified embryos were available

Wider implications of the findings: Our findings confirmed the efficacy of the double vitrification-warming procedure (at oocytes and embryos stage) that could be used for supernumerary embryos or to postpone embryo transfer when the endometrial pattern is suboptimal.

Trial registration number: not applicable

P-258 Evaluation of the relation between the value of mitochondrial DNA (MitoScore) and euploid embryo quality

M. Niag dos Santos Rocha[1], D. Freitas[2], R. Carvalho[3], T. Oliveira[3], C. Santos[3], T. Abreu[3], C. Teixeira[2], A. Almeida[2], L. Queiroz[2], G. Coelho[4]

[1]Universidade Federal do Recôncavo da Bahia, Centro de Ciências da Saúde, Santo Antônio de Jesus, Brazil ;
[2]Insituto Valenciano de Infertilidade - IVI Salvador, IVF Lab, Salvador, Brazil ;
[3]Universidade Federal do Recôncavo da Bahia, Medical School, Santo Antônio de Jesus, Brazil ;
[4]Insituto Valenciano de Infertilidade - IVI Salvador, Clinical Director, Salvador, Brazil

Study question: Can the copy number of Mitochondrial DNA (mDNA) – MitoScore – be associated with quality of an euploid embryo?

Summary answer: The evaluation of the number of copies of mitochondral DNA (Mitoscore) does not correlate with the quality of the embryo.

What is known already: Assisted reproduction has tried to identify and develop strategies that make it possible to increase the rates of embryonic implantation and, consequently, pregnancy. Implantation failure rates with morphologically and chromosomally normal embryos show that there are other factors that affect embryonic quality and fertilization rate. Mitochondria and their DNA (mDNA) have been suggested as a potential marker of embryonic viability and chances of fertilization, since their copies number is related to the energy supply of the embryo. It is known that a larger number of copies of mDNA in a blastocyst seem to be associated with a lower implantation rate.

Study design, size, duration: This is a descriptive retrospective, observational, cross-sectional study. A convenience sample was used, covering the analysis of medical records of couples diagnosed with infertility, who underwent treatment at an assisted reproduction clinic in Salvador, Bahia, Brazil, in total convenience sample of 69 cycles, from a total of 69 patients. This work was developed during the period from from August 2016 to December 2019.

Participants/materials, setting, methods: This study evaluated 173 embryos which underwent preimplantation genetic testing for aneuploidy (PGT-A) and MitoScore testing (on euploid embryos) was performed by Igenomix. Embryos were classified on the basis of embryo quality (EQ) utilizing ASEBIR criteria into three groups: Good (AA/AB/BA/BB), Fair (BC/CB), Poor (CC). Software Statistical analysis was used and the differences between three groups was estimated by ANOVA test. In all cases, p < 0.05 was considered statistically significant.

Main results and the role of chance: Data from a total of 69 cycles, of 69 women, With an average age of 36.31 (+ 5.29) years. Of the 173 embryos analyzed, there were 115 (66.47%) embryos with Good EQ, 41 (23.70%) embryos with Fair EQ and 17 (9.83%) embryos with Poor EQ. In embryo group with Good EQ, the average of Mitoscore value was 23,29 (+ 5.98); in group with Fair EQ, the average of MitoScore value was 22,76 (+ 5.42); and in group with Poor EQ, the average of MitoScore value was 24,12 (+ 6.07). There was no statistically significant difference between the groups evaluated (*p=0.7167*). In addition, it was also observed that of the 173 embryos analyzed, 86 were transferred, in a total of 63 transfer procedures (with one or two embryos). Of this total transfer, 29 procedures were implanted, which represents a 46.0% implantation rate.
Limitations, reasons for caution: The reduced number of embryos analyzed in this study does not allow establishing more precise correlations between analyzed variables. This study will be complemented with new cycles to increase the investigation about importance of MitoScore in prediction of embryo viability and implantation rates.
Wider implications of the findings: There is no association between embryo quality (EQ) and embryo's MitoScore in this study. This result is in agreement with evidences in literature. However, the knowledge of this value can be useful in the decision in order of embryonic transfer, when having embryos with similar EQ.
Trial registration number: Not applicable

P-259 Effect of Myo-Inositol and Alpha-Lipoic Acid on oocyte morphology and embryo morphokinetics: a prospective preliminary analysis of 40 overweight patients undergoing ICSI treatment

G. Gennarelli[1], C. Paschero[2], S. Canosa[1], C. Benedetto[1], A. Revelli[1]

[1]Turin University, Obstetrics & Gynaecology, Torino, Italy ;
[2]Turin University, Obstetrics & Gynecology, Torino, Italy

Study question: May the administration of a multivitamin compound based on Myo-Inositol, Alpha-Lipoic Acid and Folic Acid before controlled ovarian stimulation influence oocyte and embryo quality?
Summary answer: The administration of Myo-Inositol, Alpha-Lipoic Acid and Folic Acid may affect both oocyte and embryo morphological features and reproductive outcomes in overweight patients
What is known already: Several clinical studies have demonstrated that both Myo-Inositol and α–Lipoic Acid are involved in mitochondrial respiratory chain and energy metabolism having a positive effect oocyte quality and embryo development of women affected by PCOS. Therefore the administration in PCOS patients may improve reproductive outcomes by both affecting metabolic pathways and reducing oxidative stress. Nevertheless, data are missing on the use of Myo-Inositol in women defined poor responders undergoing ovarian stimulation for ICSI cycle. Therefore, the aim of the present study was to provide evidence on the effect of this compound in overweight patients
Study design, size, duration: This is a randomized prospective analysis of 40 patients aged 25-40 years, with 27≤BMI≤32, AMH≥0.1, FSH≤15 without diagnosis of diabetes and autoimmune diseases undergoing ICSI treatment at our IVF Unit between 2018 and 2019. According to the randomization patients assumed either the multivitamin compound (MI group, n=20) or Folic Acid alone (FA group, n=20) for three months before COS
Participants/materials, setting, methods: Clinical characteristics and reproductive outcomes (clinical pregnancy rate and miscarriage rate) of the whole cohort of patients were recorded and analysed using t-test or chi-squared test as appropriate. Oocyte Zona Pellucida (ZP) and Meiotic Spindle (MS) morphological features were examined using Polarized Light Microscopy whereas embryo quality was assessed using the Integrated Morphology Cleavage Score evaluated on day 2 (Holte 2007) integrated with morphokinetics annotation by Time-Lapse system. Statistical significance was set at p<0.05
Main results and the role of chance: The clinical characteristics of the patients and the outcome of their IVF cycles showed no statistically significant differences. A total number of 324 oocytes were observed under PLM revealing a significantly higher zona retardance (2.1±0.6 vs 1.9±0.5; p<0.0001), area (2895.3±574.4 vs 2574.8±491.1;p<0.00001) and thickness (5.3±1.4 vs 4.5±1.2; p<0.05) and a significantly shorter meiotic spindle axis (11.8±1.8 vs 12.3±2.3) in MI group (n=155) compared to FA group (n=169).

Overall, 176 embryos were obtained and assessed for conventional morphology showing a significantly higher morphological score on day 2 (7.4±2.3 vs 6.7±2.1; p<0.01) and a higher percentage of top quality embryos (score≥8) (45.2% vs 26.1; p<0.01) in MI group (n=84) compared to FA group (n=92). At variance, comparable embryo morphokinetic parameters were observed in the study groups: time of pronuclear appearance (tPNa), pronuclear fading (tPNf), completion of cleavage to two, three, four and eight cells (t2, t3, t4, t8), time between first and second cytokinesis (P2) and between second and third cytokinesis (P3).

After ultrasound-guided ET, the implantation rate was 30% (10/30) in MI group and 11% (3/28) in FA group, showing significant differences (p<0.05) and an ongoing pregnancy rate of 40% (8/20) in MI group and 5% (1/20) in FA group (p<0.01)**Limitations, reasons for caution:** The conclusions of this study may not be generalizable to other patient populations, time-lapse systems or microscopy. The number of observations is limited and the conclusions should be verified in a prospective study on a larger number of embryos
Wider implications of the findings: This is the first, preliminary evaluation of the influence of a multivitamin compound on oocyte morphological features and embryo morphokinetics. If confirmed on a larger sample size, our preliminary findings may help to a better oocyte and embryo selection in overweight patients
Trial registration number: not applicable

P-260 Post-warming culture duration and effect on live birth rates in single, top-quality vitrified blastocyst transfers – A retrospective analysis of 839 transfers.

H. Premannandan[1], S. Yasmin[1], G. Sotirchou[1], G. Srivastava[1]

[1]Homerton University Hospital, Women's and Sexual Health, Homerton, United Kingdom

Study question: Do live birth rates differ based on the post-warming culture duration in top-quality, single vitrified blastocyst transfers in good prognosis women?
Summary answer: Live birth rates were similar in top-quality, single vitrified blastocyst transfers cultured ≤ 2 hours, between 2 to 3 hours and > 3 hours post-warming.
What is known already: It is generally accepted that the post-warming culture duration should be a minimum of 2 hours before the transfer. However, the question of difference in live birth rates, when transferring a viable blastocyst that was of top-quality at vitrification, before or after the recommended post-warming culture duration, has been not fully answered.
Study design, size, duration: Retrospective cohort study of 839 frozen blastocyst transfers in a single UK centre (March 2015 - November 2018). Post-warming culture duration of ≤ 2 hours (Group A, n=208), between 2-3 hours (Group B, n=396) and > 3 hours (Group C, n=235) were compared to live birth rates. For power of 90% with 95% CI, demonstrating medium effect size, minimum 141 participants were needed in each group for statistical significance using Chi-Square ($\chi 2$) test of independence.
Participants/materials, setting, methods: Non-smoker women with BMI less than 30, age ≤ 37 years at oocyte retrieval, having a single, top-quality blastocyst at vitrification were included. All women had hormone replacement therapy (HRT) for the preparation of the endometrium. Standard dose of micronized progesterone pessaries was used for luteal phase support. Outcome measure was live birth rates.
Main results and the role of chance: In total, 839 transfers were analysed. (i) The 3 groups of post-warming culture duration intervals yielded live birth rates of 32.69%, 38.64% and 39.15% respectively. No statistical difference between the groups was found [X^2 (2, N = 839) = 2.534, p = 0.2817].
Post-warming culture duration does not impact the chance of live birth rates in single, top-quality vitrified/warmed blastocyst transfers in good prognosis patients.**Limitations, reasons for caution:** Retrospective nature of the study. The expansion of the blastocysts has not been considered in this study; however, only viable embryos were transferred.
Wider implications of the findings: In busy IVF units, top-quality vitrified blastocysts can be transferred between 2 to 4 hours without any detrimental effect on the live birth rate.
Trial registration number: not applicable

P-261 Post warming re-expansion of single top-quality blastocysts and the relationship with live birth rates (LBR) – A retrospective analysis of 839 frozen embryo transfers

G. Srivastava[1], S. .yasmin[1], H. .premannandan[1], G. Sotirchou[1], R. Homburg[1]

[1]Homerton University Hospital - E9 6SR, Fertility Department, London, United Kingdom

Study question: Do the live birth rates (LBR) differ based on the post-warming culture duration in top-quality, single blastocyst transfers in good prognosis women?
Summary answer: LBR differ significantly based on the re-expansion of vitrified top-quality blastocyst cultured post-warming for ≤ 2, 2 to 3 and ≥ 3 hours.
What is known already: Re-expansion of the vitrified blastocyst is accepted to give an indication of its implantation potential and reproductive outcomes. Failure to re-expand affects 25% of warmed blastocysts. Nonexpanded, viable, blastocysts are deemed suitable for transfer within 4 hours of post-thaw culture in many units across the world. Warming of another blastocyst is rarely justified unless substantial damage to the trophectoderm is observed.
Study design, size, duration: Retrospective cohort study of 839 frozen embryo transfers conducted in single UK centre from March 2015 to November 2018. The post-warming culture duration was divided into three groups: ≤ 2 hours (Group A, n1 = 61 n2 = 147), between 2-3 hours (Group B, n1 = 106, n2 = 290) and ≥ 3 hours (Group C, n1 = 54, n2 = 181). LBR were compared between non-expanded (n1) and expanded (n2) group respectively.
Participants/materials, setting, methods: Non-smoking women, with BMI I< than 30, age ≤ 37 years at oocyte retrieval, having a single, top-quality embryo at vitrification were included. All women had hormone replacement therapy (HRT) for the preparation of the endometrium. A standard dose of micronized progesterone pessaries were used for luteal phase support. The outcome measure was the live birth rate.
Main results and the role of chance: In total, 839 transfers were analysed with non-expanded and expanded status with an enrollment ratio of approximately 1:2.5. The study was powered at 80% with a 95% confidence interval. To demonstrate high effect size at least 143 total participants (n1+n2)were needed for each of the time intervals respectively.

The proportion tests, two-sided Z-tests at 5% level of significance for each group confirmed that the differences in live birth rates between non-expanded and expanded status at different time intervals are statistically significant (Group A: non-expanded 21.31% vs expanded 37.41%, p = 0.024; Group B: non-expanded 30.19% vs expanded 41.72%, p = 0.03; Group C: non-expanded 22.22% vs expanded 44.20%, p = 0.003)
Limitations, reasons for caution: The study was retrospective in nature.
Wider implications of the findings: In busy units, top-quality, warmed, viable, non-expanded blastocysts can be transferred between 2 to 4 hours with acceptable LBR. However,re-expanded blastocysts increased LBR significantly. We recommend, if the blastocyst has not re-expanded within 4 hours, there can be a discussion with the patient to warm remaining blastocyst to improve LBR.
Trial registration number: Not applicable

P-262 The effect of culture media microdroplet geometry and different oil overlay on pre implantation embryonic development in dry incubators: Prospective randomized study

M. Hozaien[1], A. El shimy[1], H. El khedr[1], H. Zaki[2]

[1]Ganin Fertility Center, IVF Laboratory, cairo, Egypt ;
[2]Ganin fertility center, Clinic, Cairo, Egypt

Study question: Do the culture media microdroplet geometry of different culture dishes and oil overlay affect the pre implantation embryo development in dry incubators?
Summary answer: Pre implantation embryonic development in dry incubators could be affected significantly by the geometry of culture media microdroplet and the oil overlay used.
What is known already: Commonly used embryo culture dishes are not developed especially for embryological purposes. There is a little work of physical embryonic requirements and culture platform role on human embryonic development. Different drop geometries(2D/3D dishes)results in different surface areas, evaporation rates and osmolality of media microdroplets. Oil types with different viscosities, densities and water content used for media overlay may result in changes of media evaporation rate, pH and osmolality especially in dry incubators. Minor changes in media's pH or osmolality has a dramatic effect on embryo metabolism, developmental competence and quality. Especially the blastulation rate that's much affected by high pH/osmolality.
Study design, size, duration: A prospective randomized study included 1695 MII sibling oocytes collected from 100 patients undergoing ICSI at private center from August 2019 to January 2020. We used sibling oocytes splits between two different dishes : GPS (life global, USA) and SPL (life science, Korea) with two different oils : light mineral oil (LM)(Irvine, USA) and paraffin oil (PO)(Vitro life, Sweden). All embryos cultured in dry incubators at the same conditions.
Participants/materials, setting, methods: Maternal age is ≤37 years old with ≥ 8 MII oocytes. First, we split (211 MII) between GPS and SPL dishes overlaid with LM, Other (435 MII) splits overlaid with PO, second: (176 MII) siblings were cultured in GPS dishes and splits between LM and PO, (416 MII) cultured in SPL dishes and splits between LM and PO. And, third: (457 MII) splits were cultured in GPS overlaid with PO vs SPL overlaid with LM.
Main results and the role of chance: Data collected and analyzed using statistical software, results considered significant if p value ≤ 0.05.There were no significant differences in fertilization, cleavage rates or high-quality day 3 embryos in all groups. There was significant difference in blastulation rate (75%,60%) (p = 0.02) between GPS dishes vs SPL dishes overlaid with LM respectively. GPS dishes overlaid with PO showed significantly higher blastulation rate (67% vs 47%) (p<0.001) and high-quality day 5 embryos (75%,48%) (p <0.001) than SPL overlaid with PO. On the other hand, there were no significance in SPL splits between LM vs PO overlay in any recorded embryological parameters. In GPS splits between LM vs PO groups, the only significance was in high quality day 5 embryos (51%,32%) (p = 0.01) respectively. the combined system of GPS with PO vs SPL with LM showed significant increase in high quality day 5 embryos (75%,62%) (p = 0.003) respectively, and tend to be significant in High quality day 3 embryos (75%,67%) (p = 0.06) respectively. So, media drop geometry of 3D dishes combined with paraffin oil lead to higher pre implantation embryonic development with higher morphological quality.
Limitations, reasons for caution: Small sample size and the morphological assessment would be better if combined with morphokinetics or PGT-A results, especially aneuploidy, mosaicism and deletion vs addition in the chromosomes. The study needs to be expanded to include ongoing pregnancy rate.
Wider implications of the findings: If these findings backed with larger prospective randomized trials to reach statistically powered results, the impact of dry conditions on embryonic culture media could be overcame by using 3D dishes overlaid with heavy oil.
Trial registration number: Not applicable

P-263 Validation of a deep convolutional neural network trained to assess whether an embryo meets criteria for biopsy/cryopreservation using a test set of PGT embryos

I. Souter[1], S. Vagios[1], C. Sacha[1], M.K. Kanakasabapathy-[2], P. Thirumalaraju[2], C. Bormann[1], H. Shafiee[2]

[1]Massachusetts General Hospital-Harvard Medical School, Obstetrics/Gynecology-Reproductive Endocrinology and Infertility, Boston-MA, U.S.A. ;
[2]Brigham & Women's Hospital-Harvard Medical School, Medicine/Division of Engineering in Medicine, Boston, U.S.A.

Study question: Can a deep convolutional neural network (CNN) decide whether a Day-5 (D5) embryo, previously assisted hatched (AH) for preimplantation genetic testing (PGT), meets biopsy/cryopreservation criteria?
Summary answer: The CNN exhibited an outstanding performance in identifying, among AH embryos, D5 blastocysts that met developmental criteria for biopsy and cryopreservation.
What is known already: Embryologists make procedural and disposition decisions based on embryo morphology. There is a high degree of variability in scoring embryos, likely due to the subjective nature of morphology grading. This leads to less precise decisions for identifying embryos that meet biopsy or freezing criteria. This issue can be compounded when artificially hatching an embryo as this procedure allows blastocysts to escape from the zona at an earlier stage of development. A deep CNN has been developed using untested embryos to make biopsy and cryopreservation decisions[1]. Could this CNN be used to accurately assess embryos that have undergone AH for PGT?
Study design, size, duration: Retrospective cohort study of 1944 embryos derived from 224 PGT cycles that took place at an academic fertility center between 8/2014 and 12/2019.

Participants/materials, setting, methods: We evaluated the ability of a CNN-based artificial intelligence platform, trained using untested embryos, to identify D5 embryos for biopsy and cryopreservation and compared it with highly-trained embryologists. All embryos were laser-AH on D3 to help facilitate trophectoderm biopsy at the blastocyst stage. The developmental criteria for D5 biopsy and cryopreservation are the same in our center: ≥ grade 3 embryos and grade C or better for inner cell mass and trophectoderm (Gardner grading system).
Main results and the role of chance: Deep CNN correctly identified which D5 embryos met criteria for biopsy and cryopreservation with sensitivity: 93.7% (95%CI: 91.6-95.3%), and specificity: 96.3% (95%CI: 95.1-97.3%), (n=1944). The positive and negative predictive values of the CNN-based artificial intelligence platform were 93.4% (95%CI: 91.3-95.1%) and 96.5% (95%CI: 95.2-97.4%), respectively (n=1944).
Our system displayed an accuracy of 95.4% (95%CI: 94.3-96.5%) (n=1944).
Limitations, reasons for caution: Images utilized were obtained using a single imaging platform (Embryoscope™) at one timepoint and were annotated using criteria from a single IVF program. Prospective trials should confirm our findings prior to wider application of this system in clinical practice.
Wider implications of the findings: Our results suggest that in embryology, CNNs can be used to automate decision-making related to classification and disposition of AH embryos with a high degree of accuracy. Future studies will utilize expanded datasets, additional time-points and clinically relevant patient/cycle variables to enhance the power and accuracy of testing algorithms.
Trial registration number: NOT APPLICABLE

P-264 Using Time-lapse imaging (TLI) to assess blastocyst collapse dynamics and Trophectoderm (TE) quality as a marker of implantation potential

R. Alhamdan[1], L. Zujovic[2], J. Hernandez Medrano[3]

[1]School Of Human Development, Obs & Gyne, Nottingham, United Kingdom ; [2]Nurture Fertility, Director of embryology, Nottingham, United Kingdom ; [3]University of Nottingham, Child health and obstetric and gynaecology, Nottingham, United Kingdom

Study question: Does the frequency and type of blastocyst collapsing impact implantation and wither blastocyst TE quality and embryo developmental kinetics influence the type of blastocyst collapsing observed
Summary answer: Frequency and type of blastocyst collapsing did not influence implantation potential. However, those blastocysts exhibit higher quality TE and a shorter time to form.
What is known already: Few studies have examined the phenomenon of blastocyst collapsing in mammals and their results appears to be contradictory. A study in mice reported that collapsing does not affect implantation when it is not extensive (≤ 20%). While another study in human, suggests that collapsing embryos have lower implantation potential. This reduction in implantation potential was present irrespective of whether the extent of collapsing pattern is week (≤50% separation of the TE) or strong (≥50%separation of the TE). Therefore a more comprehensive understanding of the type and frequency of blastocyst collapsing and its connection to implantation potential is required
Study design, size, duration: A retrospective analysis including a total of 500 embryos after IVF/ICSI and fresh blastocyst transfer between 2017/2018, in Nurture Fertility, The Fertility Partnership group, Nottingham, UK.
Participants/materials, setting, methods: Blastocyst collapsing dynamics were collected from the TLI (Embryoscope, Vitrolife). Exact traceability of transferred embryos was included in the analysis. The association between blastocyst collapsing dynamics and frequency (no collapse, ≥50% or <50% separation of the surface of the TE from the ZP), zona pellucida thickness (µm), blastocyst expansion (µm^2), and KID score were assessed. Embryo developmental kinetics and TE quality were also compared. Potential confounding factors, e.g: maternal age and stimulation protocol were considered
Main results and the role of chance: There was no significant difference in implantation potential based on the frequency or type of blastocyst collapse dynamics (no collapse, ≥50% or <50% separation of the surface of the TE from the ZP). However, collapsing blastocysts significantly correlated with thinner ZP (p =0.005). Blastocysts exhibiting ≥50% separation of the blastocoel cavity strongly correlated with the highest TE quality (graded as A in accordance with the Gardner's classification system). Timing to morula (-2.4 hr), blastulation (-1.85hr) and blastocysts expansion (-1.94hr) were significantly (p< 0.001) shorter in collapsing embryos. Irrespective to blastocysts collapse dynamic and frequency, embryos with TE graded A displayed an increased chance of a positive KID score (p< 0.004, OR and 95% CI (A vs. B 0.1651 (0.0518, 0.5266), A vs C 0.2122 (0.0652, 0.6908), A vs D 0.0611 (0.0045, .0.8311)). We observed no significant effect from potential confounding factors such as patient age or stimulation protocol
Limitations, reasons for caution: The retrospective design of the study limits its value. Another limitation is presented by the fact that one embryologist measured the blastocysts collapsing frequency and dynamics and therefore, no inter-operator quality assurance.
Wider implications of the findings: The study of blastocyst morphological dynamics may help to improve the selection criteria of blastocyst with higher potential to implant especially for those patients with poor prognosis.
Trial registration number: not applicable

P-265 For blastocyst frozen embryo transfer: prolonged post-thaw culture may improve transfer outcomes

S.K. Nguyen[1], K.C. Do[1], T.T.C. Bach[1], A.T. Vu[1], V.T. Phung[1], T.L. Dinh[1]

[1]Buu Dien Hospital, ART center, Hanoi, Vietnam

Study question: In comparison with two hour post-thaw culture, are the blastocyst transfer outcomes of prolonged culture (16 ± 1 hour) better or not?
Summary answer: Prolonged post-thaw culture resulted in better blastocyst transfer outcomes: significantly higher implantation rate and significantly increased clinical pregnancy rate.
What is known already: Frozen blastocysts have been commonly transferred two to four hours after thawing. However, another school of thought has advised that prolonged post-thaw culture of blastocysts for more than 20 hours could assist in monitoring the post-thaw development of blastocysts, leading to better embryo selection for transfer; thus, better outcomes ultimately. In addition, embryos that underwent two freeze–thaw cycles may experience more stress than embryos that underwent one cycle. Here, we examine the correlation between post-thaw culture duration of blastocysts and the transfer outcomes. We also analyse attentively this correlation of embryos that have undergone two frozen-thaw cycles.
Study design, size, duration: A retrospective study: data transfer cycles from 01/2019-01/2020 were analyzed. Transfers of one or two blastocysts were included (good and fair grade only; poor quality blastocyst transfers were excluded). Patients were divided into two groups: group L (n=112) comprises patients who had their frozen blastocysts thawed in the previous afternoon then transferred the next morning (16 ± 1 hour culture). Group S (n=100) includes cases of frozen blastocyst transfer two hour after thawing.
Participants/materials, setting, methods: The majority of cases in each group had their blastocysts vitrified on day 5 of development (one freeze-thaw cycle). However, each group has a subgroup of embryos that had been vitrified on day 2, thawed, let grow until day 5, underwent one more freeze-thaw cycle (two freeze-thaw cycles) (named L-twice: n=31 and S-twice: n=26) . No PGT involved; donations excluded. BetaHCG positive, implantation, clinical pregnancy were registered. t-test and Chi-square test were applied.
Main results and the role of chance: The average maternal ages of group L and group S were comparable (29.32 ± 4.26 and 29.98 ± 4.16 years, respectively, p>0.05). The average numbers of transferred embryos per cycle of group L and S were equal (1.32 ± 0.47 and 1.33 ±0.47, p>0.05). Group L (prolonged culture) showed significantly better outcomes than group S (short culture): positive BetaHCG rate was 73.21% vs 58.00% (p<0.05), CPR was 67.86% vs. 53.00%, and IR was 60.81% vs. 46.62% (p<0.05), respectively. Multiple pregnancy rate was comparable between two groups (13.92% for L group and 14.81% for S group), possibly due to similar average numbers of transferred embryos between two groups. Notably, for blastocysts which had undergone two freeze-thaw cycles, the correlation remains the same: prolong culture had better outcome. For L-twice, positive Beta-hCG rate, CPR and IR was 64.52%, 61.29% and 54.35%; while for S-twice, these rates were 57.69%, 57.69% and 52.63%, respectively. These data suggest that prolong culture may improve transfer outcomes of frozen blastocyst transfer cycles.

Limitations, reasons for caution: This is a retrospective study. Further prospective, randomized clinical trial is required. The sizes of subgroup S-twice and L-twice are small, extend analysis is required to collect larger sample size.
Wider implications of the findings: Previous reports on the impact of post-thaw culturing duration on transfer outcomes have been controversial. Our findings suggest that longer culture may assist blastocysts to "recover" from freeze-thaw cycles. Further analysis of the impact of prolonged culture on the epigenetics of the embryos may be valuable.
Trial registration number: not applicable

P-266 Selecting spermatozoa with the highest chromatin integrity

J. Stewart[1], A. Parrella[1], D. Tavares[1], M.S. Wang[1], M. Haddad[1], Z. Rosenwaks[1], G.D. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: What is the impact of selecting spermatozoa with the highest chromatin integrity on ICSI outcomes?
Summary answer: We selected spermatozoa with the highest progressive motility and chromatin integrity by microfluidic sperm selection (MFSS) and achieved superior implantation and delivery rates.
What is known already: Sperm preparation methods aim at providing specimens for insemination with the highest progressive motility independent of phenotypic and genomic integrity. It has recently been recognized that a microfluidics device yielded spermatozoa with the highest progressive motility as well as superior chromatin integrity. Here we compared two sperm selection methods: density gradient centrifugation (DGC) and MFSS.
Study design, size, duration: From October 2016 to January 2020, ejaculates that were processed by DGC and MFSS for ICSI treatment from 8 consenting men were screening for DNA fragmentation by TUNEL. In addition, ejaculates from 22 men were processed solely by MFSS for ICSI treatment. Semen parameters, chromatin integrity, embryo implantation, and pregnancy characteristics were compared.
Participants/materials, setting, methods: Fresh ejaculated specimens from consenting men were collected for standard semen analysis in accordance with WHO 2010 criteria. DGC and MFSS were used to isolate motile spermatozoa based on cell motility and fluid dynamics. Sperm chromatin fragmentation (SCF) was assessed by terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) on at least 500 spermatozoa under a fluorescent microscope utilizing a threshold of ≥15%. ICSI was performed in the standard fashion.
Main results and the role of chance: A total of 20 men (43±6 years) had the following average semen parameters: concentration of 18±15 x 106/mL, 30±18% motility, and 2.4±1% morphology. After DGC and MFSS, the sperm concentration was 2.2±1 and 1.5±12.6 x106/mL, with 49±32% and 97.4±5% motility, respectively (P<0.0001).

The morphology of the raw sperm sample improved from 2.3±1% to 4.0±1% after MFSS, while it remained at 2.6±1% after DGC.

In 8 men (43±6 years), the SCF in their raw sample was 23%, falling to 18% after DCG selection and to 1.2% after MFSS (P < 0.0001). They underwent 20 ICSI cycles with their female partners, (37±3 years) with DGS sperm selection, achieving a 58% fertilization rate (80/138). The implantation rate was 5% (2/41) with an 11% clinical pregnancy rate (CPR) (2/18) and one pregnancy loss. Subsequently, ICSI with MFSS achieved a fertilization rate of 65%, a 29% (5/17; P<0.01) implantation rate, and a 63% (5/8; P<0.001) CPR. An additional 22 men (43±7 years) underwent 28 ICSI cycles solely with MFSS due to poor reproductive history. A 76% fertilization rate (203/266) and 54% (31/57) good quality embryos were achieved. The implantation rate was 26% (15/57) with a 50% CPR (13/26).
Limitations, reasons for caution: This is a preliminary study on a small number of subjects. Although we controlled for a concurrent female factor, this cannot be excluded with certainty. As this is a new method, the health of the resulting offspring would need to be evaluated to confirm the safety of the technique.
Wider implications of the findings: According to our study, SCF appears to be linked to the kinetic characteristics of the sperm cell. This novel microfluidic device may help to identify spermatozoa with the highest functional and genomic integrity and ultimately be routinely used in ART treatments.
Trial registration number: not applicable

P-267 Duration of exposure to EmbryoGlue (EG) may significantly impact implantation and clinical pregnancy rates following Embryo Transfer (ET).

R. Ebrahimi Ghaei[1], C. Harrity[2], C. Riordan[2], C. Moran[2], D. Keane[2]

[1]University of Royal College of Surgeons in Ireland RCSI, Obstetrics & Gynaecology, Dublin, Ireland ;
[2]ReproMed Ireland, Reproductive Medicine, Dublin, Ireland

Study question: Does EG increase implantation and clinical pregnancy rates in fresh transfer Assisted Reproductive Technology (ART) cycles and is the duration of exposure significant?
Summary answer: Embryos exposed to EG >30mins have significantly lower Implantation Rates (IR) and Clinical Pregnancy Rates (CPR) than those exposed <30 mins or not at all.
What is known already: Various modifications have been made to culture media in the hope of increasing success rates, including the addition of Hyaluronan (HA). EG (Vitrolife, Goteburg) is one such medium. The 2014 Cochrane review (Bontekoe et al) concluded moderate quality evidence of benefit when using HA enriched media prior to ET.

Vitrolife, recommends equilibration of embryos in EG between 10 mins – 4 hrs prior to transfer. Studies including duration of exposure as a parameter have, to date, taken 10 mins as the cut off time. We could find no study which compared the effect of different durations of exposure to EG.
Study design, size, duration: A retrospective cohort study was designed to determine if duration of exposure to EG influenced outcomes. Cycles from 01 January 2015 – 31 December 2019 were analysed.

1859 cycles reached oocyte retrieval and were screened against the inclusion/exclusion criteria to identify relevant patients.

3 study groups were chosen

Control: Transfers without EG (138)
Group 1: Transfers with EG exposure <30mins prior to ET (170)
Group 2: Transfers with EG exposure for >30mins prior to ET (295)

Participants/materials, setting, methods: The study was performed in a single university-affiliated reproductive medicine centre. Inclusion criteria were IVF/ICSI cycles resulting in fresh blastocyst transfer.
Cycles with elective freeze, cleavage transfer, failed fertilisation, or no oocytes/embryos were excluded. From 1859 retrievals, 540 patients had 603 transfers of 809 blastocysts meeting the inclusion criteria during the study period.
Primary outcome was IR, secondary outcome was Pregnancy Rate (PR). Statistical analysis was performed using Chi-square for proportions and t-test for means.
Main results and the role of chance: Control group, no EG (n=138):

- Age: 37.0
- Anti-Müllerian hormone (AMH): 15.0 pmol/l
- Number of embryos 160
- Mean number blastocyst per ET: 1.16
- PR: 0.536
- IR: 0.269
- CPR: 0.312

Group 1, EG exposure <30mins (n=170):

- Age: 37.3
- AMH: 13.8 pmol/l
- Number of embryos 199
- Mean number blastocyst per ET: 1.16
- PR: 0.547
- IR: 0.367
- CPR: 0.429

Group 2, EG exposure >30mins (n=295):

- Age: 37.4
- AMH: 14.8 pmol/l

- Number of embryos 450
- Mean number blastocyst per ET: 1.51
- PR: 0.495
- IR: 0.156
- CPR: 0.237

There was no difference between age (p=0.2) or AMH (p=0.79) between groups. Significantly more embryos were transferred in group 2 (p<0.0001).

The difference in PR between all 3 groups was not significant (p=0.5), although this may be influenced by the number of embryos transferred. Both IR (p<0.0001) and CPR (p<0.0001) were significantly lower in the group with extended exposure to EG.

Unfortunately, this was a retrospective cohort study rather than a prospective randomised controlled trial. Therefore, the impact of bias cannot be excluded.

Limitations, reasons for caution: This is a retrospective study over 5 years, during which subtle changes may have occurred in laboratory practice and personnel. The potential impact of additional confounding factors cannot be accounted for without randomisation.

Embryo quality was not included as a parameter, but exclusion of cleavage-stage transfers should limit this impact.

Wider implications of the findings: Studies to date have shown either a potential benefit or no benefit with the use of EG. Our study supports this conclusion but also suggests that exposure to EG for >30mins may be detrimental.

Trial registration number: Not Applicable

P-268 Embryo glue transfer medium for women >= 35 years of age - outcome in fresh IVF/ICSI cycles

V. Tomic[1], M. Sommergruber[1]

[1]University hospital SALK Paracelsus Medical University, Gynaecology and Obstetrics, Salzburg, Austria

Study question: Add-on embryo glue in single embryo transfer in the women ≥ 35 years of age, does it make a difference?

Summary answer: Results showed beneficial effect of embryo glue medium in women ≥ 35 years of age and those with recurrent implantation failure.

What is known already: A Cochrane review of 6 RCTs by Bontekoe and al. found higher live birth rate using embryo glue (OR 1.41) (Bontekoe et al., 2014). However, the incidence of multiple pregnancies was also increased significantly (OR 1.86).

Afterwards, study by Signh et al.from 2017 and Fancovits et.al from 2015 did not found statistically significant difference in the clinical pregnancy rate with the use of embryo glue medium. However, the most of te studies are statistically powerless because of a small sample size and/or different criteria, and studies with a SET are currently lacking.

Study design, size, duration: A retrospective cohort study on totally 680 patients, divided into two groups undergoing IVF/ICSI, in the tertiary University center between 2013-2019.

Participants/materials, setting, methods: In total 295 patients in the study group, embryos were transferred into 50µL of Embryo-glue for 15 minutes prior to transfer and control group where embryo were transferred to conventional blastocyste culture medium. Statistical analysis was performed by SPSS ver. 22 for Windows.

Main results and the role of chance: Clinical pregnancy rate in the study group with the use of hyaluronan enriched medium (Embryo-glue) was significantly higher than the control group (36.5% vs 28.3%, p<0.05). When we analyzed subgroup of women with recurrent implantation failure, statistical difference was even more powerful with p<0.01. However, our results did not found difference in the number of retrieved eggs, days of stimulation, total dose of gonadotrophins, type of fertilization (IVF or ICSI), fertilization rate or miscarriage rate. Multiple pregnancy rate was also similar between two groups.

Limitations, reasons for caution: Limitations of the current study include retrospective design and as such bias can not be excluded. Also our study excluded women in favorable maternal age (younger then 35 years of age) so effect on embryo glue in this age group could not be commented.

Wider implications of the findings: Results of current study showed beneficial effect of Embryo-glue in selected group of patients, women in advanced maternal age and recurrent implantation failure but future RCT studies are necessary to evaluate impact of Embryo-glue on all patients.

Trial registration number: Not applicable

POSTER VIEWING SESSION

ENDOMETRIOSIS, ENDOMETRIUM AND AND FALOPIAN TUBE, AND BENIGN DISORDERS OF THE ENDOMETRIUM AND FALLOPIAN TUBE

P-269 Cumulative live birth rates after IVF-ICSI cycles in women with endometriosis-associated infertility: prolonged GnRH-agonist versus GnRH-antagonist protocols

H. Wei[1], Y. Chen[1], X. Li[1], Y. Lin[1], R. Li[1], C. Ma[1]

[1]Peking University Third Hospital, Center for Human Reproductive Medicine, Peking, China

Study question: Are cumulative live birth rates similar in prolonged GnRH-agonist and GnRH-antagonist protocols after IVF-ICSI cycles in women with endometriosis-associated infertility including all subsequent frozen–thaw cycles from the same oocyte retrieval?

Summary answer: No differences were found in cumulative live birth rates(-CLBRs) after one complete IVF-ET cycles between prolonged GnRH-agonist and GnRH-antagonist protocols in women with endometriosis-associated infertility.

What is known already: Endometriosis is known to have an impact on fertility. Women with endometriosis often require in vitro fertilization (IVF) to improve the chance of pregnancy. A reduced ovarian reserve was demonstrated in patients with endometriosis. Multiple studies of the prolonged GnRH-agonist and GnRH-antagonist protocols on pregnancy rate and live birth rate have yielded controversial findings. A 2006 systematic review of 27 RCTs showed that GnRH-antagonist protocol has a significantly lower clinical pregnancy rate and live birth rates than those in GnRH-agonist long protocol. However, a 2016 systematic review of 73 RCTs concluded that these two protocols have equivalent live birth rates.

Study design, size, duration: A retrospective case-control study comprised women with endometriosis who underwent IVF-ICSI cycles between January 2015 to December 2016, at the Reproductive Medical Center of Peking University Third Hospital. Propensity score matching (matching ratio 1:1, caliper width = 0.02) was used to create a comparable control group, including 303 women with prolonged GnRH-agonist protocol and 303 women with GnRH-antagonist protocol.

Participants/materials, setting, methods: A retrospective case-control study comprised women with endometriosis who underwent IVF-ICSI cycles between January 2015 to December 2016. Propensity score matching (matching ratio 1:1, caliper width = 0.02) was used to create a comparable control group, including 303 women with prolonged GnRH-agonist protocol and 303 women with GnRH-antagonist protocol.Cumulative live birth rates (CLBRs) upon the first complete IVF-ICSI cycles, including transfers of all resulting embryos was considered as a primary outcome measure.

Main results and the role of chance: Baseline characteristics including BMI, age, basal FSH, duration of infertility were comparable in the prolonged GnRH-agonist group and the GnRH-antagonist group. Patients in the prolonged GnRH-agonist group had a significantly higher gonadotropin consumption (3487.55 (1200-10425) vs. 2175.00 (600-5550)(IU), P<0.01) and a longer time of stimulation (13.00(8.00-24.00) vs. 10.00(4.00-19.00)(days), P<0.01) than that in the GnRH-antagonist group. There's no significantly difference between two groups of the estradiol levels on hCG trigger day (7087.00(525.00-29976.00) vs. 5995.00(676.00-26075) (pmol/mL), P=0.06). The number of oocytes retrieved per cycle and number of usable embryos achieved were comparable between two groups. The implantation rate in the GnRH-antagonist group after fresh ET was significantly lower (28.5% vs. 34.9%, p =0.047) compared with prolonged GnRH-agonist group. A GnRH-antagonist protocol appears to result in lower rates of clinical pregnancy and live birth after fresh ET (40.8% vs. 46.5%, p = 0.22; 33.2% vs. 39.1%, p = 0.19, respectively), but the difference of which did not reach

statistical significance.The cumulative clinical pregnancy rates and CLBRs were comparable for the prolonged GnRH-agonist group and the GnRH-antagonist group with 55.1% vs. 52.8%, (odds ratio(OR): 0.91; 95% CI: 0.66-1.25; P=0.57) and 45.5% vs. 43.6%, (OR: 0.92; 95% CI: 0.67-1.27; P=0.62), respectively.

Limitations, reasons for caution: One limitation of this study is its retrospective nature, however propensity score matching was selected to create control cohorts for a better matched analysis. The reproductive outcomes in different pathological types of endometriosis were not analyzed, such as peritoneal endometriosis, deep infiltrating endometriosis or endometrioma.

Wider implications of the findings: A GnRH-antagonist protocol appears to result in lower rates of implantation, clinical pregnancy and live birth after fresh ET, suggesting that a GnRH- antagonist protocol might negatively impact endometrial receptivity. However, we find similar CLBRs between the two groups in women with endometriosis-associated infertility.

Trial registration number: not applicable

P-270 Fibronectin (FN1) and Progranulin (GRN) expression in eutopic endometrium – potential biomarkers among different stages of endometriosis (EM)

I. Holzer[1], A. Machado Weber[1], A. Marshall[1], A. Freis[1], T. Strowitzki[1], A. Germeyer[1]

[1]University Hospital Heidelberg, Dept. of Gynaecological Endocrinology and Fertility Disorders, Heidelberg, Germany

Study question: Does the local endometrial gene and protein expression of FN1 and GRN vary among different degrees of EM?

Summary answer: Significant differences in gene and protein expression were identified not only between women with and without EM but also among different levels of the disease.

What is known already: Endometriosis is a common gynecological disease affecting 10 – 15 % of women of reproductive age. However, molecular mechanisms and pathogenesis are still not completely understood. Due to the absence of a reliable clinical biomarker, the only viable method for the often delayed definitive diagnosis is laparoscopic surgery. FN1 is a glycoprotein, which is involved in cell adhesion, migration and implantation. GRN, a protein with proliferative and invasive properties, seems to be involved in embryogenesis. Our objective was to investigate molecular mechanisms of these two genes and proteins among various stages of EM and analyze their potential as diagnostic markers.

Study design, size, duration: This study analyzed eutopic endometrial tissue of women suffering from different stages of EM (n = 58). Our aim was to investigate changes in endometrium of women with EM compared to healthy endometrium as well as among different levels of EM (minimal, mild, moderate) to detect potential new biomarkers for the disease.

Participants/materials, setting, methods: Endometrial biopsies were taken from women undergoing a laparoscopic surgery for benign reason. The expression on mRNA level of *FN1* and *GRN* was analyzed using real-time quantitative reverse transcription polymerase chain reaction (qRT-PCR). Protein expression of the proteins was determined using Enzyme-linked immunosorbent assay (ELISA) as well as the Avidin-Biotin method to stain cryosections for immunohistochemistry.

Main results and the role of chance: Significant differences in gene and protein expression of both examined genes were identified not only in eutopic endometrial tissue of women with EM compared to women without EM but also among different levels of the disease ($p < 0.05$). The strongest mRNA expression of both *FN1* and *GRN* was seen in women with minimal EM. However, protein expression of FN1 and GRN was significantly reduced in women with EM compared to women without EM. More precisely, the magnitude of the protein expression decreased with the severity of the disease ($p < 0.05$). While the protein expression of FN1 was mainly noticed in stromal and endothelial cells, GRN was mostly present in stromal and epithelial cells.

Limitations, reasons for caution: The main limitation of this study is its small sample size. A larger study population would be needed to validate the results.

Wider implications of the findings: These findings of different gene and protein expression between different levels of EM may support the idea of a distinct pathophysiology between mild and severe EM and suggest the potential use of FN1 and GRN as new clinical biomarkers.

Trial registration number: not applicable

P-271 Effects of chronic endometritis on fertility and pregnancy outcomes

A. Morimune[1], F. Kimura[1], A. Nakamura[1], J. Kitazawa[1], T. Hanada[1], K. Hirata[2], A. Takebayashi[3], A. Takashima[1], S. Kaku[1], S. Moritani[4], R. Kushima[4], T. Murakami[1]

[1]Shiga University of Medical Science, Department of Obstetrics and Gynecology, Shiga, Japan ;
[2]Goto Ladies Clinic, Division of Reproductive Medicine, Osaka, Japan ;
[3]National Hospital Organization Higashi-ohmi General Medical Center, Department of Obstetrics and Gynecology, Shiga, Japan ;
[4]Shiga University of Medical Science, Department of Clinical Laboratory Medicine and Division of Diagnostic Pathology, Shiga, Japan

Study question: Does chronic endometritis (CE) affect fertility and the course of pregnancy in patients without implantation failure, habitual abortion, and diseases suspected to cause implantation failure?

Summary answer: Patients with CE have lower pregnancy and live birth rates and higher miscarriage and preterm birth rates.

What is known already: Several reports have demonstrated that CE is associated with infertility and implantation failure. However, these clinical researches have mainly involved patients with recurrent implantation failure (RIF). The subsequent pregnancy rate after the diagnosis of RIF is considered to be low even without CE. Thus, RIF without CE cannot be used as the control group to examine the effects of CE on fertility and pregnancy outcomes. In the present study, patients with RIF, recurrent pregnancy loss (RPL), and diseases suspected to cause implantation failure were excluded, and the effects of CE on fertility and pregnancy outcomes were determined.

Study design, size, duration: This retrospective study reviewed a registration list of patients attending our hospital for infertility and histologically diagnosed with the presence or absence of CE from September 2013 to December 2017 to identify study patients. Patients were then followed up based on their medical charts for 1 year after the diagnosis of CE.

Participants/materials, setting, methods: Patients were treated with IVF for a year after the histological diagnosis of CE. Endometrium was collected 5–9 days after ovulation. The pregnancy and pregnancy outcome rates were analyzed. Those who received antibiotics for >7 days to treat CE, aged >40 years, or had RIF, RPL, and a suspected cause of implantation failure were excluded from the study.

Main results and the role of chance: A total of 40 non-CE and 44 CE patients were finally analyzed.

Percentages of pregnancies and live births were as follows: 95% vs. 72.7%, $P < 0.01$; 85% and 45.4%, $P < 0.0003$ in the non-CE and CE groups, respectively. Percentages of miscarriages in pregnancy were 12.8% vs. 40.0%, $P < 0.03$, whereas percentages of preterm births in ongoing pregnancy were 2.9% vs. 23.8%, $P < 0.03$ in the non-CE and CE groups, respectively.

In the logistic analysis, CE was a factor adversely affecting objective pregnancy variables associated with live births in all patients, miscarriage in pregnancy, and preterm birth in ongoing pregnancy.

Limitations, reasons for caution: This was a retrospective study; hence, inevitable limitations are observed. Patients who received antibiotic treatment for CE were excluded. Patients who are seeking antibiotic treatment might have a long history of infertility treatment and/or might have more refractory infertility. These patients were excluded only from CE.

Wider implications of the findings: Pregnancy and live birth rates within a year after the diagnosis of CE were lower in patients undergoing IVF not diagnosed with RIF, RPL, or a disease suspected to cause implantation failure. These findings suggest that patients undergoing IVF should be examined for CE.

Trial registration number: R2014-090

P-272 The pattern of vaginal/endometrial microbiome as a predictor for outcome of in vitro fertilization (IVF) in patients with or without repetitive implantation failure:a pilot study

A. Bernabeu[1], B. Lledo[2], M.C. Diaz[3], F. Lozano[2], A. Rodriguez-Arnedo[3], R. Morales[2], R. Bernabeu[1]

[1]Instituto Bernabeu, Reproductive Medicine, Alicante, Spain ;
[2]IB Biotech, Molecular Laboratory, Alicante, Spain ;
[3]Instituto Bernabeu, IVF Lab, Alicante, Spain

Study question: Is the pattern of certain vaginal/endometrial bacteria associated with failure or success to achieve pregnancy after IVF in patients with or without repetitive implantation failure?
Summary answer: The vaginal and endometrial microbiome pattern correlate with the pregnancy rate, being different between patients who suffer or not repetitive implantation failures.
What is known already: Thanks to an improved technology in the last decade as for instance, mass sequencing, a progress in the study of microbial communities was made. Successful embryo transfer depends on many factors, including the presence of microbial colonization of the upper genital tract. The vaginal microbiome plays an important role in the maintenance of the health of the woman. Currently more and more patients are using assisted reproduction techniques, which should be offered a multidisciplinary approach for diagnosis. The aim of this study is to investigate if the vaginal and endometrial microbiome in couples undergo ART could affect the pregnancy rate.
Study design, size, duration: Prospective analysis including 48 patients (18-50 years) recruited from May 2017-May 2019 (264 samples). Of these, 23 patients experienced unexplained repetitive implantation failure (RIF). All patients performed PGT-A and single embryo cryotransfer. Vaginal samples were collected on the immediate pre-transfer cycle (artificial endometrial preparation) (visit 1), on the day of the transfer (visit 2) and on the day of the pregnancy test (visit 3). Endometrial samples were taken on the immediate pre-transfer cycle (visit 1).
Participants/materials, setting, methods: DNA extraction was performed using the PureLink Microbiome DNA Purification kit. Sequencing the rRNA16S V3V4 region analysis, it was carried out according to Illumina Metagenomics protocol using the NexteraXT library on the Miseq instrument. The bioinformatic tools QIIME2, MicrobiomeAnalyst and Phyloseq have been used to determine the composition of the microbiome.
Main results and the role of chance: Regarding to the microbiome dynamics during the cycle, we observed a decrease in α-diversity from the follicular to luteal phase in the study group, in contrast to a stability of the pattern in the RIF group. As for endometrium and vagina microbiome, there were α-diversity differences (Shannon p=0.0139, Simpson p=0.046), being higher for endometrium; and also β-diversity was different (p=0.001). A greater relative abundance was observed in vagina of Lactobacillus spp., (83.17% vs 84.82%,p<0.0001), Streptococcus spp. (1.59% vs 7.74%,p=0.014) and Ureaplasma spp. (0% vs. 0.89%,p=0.006). Besides, it was lower for Delftia spp. (0.95% vs 0%,p=0.0003), Anaerobacillus spp. (1.59% vs 0%,p=0.0004), and Ralstonia spp. (3.17% vs 0%,p=0.0006). Concerning RIF, we observed differences in α-diversity for the study and RIF group (Shannon p =0.0206, Simpson p=0.0206). Moreover, we were able to observe significant differences in β-diversity between both groups. Also, we found differences for Ralstonia spp., (0.09% RIF and 0.73% control, p=0.0012). Finally, as for pregnancy rate, we found a difference between patients that did not achieve[JCCF1] or achieved a pregnancy for Lactobacillus spp. (91% vs 99%,p=0.0445 visit 1, 94.63% vs. 97.69%,p=0.0268 visit 2, 97.73% vs 99.74%,p=0.0492 visit 3) and L.reuteri (0.39% vs 0.17%,p=0.0397 visit 1, 0.15% vs 0.30%, p=0.0491 visit 3).
Limitations, reasons for caution: Future larger sample size studies are warranted to corroborate our initial results.
Wider implications of the findings: The lack of dynamism in the microbioma pattern of RIF patients might reflect a impaired adaptation to endometrial changes. A greater relative abundance of Lactobacillus spp. and L.reuteri is correlated with higher chances of pregnancy.
Trial registration number: NCT03153787

P-273 Is the fertility enhancing effect of hysterosalpingography with oil-based contrast temporary or long-lasting?

N. Van Welie[1], K. Rosielle[1], K. Dreyer[1], J. Van Rijswijk[1], C.B. Lambalk[1], N. Van Geloven[2], V. Mijatovic[1], B.W. Mol[3], R. Van Eekelen[4]

[1]Amsterdam UMC- Vrije Universiteit Amsterdam, Reproductive Medicine, Amsterdam, The Netherlands ;
[2]Leiden University Medical Center, Biomedical Data Sciences, Leiden, The Netherlands ;
[3]Monash University, Obstetrics and Gynaecology, Melbourne, Australia ;
[4]Amsterdam UMC- University of Amsterdam, Reproductive Medicine, Amsterdam, The Netherlands

Study question: Does the fertility enhancing effect of tubal flushing during hysterosalpingography (HSG) with oil-based contrast change over time?
Summary answer: The hazard ratio for ongoing pregnancy of oil-versus water-based contrast was 1.71 immediately after HSG, then decreased and plateaued towards 1 after approximately two years.
What is known already: HSG with oil-based contrast results in a 10% higher absolute ongoing pregnancy rate after six months when compared to an HSG with water-based contrast. In the long-term follow up study, this effect remained present 3-5 years after the HSG, albeit that the difference was reduced to 5% after additional IVF in both groups. The fertility enhancing mechanism of oil-based contrast remains unclear. Both immunological effects on the endometrium and peritoneum or a possible mechanical effect by dislodging debris or mucus plugs from the fallopian tubes have been proposed, which suggests a temporary or a lasting effect, respectively.
Study design, size, duration: We performed a secondary analysis of the H2Oil (long term follow-up) study, a multicenter randomized controlled trial among 1,119 women evaluating the effectiveness of oil-based contrast versus water-based contrast during HSG. Here, we investigate whether the fertility enhancing effect of oil- versus water-based contrast on ongoing pregnancy changed over time or remained stable.
Participants/materials, setting, methods: Women undergoing fertility work-up were included in the H2Oil study. We used a Cox proportional hazards model for time to pregnancy for a maximum of three years of follow-up, then evaluated whether the assumption of 'no change of effect over time' holds using plots and tests on the scaled Schoenfeld residuals and by assessing interactions between treatment and time. We repeated the analysis in a subgroup of women who experienced pain during HSG (Visual-Analogue-Scale-score ≥6).
Main results and the role of chance: Data on 1107 couples were available. Of these, 550 couples had oil-based contrast and 557 had water-based contrast at HSG. Ongoing pregnancy rates after 3 years were 77% and 71%, respectively. Median follow up was 9-10 months (5th-95th percentile: <1-36). The hazard ratio for ongoing pregnancy of oil versus water over three years of follow up was 1.26 (95%CI: 1.10-1.44). On the scaled Schoenfeld residual plots, we found a decrease of the hazard ratio that was linear with log-transformed time. After including an interaction with log-transformed time, we found that the hazard ratio immediately after HSG was 1.71 (95%CI: 1.27-2.31) and reduced to 1.06 (95%CI: 0.86-1.30) at approximately two years of follow up. There was no evidence for a change in hazard ratio over time in a subgroup of women who experienced pain during HSG.
Limitations, reasons for caution: This analysis was performed using data from women with unexplained or mild male infertility. The results should not be generalized to women with ovulatory dysfunction, women older than 39 years or women at high risk for tubal pathology based on their medical history.
Wider implications of the findings: The effect of oil-versus water-based contrast decreased in the first year after HSG to no effect after approximately two years. In women who experienced pain during HSG, the effect might last longer. Both results seem to favour the hypothesis that oil-based contrast may dislodge debris or mucus from fallopian tubes.

P-274 Functional analysis of the histidine N-methyltransferase SETD3 in endometriosis

M. Götte[1], M. Poloczek[1]

[1]Muenster University Hospital, Gynecology and Obstetrics, Münster/Westf., Germany

Study question: Does the novel actin methyltransferase SETD3 have an impact on invasive growth of endometriotic cells?
Summary answer: SETD3 affects invasive growth, cell motility and contractility of endometriotic cells in vitro.

What is known already: Endometriosis is a common, benign and chronic disease in women of reproductive age that is characterized by invasive growth of endometrial tissue outside the uterus. The novel actin-specific histidine N-methyltransferaseprevents primary dystocia and modulates actin function as a prerequisite for cell motlilty, contractility and invasive growth.
Study design, size, duration: This is an in vitro laboratory study on the immortalized endometriotic cell line 12Z and primary endometriotic stroma cells. Cells were subjected to siRNA-mediated knockdown of SETD3 or a negative control siRNA, and the impact on cell motility, contractility, invasiveness, cytoskeletal structure and gene expression were studied.
Participants/materials, setting, methods: Primary endometrial stroma cells and 12Z human immortalized endometriotic cells were used for in vitro experiments. SETD3 was knocked down by siRNA transfection with two different SETD3 siRNAs. Gene expression analysis was performed by real-time qPCR. Changes at the protein level were analysed by Western blotting, ELISA and immunofluorescence. Cell migration was investigated by scratch wound healing assay. To assess cytoskeletal functions, a collagen contraction assay was performed. Invasive growth was assessed by Matrigel assay.
Main results and the role of chance: Knockdown of SETD3 was confirmed by qPCR and Western blotting. Only moderate changes in cytoskeletal element gene expression were observed after SETD3 knockdown, whereas VEGF expression was downregulated by >40% in both experimental systems ($p<0.05$, $n>3$). At the functional level, SETD3 depletion resulted in a delay in cell motility in scratch wound assays ($p<0.05$, $n>5$), in a reduction in invasive growth of 12Z cells by 50% ($p<0.05$, $n>5$) and in a reduced capability to contract collagen gels ($p<0.05$, $n>5$). Immunofluorescence microscopy for actin revealed an altered cytoskeletal structure and cell morphology.
Limitations, reasons for caution: This is a transfection-based in vitro strudy, which needs to be confirmed in more complex experimental models.
Wider implications of the findings: The presented data suggest that methylation of beta-actin, as mediated by SETD3, contributes to the remodelling of the cytoskeleton that plays a key role in cell migration and invasion. A dysregulation of SETD3 could play a role in the process of invasive growth in endometriosis.
Trial registration number: MedK

P-275 Generalized estimating equation analysis for assessing the association between the quality of life and pregnancy outcomes of IVF treatment in patients with endometriosis-related infertility

M.H. Wu[1], H.T. Ou[2], C.W. Lin[1]

[1]College of Medicine and Hospital- National Cheng Kung University, Obstetrics and Gynecology, Tainan City, Taiwan R.O.C. ;
[2]College of Medicine and Hospital- National Cheng Kung University, Pharmacy, Tainan City, Taiwan R.O.C.

Study question: Are the quality of life (QoL) of endometriosis-related infertility women measured during IVF treatment related to the pregnancy outcomes following the treatment?
Summary answer: Improving the QoL during IVF treatment in women with endometriosis-related infertility may increase subsequent pregnancy rates.
What is known already: Generalized estimating equation (GEE) analysis that accounts for the dependence of observations from same person can minimize the potential biases commonly seen in longitudinal cohort studies, especially the studies of the IVF data that comprised a series of repeatedly measured pregnancy outcomes and associated patient characteristics from multiple embryo transfer cycles in same study subject. From emotional aspect, psychological counseling for patients undergoing IVF treatment might improve their QoL and enhance subsequent IVF pregnancy rates. In addition, oxytocin antagonist treatments given before embryo transfer in the women with endometriosis may maximize the chance of success of pregnancy outcomes.
Study design, size, duration: This longitudinal cohort study included 686 women with 1,205 embryo transfers during 2012-2017. The QoL of study women during IVF treatment was measured by FertiQoL comprising a Core module (mind/body, emotional, relational, and social domains) and a Treatment module (treatment environment and tolerability domains). The FertiQol scores were computed and scored in the range of 0-100, with higher scores indicating better QoL. The pregnancy outcomes of interest were chemical and ongoing pregnancies, and live birth.
Participants/materials, setting, methods: The QoL of study participants was assessed at the date before embryo transfer. Atosiban (a mixed oxytocin/vasopressin V1A receptor antagonist) can be administered intravenously during the embryo transfer. The GEE analysis was performed to assess the association between QoL during IVF treatment and subsequent pregnancy outcomes, with adjustment for time-varying factors (e.g., age) across multiple embryo transfers for an individual person. The analysis was further stratified by the number of embryo transfer cycle.
Main results and the role of chance: Compared to a control group of non-endometriosis women, endometriosis patients had significantly lower QoL, as indicated by the mind/body and treatment environment domain scores, total treatment scores, and total FertiQoL scores. FertiQoL scores were significantly associated with the success of pregnancy outcomes among non-endometriosis women; with a one unit increase in the emotional domain score, the probabilities of ongoing pregnancy and live birth significantly increased by 2.4% and 2.6%, respectively ($p < 0.05$). In overall study subjects (without stratified by the number of embryo transfer cycle), the use of atosiban was not significantly associated with positive pregnancy outcomes, while among those requiring more than two cycles, significantly increased pregnancy rates with atosiban use were found. These results regarding the association between atosiban use and IVF pregnancy outcomes are consistent in endometriosis and non-endometriosis groups.
Limitations, reasons for caution: This is a study enrolled the patients from a single medical center. Only the QoL from the date before ET was measured, while time-varying QoL data from different points of time during IVF treatment were not collected. The factors associated with the QoL of study patients were not further explored.
Wider implications of the findings: FeriQoL is useful in clinical practice to understand the QoL of women undergoing IVF treatment. Further developing clinical strategies to improve these patients' QoL would be of importance to enhance pregnancy outcomes. Oxytocin antagonists may enhance IVF pregnancy rates, especially among the patients requiring more than two embryo transfer cycles.
Trial registration number: nil

P-276 Resveratrol supplementation enhances decidualization of human endometrial stromal cells with concomitant decrease in cell proliferation

A.C. Mestre Citrinovitz[1], T. Strowitzki[1], A. Germeyer[1]

[1]Heidelberg University - Women's Hospital, Department of Gynecologic Endocrinology and Fertility Disorders, Heidelberg, Germany

Study question: Is resveratrol supplementation beneficial for human endometrial stromal cell *in vitro* decidualization?
Summary answer: Resveratrol supplementation enhances, in a dose-dependent manner, human endometrial stromal cell *in vitro* decidualization.
What is known already: Decidualization is the differentiation of endometrial stromal cells, a change needed to regulate trophoblast invasion and to support pregnancy. Decidualization follows endometrial stromal cell proliferation and it has been described that cell cycle arrest contributes to a proper decidualization. Interestingly, resveratrol, a natural compound derived from grapes with antioxidant properties, has been widely studied in relation to endometrial health. However, little is known about the effect of resveratrol supplementation during decidualization.
Study design, size, duration: This study was performed using primary human endometrial stromal cells (HESC). Endometrial biopsies from mid-late proliferative-phase were obtained from healthy women (34.4 +/- 1.1 years old) after written informed-consent that was obtained (approved protocol S-239/2005). HESC were decidualized *in vitro* with a decidualization cocktail containing medroxyprogesterone acetate, estradiol and 8-Bromo-cyclic adenosine monophosphate. Pre-decidualized cells (three days) were further treated with the decidualization cocktail supplemented with different doses of resveratrol (0 to 50 µM).
Participants/materials, setting, methods: Decidualization was evaluated by measuring prolactin (PRL) protein levels in cell culture supernatant and by measuring PRL and Insulin-like growth factor binding protein 1 (IGFBP1) mRNA levels by real time polymerase chain reaction (RT-PCR). Changes in the expression of genes related to cell cycle progression (KI67, CCNA1, CCNB1, CCND1, CDC2, CDK2, CDK4, p53, p21) and cell proliferation were evaluated for the

25 μM dose of resveratrol by RT-PCR and by crystal violet proliferation assay respectively.

Main results and the role of chance: Resveratrol supplementation increased, in a dose-dependent manner, the expression levels of PRL and IGFBP1, indicating an enhanced *in vitro* decidualization (PRL protein levels, mU/l: 0μM 193±35, 6.25μM 226±38, 12.5μM 270±49**, 25μM 296±61***, 50μM 274±49***; PRL mRNA levels, fold change related to 0μM of resveratrol: 0μM 1.0±0.0, 6.25μM 1.4±0.2*, 12.5μM 1.9±0.2***, 25μM 1.8±0.2***, 50μM 1.9±0.2***; IGFBP1 mRNA levels, fold change related to 0μM of resveratrol: 0μM 1.0±0.0, 6.25μM 1.4±0.2, 12.5μM 2.3±0.4, 25μM 2.4±0.6**, 50μM 1.3±0.2**). Enhanced decidualization was accompanied by a decrease in cell proliferation (25μM 4±1%* of reduced proliferation compared to 0μM) and by changes in the mRNA expression levels of key cell cycle regulators (mRNA levels; fold change related to 0μM of resveratrol: CCNB1 0.65±0.07***, CCND1 0.44±0.09**, CDK2 0.72±0.07**, CDK4 0.71±0.03***, p53 0.53±0.06***, p21 0.61±0.07***). Resveratrol supplementation seems to enhance decidualization by reinforcing the effect of the decidualization cocktail, in particular by reinforcing the inhibition in cell proliferation. Statistical differences *p<0.05 **p<0.01; ***p<0.001 compared to 0μM of resveratrol.

Limitations, reasons for caution: This study was performed *in vitro* using primary HESC. Further studies are necessary to confirm the effect of resveratrol during *in vivo* decidualization and to define the optimal dose and administration schedule for a beneficial outcome. Special caution needs to be taken in relation to resveratrol action over cell proliferation

Wider implications of the findings: Resveratrol seems to be an effective supplementation to reinforce hormone action during HESC decidualization. We believe that further insights into resveratrol action and its interaction with estradiol and progesterone signaling pathways could facilitate the identification of new therapeutic strategies for the improvement of women´s health.

Trial registration number: N/A

P-277 The Effect of Antibiotic Treatment on the Secretion of Proinflammatory Cytokines in Endometrial Stromal Cells in Patients with Chronic Endometritis

A. Nakamura[1], F. Kimura[1], J. Kitazawa[1], A. Morimune[1], A. Takashima[1], S. Kaku[1], T. Murakami[1]

[1]Gynecology, Obstetrics and Gynecology, Otsu, Japan

Study question: Can administration of oral antibiotics in patients with chronic endometritis (CE) reverse the increased inflammation observed in the endometrium?

Summary answer: The secretion of proinflammatory cytokines was reduced in the endometrial stromal cells of patients in whom CE was cured histologically but not in non-cured patients.

What is known already: CE is a mild, persistent inflammation of the endometrium, which is often asymptomatic but can cause infertility. CE is identified by the presence of plasma cells in the stromal layer of the endometrium. Plasma cell expression indicates the presence of a continuous immune response to any constituent of the endometrium. An increased pregnancy rate in CE patients treated with antibiotics has been reported. We have previously reported that CE patients had higher levels of inflammatory cytokines in their endometrial stromal cells. However, the effects on endometrial characteristics of curing CE with antibiotics are not yet known.

Study design, size, duration: Primary culture of endometrial stromal cells was performed. Thirty endometrial biopsied samples were obtained from 15 women from August 2018 to March 2019.

Participants/materials, setting, methods: The subjects were diagnosed with CE during in vitro fertilization (IVF) treatment. From each patient, endometrial biopsies were collected during the mid-secretory phase, both before and after antibiotic administration. Patients with low serum progesterone levels on the day of examination were excluded. The endometrial stromal cells from these samples were used for primary cell culture. To evaluate the status of inflammation, ELISA of the culture media was performed.

Main results and the role of chance: The numbers of patients with cured CE and persistent CE were 8 and 7, respectively.

For ELISA, endometrial stromal cells were cultured for 14 days and the supernatant was obtained. In the cured CE patients, secreted levels of TNF-α (p=0.0094), IL-1β (p=0.031), and IFN-γ (p=0.0089) were significantly decreased by the antibiotic treatment, whereas the concentration of IL-6 was not significantly altered. In the samples obtained after antibiotic treatment, secreted levels of TNF-α (p=0.024), IL-1β (p=0.019), and IFN-γ (p=0.0071) were significantly lower in the patients in whom CE was cured than in the persistent CE patients.

Limitations, reasons for caution: The number of samples was small. However, there were still significant differences in TNF-α, IL-1β, and IFN-γ levels. We speculate that with an increased number of cases, a significant difference in IL-6 may be observed.

Wider implications of the findings: When CE was cured, secretion of proinflammatory cytokines from endometrial stromal cells was normalized to the level of healthy patients. Thus, CE was related to the uterine microbiome because antibiotic treatment was effective in suppressing proinflammatory cytokine secretion from endometrial stromal cells.

Trial registration number: not applicable

P-278 Vitamin D as an effective treatment to reduce cell proliferation and extracellular matrix formation in human uterine leiomyomas regardless MED12 mutation status

A. Corachán[1], M.G. Trejo[1], M.C. Carbajo-García[1,2], A. Faus[1], J. Escrig[3], J. Monleón[3], A. Pellicer[1,4], I. Cervelló[1], H. Ferrero[1]

[1]IVI Foundation- IIS La Fe, Innovation, Valencia, Spain ;
[2]Universidad de Valencia, Pediatrics- Obstetrics and Gynecology, Valencia, Spain ;
[3]Hospital Universitario y Politécnico La Fe, Obstetrics and Gynaecology Service, Valencia, Spain ;
[4]IVIRMA Rome, Department of Reproductive Endocrinology and Infertility, Rome, Italy

Study question: Could Vitamin D be an effective treatment to reduce the size of different molecular subtypes of human uterine leiomyoma?

Summary answer: Vitamin D inhibited cell proliferation, Wnt/β-catenin and TGFβ pathways in human uterine leiomyoma primary cells from two molecular subtypes: *MED12*-mutated and wild type.

What is known already: Uterine leiomyomas, the most common benign tumor of reproductive tract, are clinically and scientifically treated as a single entity despite the existence of four molecular subtypes, among which *MED12* mutation is the most frequent genetic alteration. It has been suggested that Wnt/β-catenin and TGFβ pathways contribute to *MED12*-mutated leiomyoma growth via cell proliferation and extracellular matrix (ECM) formation stimulation. In pursuit of new treatments, several studies propose Vitamin D (VitD) as a safe therapeutic option to reduce leiomyomas. However, these studies do not examine the existing genetic heterogeneity, a crucial fact to consider in the development of an efficient treatment.

Study design, size, duration: Prospective study in which human uterine leiomyomas (UL) and matched myometrium (M) tissues (n=37) were analyzed to identify *MED12* mutations. The status of Wnt/β-catenin and TGFβ pathways was determined in a paired design study in UL and M tissues depending on the presence/absence of *MED12* mutation. Similarly, the effect of VitD treatment on proliferation and the above-mentioned pathways was evaluated *in vitro* in human uterine leiomyoma primary (HULP) cells depending on *MED12* status (n=3/group).

Participants/materials, setting, methods: UL and M were collected from 37 patients (30-61 years) and *MED12* mutations were identified by Sanger sequencing in both tissues. The expression level of *WNT4, β-Catenin* (Wnt/β-catenin pathway), *TGFβ3, MMP9* (TGFβ pathway) in UL and M was determined by quantitative PCR (qPCR). HULP cells were isolated and treated *in vitro* with/without 1000nm VitD (48h). To evaluate treatment effect, the expression of the above-mentioned genes along with *PCNA* (cell proliferation marker) was measured by qPCR.

Main results and the role of chance: Sequencing data showed that 46% of UL presented *MED12* mutations, while no mutations were detected in their corresponding M. According to this, UL were divided into two groups depending on *MED12* status: *MED12*-mutated or wild type (WT). The evaluation of Wnt/β-catenin and TGFβ pathways in UL and M tissues showed that *MED12*-mutated UL presented significant higher levels of *WNT4* (fold regulation [fr]= 13.05, p=0.02), *β-Catenin* (fr= 2.84, p=0.01), *TGFβ3* (fr= 5.27, p=0.002) and *MMP9* (fr=13.73,p=0.004) than their corresponding M, while no significant differences were found in WT UL. *In vitro* study demonstrated that VitD decreased the expression of the cell proliferation marker *PCNA* in HULP cells from

MED12-mutated (fr= -1.7, p=0.05) and WT UL (fr= -2.8, p=0.01). Likewise, the analysis of TGFβ pathway genes showed that VitD significantly inhibited *TGFβ3* expression in HULP cells from *MED12*-mutated (fr= -3.1, p=0.02) and WT UL (fr= -4, p=0.02). Accordingly, *MMP9* expression decreased after VitD treatment in HULP cells from both *MED12*-mutated and WT UL (fr=-1.47 and -1.45, respectively). Regarding Wnt/β-catenin pathway, the expression of *β-Catenin* was decreased in HULP cells from both *MED12*-mutated and WT UL (fr= -1.2 and -1.5, respectively) after VitD treatment.

Limitations, reasons for caution: Considering the great variability that exists between patients, the limitation of this work includes the small sample size in the *in vitro* study. Further studies are necessary to translate *in vitro* results into practical clinical applications.

Wider implications of the findings: Notwithstanding the molecular differences found between *MED12*-mutated and WT UL, VitD could inhibit Wnt/β-catenin and TGFβ pathways in all HULP cells. These results suggest that VitD would be an effective treatment to reduce tumor size via the reduction of cell proliferation and ECM formation in different molecular subtypes of UL.

Trial registration number: not applicable

P-279 Aberrant expression of immune cells and Notch1 activation coincides with epithelial to mesenchymal transition in the development of adenomyosis in mice.

M. Bourdon[1], P. Santulli[1], L. Doridot[2], M. Jeljeli[3], C. Nicco[2], S. Chouzenoux[2], C. Chène[2], F. Batteux[3], C. Chapron[1]

[1]université Paris Centre, Gynecology and reproductive médecine, Paris, France ; [2]INSERM, Institut Cochin, Paris, France ; [3]Université Paris Centre, Immunology, Paris, France

Study question: In a mouse model of adenomyosis, do innate and adaptive immune cells and Notch1 pathway have any role in the development of adenomyosis?

Summary answer: Notch1 activation and aberrant expression of innate and adaptive immune cells promote adenomyosis developpement through the epithelial to mesenchymal transition (EMT).

What is known already: EMT has been implicated in the development of adenomyosis, along with a dysregulated innate and adaptive immune response. One hypothesis is that immune changes in uterus may promote endometrial cells proliferation and migration to myometrium and EMT activation, leading to adenomyosis lesions. Besides, inflammation is known to be a potential activator of the Notch signaling pathways known to have capacity to favor the EMT process.

Study design, size, duration: Adenomyosis was induced in 26 female CD1 mice by neonatal dosing of tamoxifen. Another 28 were neonatally dosed without tamoxifen (control group). These mice were sacrificed serially and their tissue samples were subsequently evaluated.

Participants/materials, setting, methods: Female CD-1mice with and without induced adenomyosis were sacrificed in batch at 30,60 and 90 days of age. The depth of myometrial infiltration of endometrial tissues was assessed with histology. Immune cells markers disturbance (CD45,Ly6C1,CD86,Arginine1,CD19,CD4, CD8) were analysed by RTqPCR. Notch1 and target genes (HEY1,HEY2,HES1,HES5) were analysed by RTqPCR. The Notch intracellular domain (NICD) was measured with western blot analysis. Analysis of EMT biomarkers was performed with RTqPCR (E-Cadherin,Vimentin,TGFb,SNAIL1,SLUG,Snail 3) and Western blot (E-Cadherin,Vimentin).

Main results and the role of chance: Aberrant expression of immune cells markers was observed in uteri from adenomyosis -mice over the development of the disease. Expression of innate inflammatory cells markers, notably M1 macrophages and natural killer's cells were increased from an early stage (Day30) compared to uteri from control mice, followed by an increase of CD4 T cells at day 60. Inversely, expression of CD19 B cells were significantly decreased during all studied stage. Activated-Notch1 was also highly activated during adenomyosis development compared to control mice at day 30 and D60. Concomitantly, some markers for EMT also was increased. This Notch activation could be related to the activation of EMT and migration of endometrial cells within the myometrium.

Limitations, reasons for caution: This study is limited by the use of an animal model and the lack of intervention.

Wider implications of the findings: This study provides evidence that adenomyotic lesions could be a consequence of immune modifications and Notch1 activation. Hypothesis is that an increase in local inflammation lead to activation of Notch1pathway. NICD, induced in the nucleus, transcriptional activation of genes related to EMT leading to migration of endometrial cells through myometrium.

Trial registration number: NA

P-280 Relation between clinical profiles and adenomyosis phenotypes assessed by magnetic resonance imaging

J. Oliveira[1], M. Bourdon[1], L. Marcellin[1], C. Bordonne[1], L. Maitrot Mantelet[1], A.E. Millischer[2], G. Plu Bureau[1], P. Santulli[1], C. Chapron[1]

[1]University of Paris.- Faculty of Medicine-, Department of Obstetrics and Gynecology II and Reproductive Medicine- Cochin University Hospital., Paris, France ; [2]Centre de Radiologie Bachaumont, Centre de diagnostique médicale de Paris IMPC, Paris, France

Study question: Do adenomyosis phenotypes such as focal (in the outer myometrium) and diffuse adenomyosis, as diagnosed by magnetic resonance imaging (MRI), have the same clinical characteristics?

Summary answer: Focal and diffuse adenomyosis phenotypes exhibit distinct clinical profiles in terms of both women's characteristics (age, gravity, previous surgery, endometriosis) and symptoms (menorrhagia, infertility).

What is known already: Uterine adenomyosis is characterized by the presence of endometrial glands and stroma deep within the myometrium. Various forms have been described, including focal adenomyosis(FOC-ADE), which corresponds to nodular lesions separated from the junctional zone in the outer myometrium, and diffuse adenomyosis (DIF-ADE), which is characterized by endometrial implants scattered throughout the myometrium and enlargement of the junctional zone. Although the pathogenesis of adenomyosis is not clearly understood, several lines of evidence suggest that these two phenotypes could have distinct origins. The clinical presentation of different forms of adenomyosis in patients warrants further investigation.

Study design, size, duration: This was an observational study. Non-pregnant patients, aged between 18 and 42 years, who had undergone surgical exploration for benign gynecological conditions at our institution between May 2005 and May 2018 and with a preoperative uterine MRI were included in the study. Data was prospectively collected by a standardized questionnaire regarding women's histories and clinical symptoms, completed during a face-to-face interview conducted by the surgeon in the month preceding the surgery.

Participants/materials, setting, methods: 248 women had a radiological diagnosis of adenomyosis assessed by MRI and signed informed consent. Based on the MRI findings, the women were diagnosed as having FOC- and/or DIF-adenomyosis. The women were allocated to two groups according to the adenomyosis phenotype (FOC-ADE versus DIF-ADE). Women exhibiting an association of both the FOC- and the DIF-adenomyosis form were excluded.

Main results and the role of chance: All up, following the MRI findings, 109 women (44.0%) exhibited only FOC-ADE and 78 (31.5%) had only DIF-ADE. The women with FOC-ADE were significantly younger (mean of31.9 years of age ± 4.6 SD versus 33.8 ± 5.2 SD, respectively; p = 0.006), more often nulligravid (74.3%versus 33.3%; p ≤ 0.001), exhibited a higher rate of associated-endometriosis (p= 0.001) especially deep infiltrating endometriosis (89.0% versus 30.8%) and a higher rate of infertility (p=0.021) especially primary infertility (25.1% versus 9.0%) compared to the women in the DIF-ADE group. Moreover, the women exhibiting DIF-ADE had significantly more often a history of previous uterine surgery (21.8% versus 6.4%;p = 0.002) and menorrhagia (79.5% versus 53.2%; p= 0.001) compared to the women with FOC-ADE. No differences in the pain scores (i.e., dysmenorrhea, non-cyclic pelvic pain, and dyspareunia) were observed between the two groups.

Limitations, reasons for caution: The exclusive inclusion of surgical patients as the limitation age could constitute possible selection bias. Moreover, the women referred to our center may have suffered from particularly severe clinical symptoms.

Wider implications of the findings: In clinical practice, these two forms of adenomyosis should be differentiated using an appropriate imaging work-up in order to search for associated endometriosis and to devise a tailored therapeutic strategy. To better understand the pathogenesis, future mechanistic studies aimed at better characterization of diffuse and focal adenomyosis are needed.

Trial registration number: not applicable

P-281 Regulatory effect of prohibitin on glucose metabolism of granulosa cell in endometriosis.

M. Jingqin[1], C.Y. Zhong[1], L. Gao[1], J. Zhang[1], J.Y. Zhang[1], L. Dai[1], Y.D. Mao[1]

[1]First Affiliated Hospital of Nanjing Medical University, Clinical Center of Reproductive Medicine, Nanjing, China

Study question: What role does prohibitin play in glucose metabolism in granulosa cells of patients with endometriosis?
Summary answer: Patients with endometriosis shows the high expression of prohibitin to make up for glucose aerobic metabolism defects.
What is known already: The metabolic dysfunction in granulosa cells of endometriosis patients has been examined by various groups. Prohibitin is ubiquitously expressed, mainly presenting in mitochondria to maintain the membrane potential of mitochondrial, to facilitate in assembly of respiration chain. Meanwhile, prohibitin play a critical role in energy metabolism.
Study design, size, duration: In this study, glucose metabolic phenotype of granulosa cells were examined in vitro. The human granulosa cell line KGN were transfected with lentivirus to knock down and over express the expression of prohibitin. Afterwards, the glucose metabolism phenotype and cell vitality were evaluated.
Participants/materials, setting, methods: The primary granulosa cells were collected to test the glucose metabolism features as follows: lactate production (Lactate assay kit) glucose consumption (Glucose assay kit) and the expression of prohibitin and glucose metabolism related enzymes(q-PCR and Western blotting). The KGN was transfected with lentivirus to knock down and over express the expression of prohibitin. The mitochondrial function and cell proliferation were tested by ATP assay kit and CCK8 kit.
Main results and the role of chance: In women with endometriosis, significantly increased glucose consumption, lactate production, prohibitin expression and aberrant expression of glycolysis-related enzymes were found compared with women who do not have endometriosis ($P < 0.05$). To determine whether prohibitin regulated glucose metabolism by affecting the expression of glycolysis related enzymes, the expression of enzymes were evaluated after lentivirus transfection in KGN. When prohibitin was down regulated in KGN, the mRNA expression of HK1, ENO1α, PDHA, CS, SDHB and ATP5A were significantly decreased ($P < 0.05$). When prohibitin was over expressed, the the mRNA expression of Glut1, HK1, ENO1α, LDHA and PDHA were significantly increased ($P < 0.05$). Meanwhile, the over-expression of prohibitin led to elevated glucose consumption and lactate production ($P < 0.05$), whereas, the knock-down of prohibitin made no change. Additionally, cell viability and proliferation were significantly inhibited after the down regulation of prohibitin($P < 0.05$).
Limitations, reasons for caution: More experiments are necessary to explore the specific molecule signal pathway involved with prohibitin to regulate the glucose metabolism.
Wider implications of the findings: Women with endometriosis exhibits aberrant glucose metabolism and high level expression of prohibitin in granulosa cells. According the results, prohibitin may improve the glycolysis to make up the energy output deficiency resulting from mitochondrial dysfunction, to exert the protective effect on gruanlosa cells in women with endometriosis.
Trial registration number: 81671438, 81730041

P-282 Rectal water-contrast transvaginal ultrasonography versus sonovaginography for the diagnosis of posterior deep pelvic endometriosis: a prospective comparative study

F. Barra[1], C. Scala[2], V.G. Vellone[3], C. Stabilini[3], S. Ferrero[1]

[1]IRCCS Ospedale Policlinico San Martino- University of Genoa, Academic Unit of Obstetrics and Gynecology, Genoa, Italy ;
[2]Gaslini Institute, Unit of Obstetrics and Gynecology, Genoa, Italy ;
[3]IRCCS Ospedale Policlinico San Martino- University of Genoa, Department of Surgical and Diagnostic Sciences DISC, Genoa, Italy

Study question: To investigate the accuracy of rectal water-contrast transvaginal ultrasonography (RWC-TVS), and sonovaginography (SVG) in patients with clinical suspicion of posterior deep infiltrating endometriosis (DIE).
Summary answer: RWC-TVS and SGV have similar accuracy in the diagnosis of posterior DIE. However, RWC-TVS is more accurate in diagnosing presence and characteristics of rectosigmoid endometriosis.
What is known already: Surgical treatment of posterior DIE may be challenging for surgeons and carry significant risks for patients. Preoperative assessment by imaging of the location, characteristics and presence of posterior DIE nodules is important in order to inform the patient on the possible treatments and to provide informed consent to patients undergoing surgery. RWC-TVS and SGV consist of enhanced transvaginal ultrasound scans based on the introduction of contrast into the rectum and vagina, respectively.
Study design, size, duration: This was a prospective comparative study, enrolling 221 women with clinical suspicion of posterior DIE.
Participants/materials, setting, methods: Patients with previous diagnosis of posterior DIE by magnetic resonance, computed tomography or laparoscopy were excluded from the study. All patients underwent RWC-TVS and SVG, performed by two independent ultrasonographers, informed of the patients' clinical history and symptoms but blinded to the other diagnostic exam. The presence of rectovaginal septum, rectosigmoid, uterosacral ligaments, and vagina endometriosis was investigated. Patients underwent laparoscopy within the following 6 months. Imaging findings were compared with surgical and histological results.
Main results and the role of chance: In 89.6% (n=198/221) of the patients, posterior DIE was laparoscopically confirmed. The nodules were localized in rectovaginal septum (36.4%), rectosigmoid (24.2%), uterosacral ligaments (66.1%), and vagina (6.4%). There was no significant difference in the performance of RWC-TVS and SVG in diagnosing posterior DIE (p=0.187). The accuracy of RWC-TVS in the detection of posterior DIE was 92.2%, sensitivity was 89.4%, specificity 95.0%, positive predictive value 94.6%, negative predictive value 90.1%, positive likelihood ratio 18.0 and negative likelihood ratio 0.1. For SVG, the corresponding values were 88.8%, 82.8%, 94.9%, 94.3%, 84.4%, 16.3 and 0.2, respectively. RWC-TVS had higher accuracy than SVG in diagnosing presence of rectosigmoid endometriosis (sensitivity 91.2% vs 80.7%; specificity 95.8% vs 89.0%; p<0.001), depth of penetration of endometriosis in the intestinal muscularis propria (89.3% vs 79.5%; 90.2% vs 77.8%; p<0.001), and distance between the nodule and anal verge (91.3% vs 77.2%; 88.3% vs 74.2%; p<0.001). There was no significant difference between the two techniques in diagnosing endometriotic nodules of utero-sacral ligaments (83.5% vs 82.1%, 82.4% vs 79.1%; p=0.312) and rectovaginal septum (92.5% vs 88.2%, 87.8% vs 85.3%; p=0.431). RWC-TVS had lower sensitivity (75.0% vs 91.7%, p=0.031) but similar specificity (98.1% vs 97.6%; p=0.453) than SVG in diagnosing vaginal endometriosis.
Limitations, reasons for caution: A limitation of the study if that the diagnostic performance of both techniques is depending on the experience of the examiners. The surgeons were aware of the findings of these diagnostic exams. Both techniques cannot diagnose endometriotic nodules located above the rectosigmoid.
Wider implications of the findings: This study showed that RWC-TVS and SVG have similar performance in diagnosing deep posterior DIE. RWC-TVS is more accurate that SVG in assessing the presence and characteristics of rectosigmoid endometriosis.
Trial registration number: Not applicable

P-283 Three-dimensional rectal water contrast transvaginal ultrasonography versus virtual colonoscopy for diagnosing presence and characteristics of rectosigmoid endometriosis

F. Barra[1], E. Biscaldi[2], C. Scala[3], V.G. Vellone[4], C. Stabilini[4], S. Ferrero[1]

[1]IRCCS Ospedale Policlinico San Martino - University of Genoa, Academic Unit of Obstetrics and Gynecology, Genoa, Italy ;
[2]Galliera Hospital, Radiology, genova, Italy ;
[3]Gaslini Institute, Unit of Obstetrics and Gynecology, Genoa, Italy ;
[4]IRCCS Ospedale Policlinico San Martino - University of Genoa, Department of Surgical and Diagnostic Sciences DISC, Genoa, Italy

Study question: To compare the performance of three-dimensional rectal water contrast transvaginal ultrasonography (3D-RWC-TVS) and computed tomographic colonography (CTC) in predicting the presence and characteristics of rectosigmoid endometriosis.

Summary answer: 3D-RWC-TVS and CTC have similar diagnostic accuracy for diagnosing rectosigmoid endometriosis. However, CTC is more accurate in ruling out the presence of sigmoid endometriotic nodules.
What is known already: A non-invasive diagnosis of bowel endometriosis is relevant to provide the patients information on the potential treatments (hormonal therapies or surgery) and to obtain adequate informed consent in case of surgery. Over the last 10 years, RWC-TVS and CTC based on the distention of the rectosigmoid have been proposed with the aim to improve the diagnosis of deep infiltrating endometriosis. Both exams allow the evaluation of bowel using a pseudoendoscopic view.
Study design, size, duration: This was a prospective comparative study including patients who were referred to our institution for suspicion of rectosigmoid endometriosis between January 2018 to December 2019.
Participants/materials, setting, methods: Patients with symptoms suggestive of rectosigmoid involvement by endometriosis were included in the study. They underwent 3D-RWC-TVS performed by a sonographer skilled in the diagnosis of deep endometriosis. CTC was done within the following three months by a radiologist expert in the diagnosis of deep endometriosis, blinded to the results of the previous ultrasonographic exam. Patients underwent surgery within the following six months. Imaging findings were compared with surgical and pathologic results.
Main results and the role of chance: Out of 68 women included, 37 (48.9; 95% C.I. 38.2%-59.7%) had rectosigmoid nodules which required bowel surgery. The main nodules were located on the sigmoid in 16 (43.2%) patients, on the rectosigmoid junction in 4 (10.8%) patients, on the upper rectum in 10 (27.0%) patients and on the lower rectum in 7 patients (18.9%). There was no significant difference in the accuracy of 3D-RWC-TVS and CTC in diagnosing the presence of rectosigmoid endometriotic nodules (p = 0.118). However, a subgroup analysis demonstrated that CTC was more precise than 3D-RWC-TVS in diagnosing endometriosis located in sigmoid (p = 0.016). The presence of an endometrioma with diameter > 4 cm was positively statistically correlated to lack of identification of sigmoid endometriotic nodules (phi coefficient 0.516; p=0.039) by performing 3D-RWC-TVS. Both exams estimated similarly the largest diameter of the main endometriotic nodule, independently of their location (p = 0.090). CTC was more accurate than 3D-RWC-TVS in estimating the distance between the lower margin of the intestinal nodule and the anal verge (p = 0.030). There was no significant difference in the performance of 3D-RWC-TVS and CTC in diagnosing multifocal disease (p = 1.000).
Limitations, reasons for caution: A limitation of both techniques is represented by the extensive experience of the radiologist and the gynecologist performing CTC and 3D-RWC-TVS, respectively, which may have influenced the performance of these techniques in ruling out the presence of rectosigmoid endometriosis.
Wider implications of the findings: 3D-RWC-TVS and CTC have similar diagnostic performance for diagnosing rectosigmoid endometriosis, although 3D-RWC-TVS is less accurate in detecting sigmoid nodules. CTC may be combined with 3D-RWC-TVS because of the high diagnostic performance in detecting rectosigmoid endometriosis and the ability to diagnose endometriotic nodules located above the rectosigmoid junction.
Trial registration number: Not applicable

P-284 In silico screening and variant analysis in the transcript profile of eutopic endometrium from infertile women with endometriosis and controls during the implantation window

M. Da Broi[1], J. Plaça[2], R. Ferriani[1], P. Navarro[1]

[1]Ribeirão Preto School of Medicine- University of São Paulo, Department of Obstetrics and Gynecology, Ribeirão Preto, Brazil ;
[2]Center for Medical Genomics- HCFMRP/USP, Department of Genetics, Ribeirão Preto, Brazil

Study question: Is there a pattern of functional mutations in transcripts of the eutopic endometrium of infertile women with endometriosis during the implantation window that could be related to impaired endometrial receptivity?
Summary answer: No pattern of functional mutations was identified in the transcripts of the eutopic endometrium of infertile women with endometriosis during the implantation window.
What is known already: The molecular and functional impairment of the eutopic endometrium in women with endometriosis is questioned as a possible mechanism involved in the disease-related infertility. Recently, the sequencing of mRNAs (RNA-Seq) did not show differential expression in the transcripts of infertile patients with endometriosis when compared to infertile and fertile controls during the implantation window. However, these findings do not exclude the possibility of existing other molecular alterations with possible impact on protein synthesis and, potentially, on the establishment of endometrial receptivity.
Study design, size, duration: In this descriptive study, data from RNA-Seq analysis of endometrial biopsies collected during the implantation window from 17 patients (3 infertile women with endometriosis I/II, 3 infertile women with endometriosis III/IV, 6 infertile controls and 5 fertile controls) were *in silico* analyzed by bioinformatics tools for variant discovery, functional mutations identification and selection of proteins possibly affected. A targeted study of the alterations found was performed to understand the data in the disease's context.
Participants/materials, setting, methods: Analyzes were performed in the GATK (Genome Analysis Toolkit), following the best practices recommended for the discovery of variants in RNA-Seq data. Data were filtered according to the coverage, gene region, variant function and description in NCBI databases. Subsequently, the variants were evaluated by Pathogenicity Predictors. The first predictor applied was the CADD, followed by the agreement of the predictors PROVEAN, SIFT and Polyphen 2 in classifying deleterious or possibly deleterious variants.
Main results and the role of chance: None of the variants found were common to other samples within the same group, as well, no mutation was repeated in patients with endometriosis, infertile controls and fertile controls. In the endometriosis group, 9 mutations predicted to be harmful were identified. Only one of the mutations (in the gene *SLC2A9*) had already been described as associated with clinical conditions (familial renal hypouricemia), with no evident impact on the endometrium. However, when crossing the genes related to the 9 mutations found with the keywords "endometriosis" and/or "endometrium", the gene *CMKLR1* was associated either with the inflammatory response in endometriosis or with important endometrial processes for pregnancy establishment.
Limitations, reasons for caution: The small sample size does not allow us to state whether there are differential mutations among women with endometriosis compared to fertile and infertile controls. Moreover, the search for variants was performed on RNA-Seq data and only expressed transcripts were evaluated. Regulatory regions were not analyzed.
Wider implications of the findings: Despite no pattern of mutation was found, we ponder the small sample size and the analysis on RNA-Seq data. Considering the study's purpose of screening and the *CMKLR1* importance on endometrial modulation, it could be a candidate gene for further studies evaluating mutations in eutopic endometrium from endometriosis patients.
Trial registration number: Not applicable

P-285 Pretreatment with dienogest in women with endometriosis undergoing in vitro-fertilization after a previous failed cycle

F. Barra[1], C. Scala[2], G. Evangelisti[1], S. Ferrero[1]

[1]IRCCS Ospedale Policlinico San Martino - University of Genoa, Academic Unit of Obstetrics and Gynecology, Genoa, Italy ;
[2]Gaslini Hospital, Unit of Obstetrics and Gynaecology, Genoa, Italy

Study question: To investigate the effect of dienogest (DNG) administered in women with endometriosis undergoing IVF after a previous failed cycle.
Summary answer: In women with endometriosis, particularly in those with large endometriomas, implantation rate and clinical pregnancy rate can be improved by pretreatment with DNG.
What is known already: It is generally assumed that diminished ovarian reserve, impaired endometrial receptivity and low quality of embryos may be causes of the lower *in vitro* fertilization (IVF) outcomes of women with endometriosis. The use of prolonged courses of hormone therapy may improve IVF outcome of patients with endometriosis.
Study design, size, duration: This was a retrospective analysis of a prospective database collected between January 2016 to July 2019. Women who failed a previous IVF cycle and all subsequent embryo transfers, with concomitant diagnosis of endometriosis at transvaginal ultrasonography or magnetic resonance imaging were included in this study.
Participants/materials, setting, methods: Inclusion criteria were age ≤40 years; basal FSH <14.0 IU/L and anti-Müllerian hormone (AMH) blood level

≥0.5 g/mL. Women who underwent previous surgical treatment of endometriosis were excluded. Following a failed IVF cycle, patients either directly underwent IVF without receiving hormonal treatment or received a three-month DNG (2 mg daily) treatment before IVF. The choice of treatment was based on patients' preference.

Main results and the role of chance: 151 patients were included in the study, 88 (58.3%) underwent IVF without previous hormonal treatment and 63 (41.7%) received pretreatment with DNG. At baseline, there was no significant difference in age, average duration of infertility, antral follicle count, basal serum FSH, AMH and presence of endometriomas between the two groups. The implantation rate and clinical pregnancy rate were significantly higher in the DNG-treated group (39.7% and 33.3%) compared with the non-treated group (23.8% and 18.2%; p=0.037 and p=0.033, respectively). The largest diameter and volume of endometriomas significantly decreased after pretreatment with DNG (-0.7 ± 0.8 cm and -3.1 ± 7.7 cm^3, p<0.001 and p<0.001, respectively). A subgroup analysis demonstrated that the use of DNG increased significantly the number of oocytes retrieved (6.1 ± 2.8 versus 5.3 ± 2.2, p=0.039), of 2 pronuclear (2PN) embryos (2.9 ± 1.6 versus 2.2 ± 1.8, p=0.015) and of blastocysts (2.4 ± 1.6 versus 2.0 ± 1.4, p=0.049) obtained in patients with endometriomas with diameter ≥ 4 cm.

Limitations, reasons for caution: While baseline demographics and first IVF cycle stimulation parameters for the studied patients were comparable, the non-randomized allocation of subjects may mask a hidden bias in this study.

Wider implications of the findings: IVF outcomes of women with endometriosis seem to be improved after pretreatment with DNG. In particular, this progestin may give a benefit in patients with large endometriomas.

Trial registration number: Not applicable

P-286 Dynamic properties of endometrial macrophages regulate tissue homeostasis and disease in the uterus

E. Mann[1], N. Scott[1], L. Lacerda Mariano[2], P. Ruane[3], M. Ingersoll[2], L. Mohiyiddeen[4]

[1]University of Manchester, Lydia Becker Institute of Immunology and Inflammation, Manchester, United Kingdom ;
[2]Institut Pasteur, Immunology, Paris, France ;
[3]University of Manchester, Maternal and Fetal Health Research Centre, Manchester, United Kingdom ;
[4]Manchester NHS Foundation Trust, Reproductive Medicine, Manchester, United Kingdom

Study question: Do macrophages contribute to tissue remodelling and repair in the uterus, and contribute to pathology in fibrosis/Asherman's syndrome when their function is dysregulated?

Summary answer: Monocytes recruited from the bloodstream generate uterine macrophages with distinct roles in tissue repair and remodelling, and macrophages may be dysregulated in Asherman's syndrome.

What is known already: Dysregulated tissue degradation, repair and remodelling and can lead to fibrosis and adhesions in the uterus (known as Asherman's syndrome), causing reproductive dysfunction. In other tissues, macrophages (immune cells) are central to tissue remodelling and repair. However, the ontogeny and functions of macrophages within the uterus are poorly defined, despite dysregulation of macrophage recruitment and function driving fibrosis at other mucosal sites.

Study design, size, duration: Macrophages were characterized at different stages of the estrous cycle in mice (proestrus, estrus, metestrus and diestrus), which reflects the hormone fluctuations that regulate tissue remodelling and receptivity to embryo implantation occurring in the human uterus (n=10-15 per estrous cycle stage). Differentiation of murine endometrial macrophages from infiltrating blood monocytes *in vivo* was assessed using methods described below (n=6-12 per time point). Macrophages were characterized from human endometrial biopsies, obtained following informed consent (n=5).

Participants/materials, setting, methods: Macrophages were characterised from uterine tissue (mouse and human) by multi-parameter flow cytometry following enzymatic digestion. Mice were staged using vaginal smear cytology to determine estrous cycle phases according to proportions of epithelial cells, cornified cells and leucocytes. Ontogeny of murine endometrial macrophages was defined at multiple time points 8 and 20 weeks after reconstitution of irradiated mice (uterus lead shielded) with congenic bone marrow to allow tracking of donor cells in uterine tissue.

Main results and the role of chance: Mature macrophages were present at all stages of the murine estrous cycle and expressed features indicating involvement in tissue remodelling and repair, including high levels of the IL-4 receptor, CSF-1 receptor, mannose receptor CD206 and protein Relmα (critical for remodelling and repair in other tissues). Accordingly, endometrial macrophages were more responsive to IL-4 than mucosal macrophages from other tissues (p<0.001). Unlike other tissue macrophages, endometrial macrophages did not proliferate *in situ* but the substantial majority were differentiated from circulating monocytes recruited into the endometrium in a manner dependent on the chemokine receptor CCR2 (p<0.01). By 20 weeks post irradiation, turnover of macrophages in the uterus from blood monocytes was higher than in the intestine (p<0.05), previously demonstrated to have one of the highest rates of replenishment. Numbers of monocytes in the uterus were profoundly increased during estrus (receptivity period when estrogen is low; p<0.01), likely accounting for the high rate of turnover into macrophages. These recruited macrophages were highly responsive to IL-4 and exhibited enhanced levels of CD206 and Relmα compared to their tissue-resident counterparts (p<0.001). Preliminary data suggest human endometrial macrophages are drastically expanded in Asherman's syndrome and that these cells have immature properties suggesting dysregulated differentiation.

Limitations, reasons for caution: The remodelling events that occur throughout the murine estrous cycle differ from those in the human menstrual cycle in terms of endometrial shedding/menstruation which does not occur in mice. Nonetheless, mouse models provide the opportunity to perform the *in vivo* ontogeny and functional studies that are not possible in humans.

Wider implications of the findings: The estrous cycle is marked by dynamic changes in populations of endometrial monocytes/macrophages that are likely to play a key role in tissue remodelling during the receptivity period in which implantation can occur in homeostasis, but may contribute to pathology in fibrotic disease such as Asherman's syndrome when dysregulated.

Trial registration number: not applicable

P-287 Suppression of ovarian activity during co-administration of the oral gonadotropin-releasing hormone receptor antagonist relugolix, estradiol, and norethindrone acetate in healthy female volunteers

I. Duijkers[1], C. Klipping[1], C. Draeger[2], B. Schug[3], R.S. Wedemeyer[3], J. Li[4], J.C. Arjona Ferreira[4], E. Migoya[4]

[1]dinox consultancy, Groningen, The Netherlands ;
[2]dinox GmbH, Berlin, Germany ;
[3]SocraTec R&D GmbH, Oberursel, Germany ;
[4]Myovant Sciences Inc., Brisbane, U.S.A.

Study question: Does relugolix combination therapy (relugolix, oral gonadotropin-releasing hormone (GnRH) receptor antagonist, 40mg, estradiol (E_2) 1mg and norethindrone acetate (NETA) 0.5mg) suppress ovarian activity and ovulation?

Summary answer: Once daily oral administration of relugolix combination therapy for 84 days suppressed ovarian activity and inhibited ovulation in 100% of subjects.

What is known already: Relugolix competitively binds to the GnRH receptor, preventing the release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH), thereby decreasing the production of E_2 and progesterone (P). By lowering systemic concentrations of E_2 and P, oral administration of 40 mg relugolix monotherapy is effective in the treatment of symptoms associated with uterine fibroids, however, is associated with hypoestrogenic symptoms and bone mineral density loss. In current phase 3 trials in patients with uterine fibroids or endometriosis, relugolix treatment is combined with 1 mg E_2 and 0.5 mg NETA to mitigate hypoestrogenic side effects.

Study design, size, duration: An open-label, single treatment-group clinical study in 70 women, 67 of which completed the study. The study included a pre-treatment cycle to assess ovulatory status, an 84-day treatment period to assess ovarian activity during combination treatment (co-administration of a relugolix 40mg tablet and an E2/NETA 1mg/0.5mg tablet (Activelle®)), and a post-treatment cycle to assess return of ovulation. Subjects visited the study center every third (± 1) day during the entire study.

Participants/materials, setting, methods: The study, conducted in a clinical research center, included healthy premenopausal women 18-35 years of age. During the study visits ultrasound measurements of follicular growth and endometrial thickness, and blood sampling for determination of serum E_2, P, FSH and LH concentrations were performed. Ovarian activity was categorized using the Hoogland-Skouby score. Safety parameters and vaginal bleeding were also assessed. The primary endpoint was the proportion of subjects with Hoogland-Skouby scores <5 during the treatment period.

Main results and the role of chance: Once-daily dosing with relugolix combination therapy resulted in suppression of ovarian activity and inhibition of ovulation in 100% of women as demonstrated by Hoogland-Skouby scores <5 during the entire 84-day treatment period. In most subjects the largest follicular diameter remained below 10 mm throughout treatment, resulting in a Hoogland-Skouby score of 1 (no ovarian activity). Mean and median E2 concentrations, reflecting both endogenous and exogenously-administered E_2, were between 110 and 160 pmol/L (30 and 44 pg/mL). Serum P, FSH, and LH concentrations were suppressed for the duration of treatment. Ovarian activity resumed after treatment discontinuation with ovulation occurring a mean of 23.5 days after the last treatment day. Relugolix combination therapy was generally well tolerated in premenopausal women over 84 days of treatment.

Limitations, reasons for caution: Compliance regarding tablet intake could be lower in clinical practice than in the setting of a clinical trial, therefore these results may differ from those in the clinical setting. However, the robustness of the ovarian suppression limits the risk of escape ovulations due to missed medication intake.

Wider implications of the findings: Since relugolix combination therapy completely inhibited ovulation, the use of non-hormonal contraception during treatment may not be required for prevention of pregnancy. The rapid and predictable return of ovulation after treatment discontinuation is advantageous for patients who wish to conceive after completion of treatment.

Trial registration number: EudraCT 2018-004130-15

P-288 Interventions for women with thin endometrium undergoing assisted reproductive treatment (ART)- A systematic review and meta-analysis.

L. Polanski[1], M. Baumgarten[2], K. Jayaprakasan[3]

[1]Assisted Conception Unit, Guy's and St Thomas' NHS Foundation Trust, London, United Kingdom ;
[2]Addenbrooke's Hospital, Obstetrics and Gynaecology, Cambridge, United Kingdom ;
[3]Royal Derby Hospital, Derby Fertility Unit, Derby, United Kingdom

Study question: What interventions, if any, have been shown to improve ART outcomes in women with thin endometrium defined as <7mm despite routine treatments?

Summary answer: A number of interventions have been identified. Study quality was rated as poor and live birth rates were reported by only 6 studies.

What is known already: Normal endometrial receptivity is essential for pregnancy establishment and normal development. Endometrial thickness <7 mm is associated with a reduced chance of pregnancy in ART, an increased risk of miscarriage and adverse obstetric outcomes. The aetiology of thin endometrium remains uncertain, however damage of the endometrial basal layer is the likely underlying cause. Prevalence of thin endometrium is reported in 2.4%- 8.5% of women undergoing ART, fresh or frozen cycles. Many interventions have been proposed to improve endometrial thickness and reproductive outcomes in these women.

Study design, size, duration: Design- systematic review and Meta-analysis
We identified 31 studies, comprising 2421 women, that compared treatments for thin endometrium in fresh or frozen embryo transfer cycles. Randomized controlled trials (RCTs), case controlled studies and cohort studies with a control population were included. Medline, Embase and CENTRAL databases have been systematically searched until 08.11.2019 using terms (thin OR atrophic AND endometri*) AND (assisted conception OR reproduction OR in vitro fertili*(IVF) OR intracytoplasmic sperm injection(ICSI) OR frozen embryo).

Participants/materials, setting, methods: Infertile women undergoing fresh or frozen autologous embryo transfer where endometrial thickness as defined by the authors was thin (<8mm) were included in the analysis. Control populations included women with no intervention or previous cycle data (for endometrial thickness). The main outcome was live birth, secondary outcomes included endometrial thickness, implantation rate, clinical pregnancy rate, miscarriage rate, complications of treatment and obstetric/perinatal outcomes. Mantel-Haenszel odds ration with random effects was used as analysis method.

Main results and the role of chance: A total of 350 items were identified, after deduplication 266 titles were screened. 47 papers were included for detailed analysis with 31 studies included in the meta-analysis. Identified treatments included infusion of granulocyte colony stimulating factor (G-CSF); infusion of platelet rich plasma (PRP); long term treatment with pentoxyfilline and tocopherol; pelvic flood bionic stimulation, growth hormone injections, high dose estrogen therapy, use of prostaglandins, addition of gonadotrophin releasing hormone agonists (GNRH-a) as luteal phase support.
Live birth rate was reported by 6 studies with addition of GnRH-a to luteal phase showing an odds ratio (OR) of 8.80 [95% Confidence Intervals(CI) 2.44-31.73, P=0.0009, one study). Most significant increase in endometrial thickness was noted with long treatment with pentoxifylline and tocopherol (mean difference 2.40, 95% CI 2.15-2.65, P<0.00001, one study). Endometrial perfusion with PRP demonstrated highest chance of implantation (OR 4.92, 95% CI 1.78-13.58, P=0.002, two studies). Addition of GnRH-a to luteal support demonstrated highest chance for clinical pregnancy (OR=3.76; 95% CI 1.51-9.36, P=0.004, one study). No complications or obstetric outcomes were reported.
Based on the risk of bias, only one study rated as good with majority rated as poor. Heterogeneity ranged from I^2=0 (low) to >80% (high).

Limitations, reasons for caution: Only 10 randomized controlled trials were identified with the largest including only 135 patients. The quality of the studies was mainly poor to moderate. Studies reporting other therapies identified by the search did not have adequate data to carry out meta-analysis.

Wider implications of the findings: Our study highlights the lack of good quality evidence for different types of treatments for women with persistently thin endometrium. Addition of GnRH-a to luteal phase support shows some promise however, larger studies are necessary to validate this finding. Other therapies require more well-designed RCTs to confirm their clinical benefit.

Trial registration number: PROSPERO registration number CRD42019154704.

P-289 The effect of endometriosis in the chromosomal status and developmental competence of cleavage-stage embryos. Differences with embryos in the blastocyst stage.

P. Hernandez[1], B. Gadea[2], V. Lozoya[3], V. Legidos[4], M. Muñoz[4]

[1]IVI Alicante, Local Research Department, Alicante, Spain ;
[2]IVI Alicante, IVF Laboratory, Alicante, Spain ;
[3]IVI Foundation, Research Support and Management UAGI, Alicante, Spain ;
[4]IVI Alicante, Gynecologist, Alicante, Spain

Study question: Is there any difference in the PGT-A results between trophectoderm and blastomere biopsies from patients with endometriosis compared to control patients?

Summary answer: Unlike PGT-A results in blastocyst, the number or euploid cleavage-stage embryos is lower in endometriosis patients but it does not affect embryo developmental arrest.

What is known already: Endometriosis affects around 30-50% of infertile women undergoing fertility treatment and negatively impacts on their chances of successful IVF outcomes. Among the underlying mechanism responsible for the poor outcomes, oocyte meiotic spindle alterations and chromosomal instabilities, subsequently resulting in embryo aneuploidies, have been suggested. The only data available for human embryo chromosomal analysis suggested that endometriosis does not impact on aneuploidy rates but only embryos reaching the blastocyst stage were included in the analysis. Therefore, aneuploidies leading to embryonic developmental arrest before the blastocyst stage may not have been detected.

Study design, size, duration: Multicenter retrospective cohort study to evaluate the chromosomal status of both cleavage-stage and blastocyst embryos from patients with endometriosis (n=507) compared with disease-free control women (n= 7969). Women aged 18-42 years old undergoing IVF with preimplantation genetic testing for aneuploidies (PGT-A) in IVIRMA Clinics between 2012 and 2019 were included. Both, developmental competence and PGT-A results were also examined in the cleavage-stage biopsied embryos to ascertain the effect of endometriosis on aneuploidy-related embryonic arrest.

Participants/materials, setting, methods: Presence of endometriosis was evidenced at the time of abdominal surgery or after pelvic ultrasound or NMR.

Severe male factors and patients with chromosomopathy in previous embryos or pregnancies were excluded. Both D3 and D5-7 biopsies were analyzed using comparative genomic hybridization (CGH) arrays or next generation sequencing (NGS). For the statistical analysis, chi-square test for categorical variables or Student's t-test for quantitative data were applied to compare baseline characteristics between groups.

Main results and the role of chance: Two thousand seventy-two embryos from patients with endometriosis were analyzed and 32008 were included in the control group. Among them, 9049 were cleavage-stage embryos (943 and 8106 embryos in endometriosis and control group, respectively) and 25031 were blastocyst (1129 and 23902 blastocysts from patients with endometriosis and control women). The mean number of euploid embryos from patients with endometriosis (1.04; CI: 0.93-1.15) tends to be lower than in the control group (1.17; CI: 1.14-1.2). We only found significant differences in the number of euploid embryos when results from D3-biopsies were considered (0.94 vs. 1.18; p=0.0084 in endometriosis vs. control group). Although no significant differences were shown, a similar trend was observed when ploidy rates from D3 embryos were analyzed (euploid rates: 0.18 vs. 0.21 in endometriosis vs. control group; p= 0.08). In D3-biopsied embryos, we also analyzed the ability of blastocyst formation and its relationship with their ploidy status. Similar frequencies of embryo arrest before reaching the blastocyst stage were found in both groups (20.13 % vs. 22.66 % in endometriosis and control group; p=0.09). Focusing on the PGT-A results, data showed no differences in the ploidy status when arrested embryos from both patients' groups were compared (OR: 1.12; (0.51-2.02)).

Limitations, reasons for caution: Although the study groups were as homogeneous as possible, results should be taken into caution due to the retrospective nature of the study. Multivariate regression models to avoid confounding variables are still pending. Differences in ploidies according to the severity of the disease have not been evaluated.

Wider implications of the findings: Further research is needed to firmly convey no association between endometriosis and embryo aneuploidy rates. Prospective and well-designed studies stratifying PGT-A of women with different stages of endometriosis are required. Moreover, association between aneuploidy and embryo developmental arrest should be considered in the analysis.

Trial registration number: Not Applicable

P-290 Effects of the levonorgestrel intrauterine system on the endometrium after long-term exposure to mifepristone: secondary outcomes of a randomized controlled trial

K. Papaikonomou[1], F. Caroline[1], A.R. Williams[2], K. Gemzell Danielsson[1]

[1]Karolinska Institutet and Karolinska University Hospital, Department of Women's and Children's Health- Division of Obstetrics and Gynecology, Stockholm, Sweden ; [2]The Royal Infirmary of Edinburgh- The University of Edinburgh, Division of Pathology, Edinburgh, United Kingdom

Study question: Is direct placement of a levonorgestrel intrauterine system (LNG-IUS), after long-term treatment with the progesterone receptor modulator (PRM) mifepristone, a safe alternative regarding the endometrium?

Summary answer: LNG-IUS placed immediately following long-term treatment with a PRM without any prior endometrial shedding may represent a safe treatment regimen for the endometrium.

What is known already: Clinical trials on long-term administration of mifepristone have demonstrated its potential use for contraception, medical treatment of uterine fibroids, endometriosis, improvement of bleeding patterns in women using progesterone only contraceptives and optimization of in vitro fertilization treatment. Ulipristal acetate, another PRM, is licensed for treatment of uterine fibroids and more PRMs are under development. However, continuous administration of PRMs is associated with a risk of developing a characteristic endometrial morphology described as progesterone receptor modulator associated endometrial changes (PAEC). Although accumulating evidence implies that this histological entity is benign, its long-term safety profile remains uncertain.

Study design, size, duration: We report the secondary outcome from a double-blinded randomized controlled trial conducted from November 2009 to January 2015. Eligible women were randomized to 50mg mifepristone (n=29) or the comparator (vitamin B) (n=29) for two months, followed by insertion of the LNG-IUS 52mg. Endometrial biopsies were obtained at baseline and three months after placement of the LNG-IUS, with the device in situ. Paired samples were histologically assessed by an expert pathologist blinded to the treatment.

Participants/materials, setting, methods: The study was conducted in a single center in Sweden. Eligible were healthy women opting for a LNG-IUS, aged 18-43, with normal menstrual cycles. The paired endometrial samples were stained with hematoxylin and eosin and assessment involved classifying biopsies according to (1) primary diagnosis (benign, hyperplastic or malignant), (2) whether appearances represented a physiological state or not and if physiological, record the stage of the menstrual cycle and (3) the presence or absence of PAEC.

Main results and the role of chance: This is the first study assessing endometrial safety and presence of PAEC after long-term treatment with a PRM with subsequent placement of an LNG-IUS with no prior endometrial shedding. There were no differences in baseline characteristics between the groups. Nine paired biopsies in the mifepristone group and eight paired biopsies in the comparator group were included in the histological analysis after study drop-outs, loss of samples and failure in endometrial retrieval. All endometrial biopsies at baseline revealed a normal histological appearance. Endometrial biopsies after three months with the LNG-IUS in situ showed no PAEC in either group and as expected, they were consistent with progestin effects using the LNG-IUS. While PAEC are now well described, considered benign, and seem reversible after cessation of treatment, the mechanism of their development and their long-term significance remain unknown. This constitutes the reason for the clinical recommendation of treatment cessation after three months of continuous PRM use for medical treatment of uterine fibroids and endometrial shedding after PRM treatment to ensure that PAEC disappears before commencing any long-acting contraceptive method. This could though constitute a draw-back in women with uterine fibroids or endometriosis. Additionally, treatment gaps in fertile women can result in unplanned pregnancies.

Limitations, reasons for caution: Since this is a pilot study and no prior similar studies have been conducted, no specific power calculation was performed for the secondary outcome reported. Even though the sample size was small, these data still provide us with unique findings concerning the safety of endometrial morphology following this treatment regimen.

Wider implications of the findings: Our results suggest that it is safe to proceed with a long-acting progestin such as the LNG-IUS immediately after long-term PRM treatment for uterine fibroids or endometriosis. However, the endometrial safety with this or similar treatment regimens needs to be further explored in larger data settings.

Trial registration number: ClinicalTrials.gov NCT01931657

P-291 The impact of chronic endometritis on endometrial receptivity array and pregnancy rates

K. Kuroda[1], T. Horikawa[1], A. Moriyama[1], K. Nakao[1], H. Juen[1], S. Takamizawa[1], Y. Ojiro[1], K. Nakagawa[1], R. Sugiyama[1]

[1]Sugiyama Clinic Shinjuku, Division of Reproductive Medicine and Implantation Research, Tokyo, Japan

Study question: To identify the effects of chronic endometritis (CE) on endometrial receptivity array (ERA) outcomes.

Summary answer: Most patients with CE have 'non-receptive' endometrium in the ERA test.

What is known already: ERA is a novel tool for the objective identification of the personal window of implantation (WOI). CE is a chronic localized inflammatory condition of the endometrium with the CD138-positive plasma cells, yet essentially asymptomatic and undetectable by common infertility testing. Recovery from CE can lead to the improvement of pregnancy outcomes in IVF treatment. CE is associated with decreased expression of decidual markers. Therefore, CE may have adverse effects on endometrium decidualization and formation of an optimal WOI; however, the clinical impact of CE on the ERA test has not been established.

Study design, size, duration: A retrospective cross-sectional study was performed between August 2018 and October 2019 on 66 infertile women who underwent histological examinations and endometrial sampling for ERA testing. The study protocol was approved by the Ethics Committee of Sugiyama Clinic.

Participants/materials, setting, methods: Of 66 women, we recruited 56 who underwent ERA testing and immunohistochemistry (IHC) of CD138 within 3 months. We divided the subjects into 3 groups as follows: women without CE

(non-CE group, n=26), women with untreated CE at the time of ERA (CE group, n=12), and women successfully treated for CE before ERA (cured-CE group, n=18). CE diagnosis was defined as ≥5 CD138-positive cells per 10 nonoverlapping random stromal areas visualized at 400 ×magnification.

Main results and the role of chance: In the non-CE, CE, and cured-CE groups, the number of CD138-positive plasma cells per 10 random stromal areas within 3 months before or after ERA testing were 0.5 ± 0.9, 29.9 ± 31.3, and 0.9 ± 1.0, respectively. The difference in number of CD 138-positive cells between each group was found to be statistically significant ($p < 0.001$). Regarding ERA results, the rate of 'receptive' endometrium in the non-CE and cured-CE groups were 57.7% (15/26) and 55.6% (10/18), respectively; however, in the CE group, the 'receptive' endometrium rate was 8.3% (1/12), which was significantly lower than the other 2 groups ($p < 0.001$). In the CE group, 'non-receptive' endometrium was observed in most patients, including 'late or post-receptive' in 58.4% of patients, on 5 days after the initiation of progesterone administration. When CE was recognized, it was treated with antibiotic therapy prior to ET in all patients. The clinical pregnancy rates in the first ET at the time designated by ERA results in non-CE, CE, and cured-CE groups were 66.7% (14/21), 16.7% (2/12), and 50.0% (8/16), respectively ($p = 0.022$). Despite completion of CE treatment, poor pregnancy rates were observed in the CE group.

Limitations, reasons for caution: In limitations, a retrospective study and the small sample size are the main sources of bias.

Wider implications of the findings: WOI may be negatively affected by CE. And the patients may achieve optimal WOI after proper CE treatment. Therefore, screening and appropriate treatment for CE should be considered prior to ERA testing. Moreover, ERA outcomes in patients with CE may be unreliable.

Trial registration number: not applicable

P-292 Design and evaluation of a novel nanodrug delivery system for reducing the side effects of clomiphene citrate on the endometrium

M. Ajdary[1], R. Aflatoonian[2], F. Keyhanfar[3], F. Amjadi[4], Z. Zandieh , zandie.dvm@gmail.com[4], M. Ashrafi , ashrafi.m@iums.ac.ir[5], M. Mehdizadeh , mehdizadeh.m@iums.ac.ir[6]

Study question: Is there a change in the expression of genes involved in implantation in cells treated with clomiphene citrate compared to clomiphene citrate loaded in PBF?

Summary answer: A significant difference was found between genes involved in the implantation of cells treated with clomiphene citrate compared to clomiphene citrate loaded in PBF.

What is known already: Growing evidence suggests that a disorder of endometrial receptivity may contribute to the adverse reproductive outcomes in the stimulation of ovulation by clomiphene citrate (PCOs). And by developing a slow-release property in lipophilic drugs, Phospholipids can prevent the damage of lipophilic drugs to non-target tissues.

Study design, size, duration: This study was a basic genomic analysis of human endometrial biopsies taken from eight healthy fertile women in the secretory phase.

Participants/materials, setting, methods: PBF containing a mixture of phosal 50PG, glycerol and deionized water was prepared using a probe sonicator. In vitro model, human endometrial cell were into four groups. The control group was incubated only with DMEM medium containing antibiotics and 10% FBS and the experimental groups *co-cultured* with sperm, *co-cultured* with sperm and clomiphene citrate, *co-cultured* with sperm and nano-clomiphene citrate were incubated for 24 h and the next day, cells were harvested for q-PCR.

Main results and the role of chance: The optimized PBF contained Phosal 50PG/glycerol in a 2:8 ratios (w/w) and mean particle size of Nano drug used were 67±9.0 nm, the release of CC from Nano emulsion was slightly faster in the first 24 hours; during this period, 29% of CC was released. After 120 hours 76% of CC was released. The mean mRNA level of MUC1 gene was significantly increased in CC and CC / PBF group compared to control ($P < 0.001$). The mean mRNA level of PGR gene was significantly increased in the sperm-treated group ($P < 0.05$) and in the sperm and PBF group compared to CC ($P < 0.001$). The mean mRNA level of VEGF gene in sperm and PBF group was significantly increased ($P < 0.05$) compared to control and CC / PBF was significantly increased ($P < 0.001$) compared to CC and control.

Limitations, reasons for caution: The main limitation of this study is a low number of human endometrial samples

Wider implications of the findings: Formulation sustained release of clomiphene citrate increased its targeting efficiency and improved the impact of the CC on the serum levels of estradiol and expression of genes involve implantation. A new Phosal-Based Formulation (PBF) was introduced to decrease side effect of clomiphene citrate on endometrium.

Trial registration number: 6736

P-293 Use of a Vaginal Probiotic Suppository and Antibiotics in the Treatment of endometrial microbiota.

D. Kadogami[1], Y. Nakaoka[1], Y. Morimoto[2]

[1]IVF Namba Clinic, medical office, Osaka, Japan ;
[2]HORAC Grandfront Osaka Clinic, medical office, Osaka, Japan

Study question: What is an effective treatment for endometrial microbiota?

Summary answer: The combination use of vaginal probiotic suppository and antibiotics was effective for the treatment of endometrial microbiota.

What is known already: The development of next-generation sequencing (NGS) technologies has made it possible to quantify subdivided bacteria using the variable region of the 16S rRNA gene, enabling a more comprehensive assessment of the microbiota. Through this innovation, various studies have focused on the relationships between the female genital microbiota and pregnancy. Some authors evaluated the endometrial microbiota of IVF patients using NGS and showed that the group with 90% or higher *Lactobacillus(LD)* had significantly higher implantation rates and pregnancy rates than those with less than 90% *Lactobacillus(NLD)* . Therefore, new strategies are needed to improve pregnancy rates in patients with NLD.

Study design, size, duration: Randomized controlled trial in our clinic, between December 2018 to October 2019.
Evaluation of the endometrial microbiota was performed in 224 patients with RIF. NLD cases were randomly assigned to treatment groups that combine Lactoferrin(oral prebiotic), Lebenin(oral probiotic), inVag(vaginal probiotic suppository) and Metronidazole in various ways. Re-analysis was performed after treatments and results were presented as healing rates. The healing rate was defined as the rate of cured cases among treated cases.

Participants/materials, setting, methods: The treatment protocol was determined as follows. Protocol A was Lactoferrin(300mg/day for 30days) and Lebenin(3g/day for 30days), B was Metronidazole(vaginal suppository 250mg, only once and oral 750mg/day for 7days), C combined A and B, D was Lactoferrin(600mg/day for 30days) and Lebenin(3g/day for 30days) and Metronidazole (vaginal suppository 250mg and oral 750mg/day for 7days), E was inVag(1capsule/day for 7days), F was inVag (1capsule/day for 7days) and Metronidazole(vaginal suppository 250mg and oral 750mg/day for 7days).

Main results and the role of chance: Evaluation of the endometrial microbiota was performed in 224 patients with RIF. LD was found in 114 patients (50.9%), whereas NLD was found in 110 patients (49.1%). There were no significant differences in patient backgrounds between groups. In NLD cases, *Gardnerella* was

the most abundant bacteria, and *Atopobium*, *Streptococcus*, and *Prevotella* were detected abundantly, after excluding *Lactobacillus* and *Bifidobacterium*.
About protocol A, B and C, the healing rate was only 30%, and there were no significant differences in healing rate between treatment groups ($P = 0.91$ and $P = 0.60$, respectively). Especially in A, there were no cured cases among patients those *Lactobacillus* proportion was less than 70% before treatment. These results suggested that oral prebiotics and probiotics alone were not sufficient to improve the endometrial microbiota and that antibiotics were necessary. Between C and D, there were no significant difference in healing rate (33.3% versus 32.5%, respectively, $P = 1.00$).

However, higher healing rate was reported in E compared with D(32.5% versus 43.6%, respectively, $P = 0.39$). Further, F had a significantly higher healing rate compared with D(32.5% versus 72.7%, respectively, $P = 0.02$).

Throughout this study, no side effects that were likely related to the medication were observed.

Limitations, reasons for caution: Assessment of the endometrial microbiota requires transvaginal collection of endometrial fluid using a catheter tube, which may cause contamination. Moreover, although NGS is useful for quantifying bacteria, it only measures the bacterial 16S rRNA gene and does not guarantee bacterial viability.

Wider implications of the findings: The endometrial microbiota was evaluated in patients with RIF, and 49.1% of cases had less than 90% *Lactobacillus* . In such cases, probiotics combined with vaginal probiotic suppository and antibiotics proved to be highly effective. In our future studies, we will examine pregnancy rates after treatment of the endometrial microbiota.

Trial registration number: UMIN-CTR 000038582

P-294 Surgical management of deep endometriosis and in vitro fertilization outcomes: A systematic review and meta-analysis

B. Woolnough[1], C. Qianqian Wu[1], T. Vause[1], H. Shenassa[1]

[1]University of Ottawa, Obstetrics and Gynecology, Ottawa, Canada

Study question: In women with deep endometriosis (DE), does surgery followed by in vitro fertilization (IVF) improve fertility outcomes compared to first-line IVF?

Summary answer: Considering limited evidence, surgical management of DE before IVF is associated with improved pregnancy rates but similar live birth rates when compared with first-line IVF.

What is known already: Surgical management of DE in infertile women prior to in vitro fertilization (IVF) is controversial. Surgeries are often invasive and may cause significant complications. Recent evidence suggests that surgery may improve IVF outcomes, however studies have been small and underpowered.

Study design, size, duration: We conducted a systematic review and meta-analysis, which identified studies including a total of 538 women. We searched MEDLINE, EMBASE and the Cochrane Library (inception to October 2019) for studies comparing fertility outcomes in women with DE with and without surgical treatment prior to IVF.

Participants/materials, setting, methods: The study population included all identified women with deep endometriosis who received treatment of either surgery followed by IVF or IVF alone. Study selection, data extraction and quality assessment were conducted independently by 2 reviewers. Meta-analysis was conducted using a random effects model.

Main results and the role of chance: Four studies meeting the inclusion criteria were identified, one prospective and three retrospective cohort studies. Three of these were able to be included in the quantitative meta-analysis. Clinical pregnancy rate was significantly higher in the surgery group (risk ratio [RR] = 1.41; 95% CI = 1.03 to 1.95; P = 0.03; $I^2 = 25\%$). Live birth rates were comparable between the groups (RR = 1.60; 95% CI = 0.97 to 2.62; P = 0.06; $I^2 = 48\%$). The total number of oocytes retrieved, gonadotropin dose used, and miscarriage rates were also similar between the two groups.

Limitations, reasons for caution: The retrospective nature of the included studies permits introduction of bias, limiting the conclusions that can be made.

Wider implications of the findings: The potential benefit of surgery must be weighed against risk, including potential reduction in ovarian reserve. While this study suggests similar outcomes, well-designed and appropriately-powered randomized controlled trials are needed to determine if there is any clinical advantage to surgical management of DE prior to IVF.

Trial registration number: not applicable

P-295 Sonographic Quantification of Myometrial Conditions in Adenomyosis Patients with Computer Assisted Image Analysis-A Pilot Study

S.Y. Chou[1], L. Buo Jia[1], C. Yi-En[1], C. Cindy[1], C. Ching Hui[1], C. Chi-Huang[1]

[1]Taipei Medical University Hospital, Reproductive medicine and science, Taipei, Taiwan R.O.C.

Study question: We examined the diagnostic feasibility of using artificial neural network (ANN)-analyzed sonographic gray-scale histograms to assess myometrial conditions based on serum cancer antigen 125 (Ca-125) levels in patients with adenomyosis.

Summary answer: By analyzing the gray scale histograms of the myometrium on ultrasonographic images, this quantitative approach may help in the initial diagnosis of adenomyosis.

What is known already: The only definitive method for the diagnosis of adenomyosis is to perform a hysterectomy combined with histological examination. However, there is no universal agreement on the exact histological criteria, and the diagnostic methodcannot be made prior to invasive surgery.

The accuracy of using only a serum Ca-125 assay to diagnose adenomyosis remains limited, Ca-125 can help in the initial screenings of women with possible adenomyosis
Ultrasonography technology is a quick, safe, easy to use, and inexpensive modality that makes it possible to recognize adenomyosis without surgery. However, there are no standard diagnostic imaging criteria for adenomyosis.

Study design, size, duration: This was a retrospective observational study of 26 female patients attending Taipei Medical University Hospital, Taiwan for infertility between September 1, 2018 and March 31, 2019.The research protocol of this study was approved by the Institutional Review Board of Taipei Medical University Hospital (IRB number: N201711084).

Participants/materials, setting, methods: A total 54 ultrasonographic images of the myometrium were divided into three groups based on serum Ca-125 levels:15 images from patients with Ca-125 values <35 U/ml, 19 images from patients with Ca-125 values between 35 and 100 U/ml, and 20 images from patients with Ca-125 values >100 U/ml. Each patient with the same machine and settings, and sonographic gray-scale histograms of the endometrium were analyzed with ImageJ image processing software using the ANN model.

Main results and the role of chance: ANN classification was used to characterize the sonographic data. Although the median signal intensity score of the Ca-125>100 group (2333811) was higher than that of the Ca-125<35 group (1652460) and the 35≤Ca-125≤100 group (1915953), Kruska-Wallis statistical analyses indicated no significant difference among groups (p=0.55).

The Youden index is a measure for evaluating the effectiveness of a biomarker. The cut-points of signal intensity scores among the three groups according to the Youden index and their sensitivity and specificity in predicting adenomyosis probability are shown. For the comparison between Ca-125<35 and 35≤Ca-125≤100, the sensitivity and specificity were 36.8% and 86.7%, respectively; for the comparison between Ca-125<35 and Ca-125>100, the sensitivity and specificity were 40% and 93.3%, respectively; for the comparison between 35≤Ca-125≤100 and Ca-125>100, the sensitivity and specificity were 35% and 84.2%, respectively.

This quantitative approach had a high specificity, which might be useful in the early diagnosis of adenomyosis.

Limitations, reasons for caution: This study was highly operator-dependent and did not detract from the observational experience required in ultrasonographic examinations.

The diagnosis was made by ultrasonographic examination, with no histopathological confirmation, which may limit the accuracy of our findings.
The small sample size and irregular distribution of baseline characteristics may have influenced the results.

Wider implications of the findings: In our study, not only the size and volume of the uterus but also its contents and textures were accessed quantitatively by analyzing the gray-scale histogram of the myometrium. Our approach is of great assistance in the initial screening of women with suspected adenomyosis.

Trial registration number: N201711084

P-296 3D-Saline Contrast Sonohysterography in detecting uterine anomalies and pathologies among sub-fertile women and women with AUB

D. Al-Jaroudi[1], F. Khan[1], M. Al-Tannir[2], I. Al Fayyad[2]

[1]King Fahad Medical City, Women's Specialized Hospital, Riyadh, Saudi Arabia ;
[2]King Fahad Medical City, Research center, Riyadh, Saudi Arabia

Study question: Does 3D-SCSH detect both congenital uterine anomalies and uterine pathologies in sub-fertile and AUB patients?
Summary answer: 3D-SCSH detects both congenital uterine anomalies and uterine pathologies in sub-fertile and AUB patients and is a tool to be used when suspecting uterine pathology.
What is known already: Uterine cavity anomalies could be a contributing cause of subfertility in women, and abnormal uterine findings are reported in as many as 50% of women with recurrent implantation failure.
Study design, size, duration: A prospective cohort study was conducted over three years. Total number of 3D-TVS performed was 2,222. 1477 women were from the sub-fertile group and 745 patients from AUB group.
Participants/materials, setting, methods: A prospective cohort study was conducted over three years. The women were recruited from the outpatient department and Reproductive Endocrinology and Infertility Medicine Department. All women of reproductive age group, either with abnormal uterine bleeding (AUB) or sub-fertile underwent 3D-TVS. If initial 3D-TVS detected any uterine abnormality, then the patient was booked for 3D-SCSH. Uterine anomalies were recorded according to the new ESHRE/ESGE classification of uterine anomalies and compared in the two groups.
Main results and the role of chance: Results: Total number of 3D-TVS performed was 2,222. 1477 women were from the sub-fertile group and 745 patients from AUB group. Total of 330 women required 3D-SCSH, of whom 215 (65%) were sub-fertile women, and 115 (35%) were AUB. Uterine anomalies were found in 15 (7%) in the sub-fertile group compared to 2 (1.7%) In the AUB group. The partial septate uterus was the most common finding among the sub-fertile group 7 (3.3%) versus 2 (1.7%) with dysmorphic uterus in the AUB group. Uterine polyps were the commonest uterine pathology in both groups.
Conclusion: 3D-SCSH may detect congenital uterine anomalies in sub-fertile and AUB patients. This diagnostic accuracy may support the adoption of 3D-SCSH as a routine investigation in the evaluation of sub-fertile women prior to IVF.
Limitations, reasons for caution: NA
Wider implications of the findings: The prevalence of uterine anomalies among sub-fertile women was found to be higher in comparison to women with AUB. 3D-TVS and 3D-SCSH are accurate, and safe in determining the prevalence of congenital uterine anomalies in sub-fertile women.
Trial registration number: NA

P-297 Introducing intrauterine antibiotic infusion as a means towards eradicating chronic endometritis and restoring reproductive dynamics: A randomized pilot study

K. Sfakianoudis[1], M. Simopoulou[2], E. Maziotis[2], A. Rapani[2], P. Tzonis[1], N. Nitsos[1], P. Giannelou[2], S. Grigoriadis[2], P. Tsioulou[2], M. Koutsilieris[2], K. Pantos[1]

[1]Genesis, Assisted Conception Unit, Chalandri- Athens, Greece ;
[2]National and Kapodistrian University of Athens, Physiology, Athens, Greece

Study question: Does intrauterine antibiotic infusion in combination with per os administration in patients with Chronic Endometritis (CE) enhance treatment and fertility status?
Summary answer: The combination of oral administration and intrauterine infusion of antibiotics provided enhanced treatment results when compared to oral antibiotic administration for CE patients.
What is known already: An infectious endometrial environment caused by certain pathologies could compromise pregnancy rates for patients pursuing fertility treatment. In the case of persistent endometrial inflammation, a diagnosis of CE may be established. Oral antibiotic administration constitutes the gold standard approach for treating CE cases and has been confirmed to contribute to a clearance rate, albeit without adequate treatment rate.
Study design, size, duration: Women included in the present study were referred for CE investigation following either repeated implantation failure (RIF) (N=40) or recurrent miscarriage (RM) (N=40) originating from natural conception, without any other infertility aetiology. Following diagnosis of CE, patients were randomized into two groups, one receiving oral treatment and the other receiving a combination of oral antibiotics and intrauterine infusion, stratified by the referral diagnosis. Enrolment of patients was performed from March 2017 till February 2019.
Participants/materials, setting, methods: Diagnosis of CE and treatment evaluation were performed by employing hysteroscopic investigation, endometrial biopsy, along with histological analysis and microbiological culture. Patients following successful treatment proceeded with pursuing a pregnancy via natural conception or IVF, according to the original referral diagnosis. Patients presenting with RIF proceeded with a single IVF cycle. Patients presenting with RM were invited to conceive naturally over the course of six months. The study was conducted in a single IVF center.
Main results and the role of chance: The combined oral and intrauterine administration of antibiotics provided statistically significant improved results regarding efficiency of treatment when compared to oral antibiotic administration only (34/40vs25/40; RR:1.36; 95%CI:1.04-1.79; p=0.04). It should be mentioned that the number of treatment days was also statistically significantly increased (29.93vs15.00; p<0.001) in the combination group. Regarding the IVF arm no statistically significant difference was indicated between the combination group (13/18) and the oral administration (9/13) regarding neither clinical pregnancy (CP) (13/18vs9/13; RR:1.04; 95%CI:0.66-1.66; p=0.85) nor live-birth (LB) (13/18vs8/13; RR:1.17; 95%CI:0.70-1.96; p=0.70). Intention-to-treat (ITT) analysis did not alter the results regarding neither CP (RR:1.18; 95%CI:0.71-1.97; p=0.75) nor LB (RR:1.63; 95%CI:0.87-3.04; p=0.20). Regarding the natural conception arm no statistically significant difference was presented between the combination group (11/17) and the oral administration group (7/12) regarding neither CP (11/17vs7/12; RR:1.12; 95%CI:0.66-1.66; p=0.85) nor LB (10/17vs7/12; RR:1.00; 95%CI:0.54-1.87; p=0.98). ITT did not alter the results regarding neither CP (RR:1.49; 95%CI: 0.80-2.78; p=0.34) nor LB (RR:1.35; 95%CI 0.73-2.50; p=0.52). Pooling of data presented a marginally statistically significant improvement in the combination group compared to oral administration regarding both CP (25/40vs16/40; RR:1.56; 95%CI:1.00-2.45; p=0.05), and LB (24/40vs15/40; RR:1.58; 95%CI:1.00-2.05;p=0.05).
Limitations, reasons for caution: The small sample size along with the fact that the study was carried out in a single center are limitations for the study. Moreover, since CE is regarded as a Sexually Transmitted Disease the lack of follow-up regarding the male partner stands as a reason for caution.
Wider implications of the findings: Results indicate that intrauterine antibiotic infusion may hold the key to a long-term effective treatment, extending to establishing a favorable basis for achieving pregnancy for patients diagnosed with CE and subsequent infertility. This study establishes preliminary grounds for conducting research focused on a pharmaceutically developed drug appropriate for endometrial administration.
Trial registration number: Not applicable

P-298 Expression of claudin 3 and caludin 4 in deep endometriosis

M. Mendonça Carneiro[1],[2,3], P. Vidigal[4], L.P. Costa[3], C. Moreira[1], T. Moreira[1], V. Campos[1], P. Gouvea[3], T. Pardini[1], A. Silva Filho[1], I. Ávila[3]

[1]Universidade Federal de Minas Gerais, Obstetrics and Gynecology, Belo Horizonte, Brazil ;
[2]Rede Mater Dei de Saúde, Center for Human Reproduction, Belo Horizonte, Brazil ;
[3]Biocor Instituto, Endometriosis Multidisciplinary team, Belo Horizonte, Brazil ;
[4]Universidade Federal de Minas Gerais, Pathology, Belo Horizonte, Brazil

Study question: To evaluate the association between immunoexpression of claudin 3(CLND-3) and 4 (CLDN-4) with clinical, surgical and biochemical data in women with deep endometriosis (DE).
Summary answer: DE expresses both CLDN-3 and CLDN-4. Expression was weak and not influenced by clinical parameters. CLDN-3 expression was significantly higher and related to disease extension.
What is known already: DE is characterized by lesions which extend more than 5 mm underneath the peritoneum and is responsible for painful symptoms. Numerous molecular abnormalities have been related to DE pathogenesis including immunological, inflammatory, genetic and hormonal alterations. Claudins are

the main junctional proteins between epithelial cells and may be may play a role in tissue remodeling and invasion. CLND-3 and CLDN-4 have been studied in endometrial hyperplasia and cancer with growing evidence showing a possible contribution in their pathogenesis and thus prompted studies to assess their possible role in endometriosis. CLDN3 and 4 have not been studied in DE so far.
Study design, size, duration: women undergoing surgical treatment of DE at a tertiary center (Biocor) with confirmed histological diagnosis from August/2011 to Decemer/2016 comprised the study group whereas the control group included women undergoing surgery for other benign gynecological conditions (pelvic organ prolapse or uterine fibroids) who gave their consent to participate. The study protocol was approved by the local ethics committee.
Participants/materials, setting, methods: Samples were otained during surgery in both groups and prepared for IHC using antibodies for both CLDN-3 and CLDN-4. IHC expression was considered present (+) or absent (-) and intensity classified into three categories: weak (+), moderate (++) and strong (+++ and ++++). IHC was performed with the Streptavidin-Biotin protocol using antibodies against CLDN3 and CLDN4. The data was analysed using the Z test for proportions, Fisher's exact chi-square test and an ordered logistic regression.
Main results and the role of chance: This case-control study involved immunohistochemical evaluation (IHC) of 48 samples from 36 patients undergoing surgical endometriosis treatment at a tertiary center by a multidiscplinary endometrisis team.Thirty-five (73%) subjects had DE diagnosis. CLDN-3 expression was positive in 60% of DE and 80% of CLDN-4 samples. Expression was higher in the intestines (CLDN-3: p 0.016; CLDN-4: p 0.000). In other sites a weak intensity expression predominated, both from CLDN-3 (75.4%) and CLDN-4 (73.8%). Expressions of CLDN-3 and CLDN-4 were not associated with preoperative hormone use, body mass index (BMI), vitamin D, and serum 125 (CA125) antigen. CLDN-3 showed more positivity in the more advanced stages of endometriosis (moderate and severe). CLDN-3 expression was significantly higher than in controls ($p < 0.001$)
Limitations, reasons for caution: Although DE lesions expressed both CLDN 3 and 4, the sample is small and comes form a single center. Claudin 3 and 4 expression was studied only by IHC.
Wider implications of the findings: CLDN-3 expression was significantly higher than in controls and showed more positivity in the more advanced stages of endometriosis (moderate and severe). The role of CLDN3 in DE remains to be established.
Trial registration number: NOT APPLICABLE

P-299 Assessing the endometrium in recurrent implantation failure (RIF) – a prospective controlled cohort study

M. Hviid[1], T. Hallager[2], G. Persson[3], L. Grupe[2], K. Birch Petersen[4], T.V. Hviid[3], N.S. Macklon[4]

[1]Zealand University Hospital, Department of Gynaecology- Obstetrics- and Fertility, Roskilde, Denmark ;
[2]Zealand University Hospital, Pathology Department, Roskilde, Denmark ;
[3]Zealand University Hospital, Department of Clinical Biochemistry, Roskilde, Denmark ;
[4]Zealand University Hospital, Department of Gynaecology- Obstetrics and Fertility, Roskilde, Denmark

Study question: What markers of endometrial dysfunction can be identified among women experiencing RIF and do they differ compared to control patients?
Summary answer: Women with RIF reveal a range of endometrial dysfunctions different in prevalence from control patients.
What is known already: The endometrial factor is recognized as a cause of RIF. However, management remains largely empirical and of questionable efficacy. There is a need to guide therapy by making an endometrial diagnosis where possible.
Study design, size, duration: Prospective controlled cohort study. Between November 2017 – September 2019, 86 women with a history of RIF (defined as failure to conceive after at least three transfers of high quality embryos), referred to a University Hospital-based 'Implantation Clinic', and 37 women with no history of RIF underwent timed endometrial diagnostic profiling in a hormone substituted cycle. Samples were collected throughout the span of a year.
Participants/materials, setting, methods: Endometrial and blood profiling was carried out in all participants in a hormone substituted cycle using estradiol and progesterone and sampled after five days of progesterone treatment. Endometrial biopsies were analysed by histology, immune cell profiling (CD56, CD16, CD163, CD138, regulatory T cells), and gene expression (ERA® test, Igenomix, Spain). The vaginal microbiome was analysed using a NGS technology (ArtPRED®, The Netherlands). Blood tests included estradiol, progesterone, prolactin, TSH, anti-phospholipid screening, and vitamin D.
Main results and the role of chance: Patients with RIF demonstrated different individual endometrial profiles, indicating that a 'one treatment fits all' approach is inappropriate. Compared with controls, women with RIF demonstrated a higher prevalence of chronic endometritis as defined by cells staining positive for CD138 by immunohistochemistry (25% vs. 3% in the control cohort, $p = 0.004$), a lower mean level of vitamin D (43 nmol/L vs. 51 nmol/L; $P = 0.04$), and a borderline lower mean mid-luteal phase progesterone (39 nmol/L vs. 44 nmol/L; $P = 0.08$). Compared with controls, women with RIF appeared to have a higher prevalence of a vaginal microbiome reported to be predictive of implantation ($P = 0.04$). While the RIF cohort was slightly older than the controls (mean age 33.8 years vs. 30.2 years $P = 0.0001$) no differences between the two groups were observed with regard to AMH, BMI, anti-phospholipid antibody prevalence, mean mid-luteal estradiol, prolactin, TSH levels, number of CD56 cells, CD16 cells, regulatory T cells or macrophages present in the mid-luteal endometrial biopsy.
Limitations, reasons for caution: The tests performed in the study were taken in a standardised hormone substituted cycle and results should be interpreted in that clinical context. The control cohort consisted of women referred for fertility treatment with male factor infertility or tubal factor, hence not representing a proven fertile population.
Wider implications of the findings: Diagnosing the endometrium in women with RIF permits targeted rather than blind empirical interventions. Relative Vitamin D deficiency, lower mid-luteal progesterone, and chronic endometritis are ready targets for treatment. Understanding the role and treatment of an unfavourable vaginal microbiome needs further investigation.
Trial registration number: REG-117-2017

P-300 Differences in the effects of metformin treatment on viability and migration of endometrial cancer cells in a normal or high glucose environment

C. Lange[1], A. Machado Weber[1], T. Strowitzki[1], A. Germeyer[1]

[1]University Women's Hospital Heidelberg, Department of Gynecological Endocrinology and Fertility Disorders, Heidelberg, Germany

Study question: Does metformin treatment have effects on cell viability and migration of endometrial cancer cells and do these effects vary in a normal or high glucose environment?
Summary answer: Metformin decreased cellular viability and migration in endometrial cancer cell lines. However, variation of glucose levels had no effect on cellular viability and migration.
What is known already: Endometrial cancer (EC) is one of the most common gynecological malignancies and can occur in an estrogen-dependent (type I, 70 – 80 %) or a more aggressive estrogen-independent form (type II). High estrogen levels, e.g. due to metabolic syndrome and associated polycystic ovary syndrome (PCOS), or hyperglycemia, e.g. in due to diabetes, increase the risk of developing EC and lead to higher mortality, especially in obese women. Metformin, an anti-hyperglycemic and insulin sensitizing drug, is used in the treatment of type II diabetes mellitus. However, anti-cancer effects have been observed in several studies, but detailed information is lacking for EC.
Study design, size, duration: In the present *in vitro* study, EC cells were cultured in normal (NG; 5.5 mmol/L, equivalent to 100 mg/dL) or high (HG; 17.0 mmol/L, equivalent to 306 mg/dL) glucose media (supplemented with 10 nmol/L ß-estradiol) and treated with metformin (0.1–20.0 mmol/L) over a period of 7 d. Cells were subsequently analyzed for changes in cell viability and migration rates. Untreated cells served as controls. Data was obtained from at least three independent experiments.
Participants/materials, setting, methods: The study was carried out with the two different EC cell lines HEC-1A (type II) and Ishikawa (type I). The analysis of cellular viability was based on mitochondrial dehydrogenase activity in the

MTT assay. The migration of the cells was analyzed by changes in scratch area in the wound healing assay.
Main results and the role of chance: A dose-dependent decrease of cellular viability was observed for HEC-1A and Ishikawa cells after metformin treatment, irrespective of glucose levels. At a concentration ≤0.1 mmol/L, viability remained ≥80% compared to untreated controls, both in a normal and high glucose environment. Viability dropped to ≤10% at concentrations >5.0 mmol/L (HEC-1A) and 10.0 mmol/L (Ishikawa) under any tested condition. IC_{50} values for Ishikawa cells were 5.10 mmol/L (NG; IC_{90}: 44.4 mmol/L) and 3.90 mmol/L (HG; IC_{90}: 33.7 mmol/L). For HEC-1A cells, an IC_{50} value of 0.75 mmol/L (NG; IC_{90}: 6.83 mmol/L) was established. The wound healing assay revealed that the ability to migrate into the scratch area decreased with increasing metformin concentrations, but independent of glucose levels. For HEC-1A control cells, 70% (NG) and 56% (HG) of the scratch area was covered with cells 24 h after wounding of the cell monolayer. After treatment with 0.5 mmol/L metformin, the wounded area was invaded by 53.4% (NG) and 45.4% (HG), respectively, and only by 17.7% (NG) and 20.8% (HG) at 5.0 mmol/L metformin. The same effect was observed with Ishikawa cells, although migration was generally lower. Metformin at 5.0 mmol/L even led to a small enlargement of the wound area by 2.6% (HG).
Limitations, reasons for caution: The results are obtained in an *in vitro* study with human cancer cell lines, and thus cannot be easily extrapolated to patients.
Wider implications of the findings: Results suggest that metformin treatment can lower the migration ability of EC cells, especially of the more aggressive type II. Therefore, metformin may also be able to prevent EC development in patients at high risk, e.g. with high estrogen levels (metabolic syndrome and PCOS), hyperglycemia (type II diabetes) or obesity.
Trial registration number: not applicable

P-301 E-cigarettes smoke impairs endometrial receptivity

A. La Marca[1], S. Sacchi[1]

[1]University of Modena and Reggio Emilia- and Clinica Eugin, Mother-Infant Department, Modena, Italy

Study question: Are e-cigarette (e-cig) liquids and nicotine metabolites able to alter the receptivity of stromal endometrial cells (ESC)?
Summary answer: Different e-cigarette liquids and nicotine metabolites affect ESC receptivity and viability with different efficiency by down-regulating implantation marker genes expression and promoting apoptosis of ESC
What is known already: E-cigarettes are instruments that transform a solution of propylene glycol and nicotine in a nicotine-containing aerosol by heating. Studies show that in e-cigarette not-combustion products a number of potentially toxic substances are present. While diseases in heavy cigarette smokers are well documented, the effect of e-cigarettes has been less studied. It has been shown that e-cigaretees may induce acute endothelial dysfunction and promote vascular oxidative stress. Many women are nowadays preferring this way of somoking. However only few works have analyzed effects of e-cigarette on fertility with results that are indicating a possible detrimental effect of these substances on fertility
Study design, size, duration: Endometrium sample biopsies were collected during the proliferative phase of the menstrual cycle from patients undergoing diagnostic hysteroscopy, dissected in smaller pieces then digested with collagenase. Primary cultured ESC were cultured until confluence. ESC were then treated for 1 and 3 hours with different doses of e-cigs liquids or nicotine metabolites (benzo-a-pyrene, cotinine and nicotine ditartrate)
Participants/materials, setting, methods: Primary cultures of endometrial cells were adopted as experimental model (n=7). Treated ESC were processed for total RNA extraction. Gene expression of HOXa10, mucin-1, β3 integrin (implantation marker genes) and FAS (pro-apoptotic gene) normalized by β-actin reference gene, was evaluated by RT-qPCR. Reactions were repeated in triplicate. Cells viability was evaluated by Trypan blue exclusion assay. Statistical analysis was performed with Kruskal-Wallis test followed by the Dunn-Bonferroni's test ($P < 0.05$).
Main results and the role of chance: All the treatment tested showed that e-cigarette liquids and nicotine metabolites are able to significantly down-regulate the expression of implantation marker genes although with different efficiency. E-cig liquids tested (propylene glycol and propylene glycol additioned with 18 mg/ml of nicotine) were all able to down-regulate 1.8-2 folds the HOXa10, mucin-1 and β3 integrin expression when compared to benzo-a-pyrene, cotinine and nicotine ditartate metabolites. E-cigarette liquids increased the relative expression of 2.7 fold of the pro-apoptotic gene FAS if compared to the induction generated by nicotine metabolites. E-cig liquids treatments resulted in higher percentage of cell death after 1 hour incubation (54.4% Vs 31.3%) if compared to nicotine metabolites. After 3 hours of treatments the rate o fcell death was 93.8% for e-cig liquids vs 64.8% for nicotine metabolites.
Limitations, reasons for caution: This study was conducted *in vitro*. Results obtained should be possibly confirmed *in vivo* in the context of the whole human endometrial tissue. Longer incubation to test long-term effects were not possible due to high cell death observed after 3 hours exposure.
Wider implications of the findings: This study demonstrates that e-cigarettes liquids have the same or even higher detrimental effect on the receptivity of endometrium than nicotine metabolites.
Trial registration number: na

P-302 Combined approach to treating endometriosis-associated infertility

N. Artymuk[1], L. Danilova[1], O. Zotova[2]

[1]Kemerovo State Medical University, Obstetrics and Gynecology Department, Kemerovo, Russia C.I.S. ;
[2]Kemerovo Regional Clinical Hospital, Gynecological Department, Kemerovo, Russia C.I.S.

Study question: To comparatively evaluate the effectiveness and compliance of a combined approach to treatment of patients with endometriosis-associated infertility using gestagen and a gonadotropin-releasing hormone agonist.
Summary answer: The use of gestagen and GnRH agonist in the combined therapy of patients with endometriosis-associated infertility and pelvic pain has similar efficacy, but different compliance.
What is known already: Endometriosis affects approximately 10% of reproductive-age women and at least one third of women with infertility. Prevalence of endometriosis has increased up to 50 % in women with infertility. Many studies have now shown that medical treatment for endometriosis does not improve fertility. Hormonal treatment of endometriosis cannot improve fertility and, therefore, their use only leads to delayed pregnancy. In accordance with the recommendations of the CNGOF-HAS, NICE, ESHRE guidelines, suppression of ovarian function should not be prescribed to improve fertility. Nevertheless, a combined approach in the treatment of endometriosis-associated infertility may have advantages in patients with severe pelvic pain.
Study design, size, duration: This was a randomized, open-label, monocentric trial. The study included 150 patients with histologically confirmed endometriosis-associated infertility, by excluding other causes of infertility. Patients from Group I (n=75) after surgical treatment (ablation and/or excision) has been administered the GnRH agonist (buserelin or diphereline) at a dose of 3.75 mg once every 28 days for 3 months. Patients from Group 2 (n=75) prescribed gestagen (dienogest) at a dose of 2 mg daily for 6 months continuously.
Participants/materials, setting, methods: All patients (n=150) underwent laparoscopy and surgical treatment of endometriosis (ablation and / or excision). Almost half of patients with endometriosis-associated infertility from groups I and II (45.3% and 45.3%, respectively) had stages III and IY of the disease. The predominant localization of endometriosis in infertile patients of both groups was the pelvic peritoneum (60%), the sacro-uterine ligaments (88%) and the ovary (44%). After medication therapy, primary and secondary outcomes were assessed.
Main results and the role of chance: The combined treatment of endometriosis-associated infertility via surgery, followed by the administration of both the GnRH agonist and dienogest, was highly similar effective in reducing the symptoms of endometriosis, such as pelvic pain - OR 1,95 [1,01- 3,77] (p=0,051), dysmenorrhea - OR 1,14 [0,56-2,29] (p=0,720), dyspareunia - OR 1,55 [0,77-3,10] (p=0,218), and bleeding - OR 1,44 [0,54- 3,81]. The spontaneous pregnancy rate in both groups was similar, respectively, OR - 0.948 [0.49-1.80] (p = 0.870). The fetal heartbeat registration rate at 12 weeks and live births did not differ statistically significantly between the Groups, however, patients who

were administered aGnRH had a tendency to increase the frequency of non-developing pregnancy - in 17.3% and 9.3% - OR 2.04 [0, 76-5.43], and a lower frequency of live births (p = 0.489). Clinically significant side effects were observed in 92% (69) of patients who were prescribed aGnRH and 16% (12) of women who were administered dienogest - OR 60.375 [21.387-170.441] (p <0.001). The most significant side effects in Group I were: hot flashes (82.7% (62)), decreased libido (74.7% (56)) and sweating (60.0% (45)), in Group II - decreased libido (16 % (12)).

Limitations, reasons for caution: The trial is limited in sample size, single-center, no registration number. Further extensive randomized multicenter studies are required to confirm the benefits of administering gestagens in combination therapy for patients with endometriosis-associated infertility and pelvic pain.

Wider implications of the findings: Both approaches to the management of patients with endometriosis-associated infertility and pain can be successfully used, however, the administration of gestagen has advantages due to the lower incidence of side effects.

Trial registration number: No

P-303 Green tea extract administration reduces MDA level, TNFa expression and endometriotic implants area in mice

Y. Trisetiyono[1], S.T. Hidayat[1], N. Pramono[1], W. Widjiati[2]

[1]Diponegoro University, Department of Obstetrics and Gynecology, Semarang, Indonesia ;
[2]Airlangga University, 2Department of Embryology, Surabaya, Indonesia

Study question: Can the green tea extract (GTE) decrease oxidative stress, inflammation, angiogenesis, and reduce the extent of endometriosis implants in mice?

Summary answer: GTE administration resulted in lower malondialdehyde (MDA), tumor necrosing factor-alpha (TNF-a), and smaller endometriotic implant, but no effect on vascular endothelial growth factor (VEGF).

What is known already: Several studies showed GTE contains catechins, which is a powerful antioxidant, may decrease MDA titer. It also had anti-inflammatory action by regulating the expression of inflammatory cytokines and enzymes. Other studies in mice also found that GTE inhibited microvessel formation in endometriotic implants by selectively suppressing VEGF. Some previous studies also revealed the GTE administration on endometriosis mice induced regression of this disease.

Study design, size, duration: This is an experimental study in mice. The size of the sample was obtained by using the equation of resources formula (21 mice). This research had been done in 3 months (October-December 2017).

Participants/materials, setting, methods: Twenty-one Balb/c female mice were divided into the control (C) group consisted of 7 untreated endometriosis mice model, the second group injected with 1 mg/kg BW leuprolide acetate (LA), and the third group given with 200 mg/kg BW/day GTE. MDA level was measured by spectrophotometry, TNF-a, and VEGF expression by IHC, whereas the area of the endometriotic implants was measured using computerize tracing.

Main results and the role of chance: Compared to MDA serum in the C group, both GTE and LA administration to endometriosis mice resulted in a significantly lower level (p=0.000), but they did not affect to VEGF expression (p=0.123). Only GTE has a significant effect of lowering TNF-a expression compared to the C group (p=0.04). Finally, the area of the endometriotic implants in the GTE and LA groups was smaller than the C group (p=0.008).

Limitations, reasons for caution: The treatment given to each group in different ways that may affect the pharmacological treatment and the body's response of the mice. The study also did not combine GTE and LA, so it did not answer whether GTE can strengthen the therapeutic effect of LA on endometriosis in mice.

Wider implications of the findings: The overall results of this study show that GTE has a good effect on endometriosis disease. Thus, further investigation is needed to be conducted to consider green tea as herbal medicine that can be used as an alternative therapy for endometriosis.

Trial registration number: not applicable

P-304 Autologous platelet-rich plasma optimizes endometrial thickness in women with refractory thin endometrium of varied aetiology during fresh and frozen-thawed embryo transfer cycles

Y. Dogra[1], N. Singh[1]

[1]All India Institute of Medical Sciences, Division of Reproductive Medicine-Department of Obs and Gynaecology, New Delhi, India

Study question: Does platelet-rich plasma (PRP) alters the endometrial milieu making it receptive to an embryo in women with persistent thin endometrium due to varied aetiology?

Summary answer: PRP enhances the endometrial thickness (EMT) significantly in both fresh and FET cycles in thin endometrium associated with tuberculosis(TB), PCOS and Diminished Ovarian Reserve (DOR).

What is known already: Autologous PRP increases endometrial thickness during Frozen thawed Embryo transfer (FET) in women with previous cancelled cycles due to refractory thin endometrium despite hormone replacement therapy (HRT). Limited literature is available regarding the effect of PRP in women with persistent thin endometrium planned for Fresh IVF-ET cycles as well as in thin endometrium due to different etiological factors. The role of PRP specific to underlying etiology of thin endometrium has not been studied earlier.

Study design, size, duration: A prospective interventional cohort study was conducted at Reproductive Medicine Centre at a tertiary care institute. Women with persistent thin endometrium despite HRT were enrolled in the study during a period from December 2018 to December 2019. Eighteen women underwent 21 cycles of intrauterine PRP administration during fresh and frozen embryo transfer cycles. Autologous venous blood was used to prepare PRP using double centrifuge technique .

Participants/materials, setting, methods: Women who were declined fresh IVF-ET cycles because of persistent thin endometrium were selected. PRP was administered during unstimulated cycle on day 8/9 and repeated after 48 hours until ET reached 7 mm. Women who achieved adequate ET were only enrolled. During fresh IVF, if endometrium was inadequate on day 8, PRP was infused and repeated after 48 hours if required. Women with history of prior cancelled cycles were also enrolled for PRP during FET.

Main results and the role of chance: Out of 18 patients, 11 had tubal factor with either hysteroscopic or laparoscopic evidence of TB, 4 patients had DOR, and 3 had PCOS as cause of infertility. Out of 21 PRP cycles in 18 patients, 12 had fresh IVF and 9 had FET. Data obtained was analysed using STATA (version 12.0). Mean age was 31.81±3.5 years. Mean baseline ET was 4.76±0.72 mm. Mean ET after HRT was 5.45±0.53 mm. During Fresh IVF, mean ET before PRP was 5.87 ± 0.86 mm and after PRP was 7.2 ± 0.5mm (t -7.737, df 11, p-value 0.000) with average increase of 1mm. During FET cycles, mean ET before PRP was 5.5±1.02 mm and after PRP was 7.2 ± 0.75mm (t -4.703, df 8, p-value 0.002) with average increase of 0.9mm. There was no significant difference between clinical pregnancy rate (CPR) and implantation rate (IR) in fresh vs FET cycles(25% and 13.7% vs 11.1% and 4.5%, p=0.6). The average increase in ET after first PRP was significant in both TB and DOR (1mm and 1mm, $p < 0.05$) as compared to PCOS (0.7mm, p= 0.07). There was no significant difference in CPR among three etiological factors (23% vs 20% vs 0%, p=0.99).

Limitations, reasons for caution: The limitation of present study is its small sample size. However, the study is currently being endeavoured, and these are the interim results of the same. Further, more extensive studies in broader horizons are required to assess the efficacy of PRP on thin endometrium of various pathophysiologies.

Wider implications of the findings: The present study favours the role of PRP in women who were deferred to undergo IVF or to opt for surrogacy because of their refractory thin endometrium. PRP should be administered to improve the reproductive outcome only in the selected group of population with a persistent thin endometrium.

Trial registration number: CTRI/2018/12/016799

P-305 Microbial roadmap along the menstrual cycle: a new approach to identify active microorganism in the uterus

A. Sola-Leyva[1,2], N.M. Molina[1,2], E. Andrés-León[3], J. Plaza-Díaz[4], M.J. Sáez-Lara[1], J. Fontes-Jiménez[2,5], J. Mozas-Moreno[2,5], B. Romero-Guadix[2,5], S. Ruiz-Durán[2,5], L. Martínez-Navarro[2,5], S. Altmäe[1,2,6]

[3]Instituto de Parasitología y Biomedicina "López-Neyra" CSIC, Unidad de Bioinformática, Granada, Spain ;

[4]University of Granada- Faculty of Pharmacy, Biochemistry and Molecular Biology II, Granada, Spain ;
[5]HU Virgen de las Nieves, U. Reproducción- UGC Laboratorio clínico y UGC Obstetricia y Ginecología, Granada, Spain ;
[6]Competence Centre on Health Technologies, Biotechnology Company, Tartu, Estonia

Study question: Does endometrium harbour functionally active microorganisms and whether these microbes differ between proliferative and mid-secretory phases?
Summary answer: Endometrium possesses active microorganisms, and the composition and metabolic function of these microorganisms change along the menstrual cycle.
What is known already: Endometrium harbours its unique microbial composition, however, as all the microbiome studies are based on microbial DNA sequence analysis, there is no knowledge whether these detected bacterial sequences reflect functionally active/alive bacteria within the uterus. Additionally, it is not clear whether there are microbial changes along the menstrual cycle, as a number of studies have detected no microbiome differences between different menstrual cycle phases, while other studies have noticed differences. Thus, whether endometrium harbours alive microbes and whether there are changes along the menstrual phase remains an open issue.
Study design, size, duration: RNA-seq data from 14 endometrial paired samples from healthy women, 7 samples from the mid-secretory phase and 7 samples from the consecutive proliferative phase were analysed for the microbial RNA sequences.
Participants/materials, setting, methods: The raw RNA sequencing data was converted into FASTQ format using SRA Toolkit. In order to eliminate rRNA reads SortMeRNA software was used. R package MetagenomeSeq was used for metataxonomic microorganismal analyses and HUMAnN2 algorithm was used for functional metagenome. The microbial maps were created using Kraken metagenomic sequence classification. With this approach we were able to identify and map the 'active' microorganisms within the samples.
Main results and the role of chance: With our study approach we were able to map the existing functionally active microorganisms in the endometrium along the menstrual cycle. Microbes such as bacteria, fungi, viruses and archaea were identified. At the taxonomical level, after stringent multiple correction, significant differences in the microorganismal composition between proliferative and mid-secretory phases were detected. Further, these microbes were involved in different metabolic functions, where amino acid and carbohydrate metabolisms were more active in the proliferative phase while lipid and energy metabolisms were more active in the secretory phase.
Limitations, reasons for caution: These first pilot study results should be confirmed in a bigger sample size.
Wider implications of the findings: Our study confirms the presence of 'active' bacteria, fungi, viruses and archaea in the human uterus. We detected significant differences in the microbial composition and the involved metabolic functions between the proliferative and mid-secretory phases. Our study findings support the hypothesis that endometrial microbiome plays role in the endometrial functions.
Trial registration number: not applicable

P-306 Heat Shock Protein 90 Inhibitor 17-AAG Inhibits Proliferation of Human Endometriotic Stromal Cells by Repressing Estrogen Receptor Transcriptional Activity.

J. Li[1], P. Chen[2], X. Liang[1]

[1]the Sixth Affiliated Hospital- Sun Yat-sen University, Reproductive Medicine Research Centre, Guangzhou- Guangdong, China ;
[2]the First Affiliated Hospital- Sun Yat-sen University, Department of Pharmacy, Guangzhou, China

Study question: HSP90 is known to be associated with estrogen receptor (ER) and regulates ER mediated cell proliferation. Whether 17-AAG, a HSP90 inhibitor, suppresses the growth of endometriotic cells is still unknown.
Summary answer: 17-AAG could control the progress of endometriotic stromal cells in vitro via inhibiting transcriptional function of the estrogen receptor.
What is known already: The prevalence of endometriosis is between 2% and 10% in the general population and 50% in the infertile population. Current medical treatments such as GnRH agonists and oral contraceptives, are often associated with high recurrence rates and side effects such as hot flushes, episodes of depression and iatrogenically induced osteoporosis. The identification of new compound candidates for endometriosis treatment is needed. Endometriosis is an estrogen-dependent disease. ER is a nuclear receptor that controls the expression of estrogen responsive genes containing estrogen-responsive elements (EREs). Hsp90 is essential for ER binding to the EREs.
Study design, size, duration: Patient recruitment was carried out at the Sixth Hospital of Sun Yat-sen University. Ectopic endometrium (endometriotic tissue, n=12) was collected from patients with ovarian endometriotic cysts undergoing laparoscopy from January 2018 to January 2019.
Participants/materials, setting, methods: Primary cultured human endometriotic stromal cells were seeded and incubated with 10nM, 100nM, 1μM and 10μM 17-AAG for 24 h. Cell viability was tested by MTT assay. Cell proliferation was detected by a colorimetric BrdU incorporation assay. Caspase-3 activity was assessed by Caspase-Glo luminescent-based assays. Transcriptional activity of ER was measured by transient transfection of an ERE-tk-Luc reporter construct that contained the consensus ERE sequences. Luciferase activity was performed to evaluate the activity of ER.
Main results and the role of chance: 17-AAG inhibited the viability of human primary endometriotic stromal cells in a dose-dependent manner from the concentration of 10nM. The growth inhibition by 17-AAG started at 100nM and increased up to 10 μM. The caspase-3 activities were enhanced 2-, 8-, and 11-folds in endometriotic stromal cells after 100nM, 1μM and 10μM 17-AAG treatment for 24h. Similarly, transcriptional activity of ER were inhibited significantly by 17-AAG in a dose-dependent manner.
Limitations, reasons for caution: An experimental mouse model should be established to evaluate the therapeutic effect of 17-AAG. Further molecular mechanism of 17-AAG on ER transcriptional function also need to be explored.
Wider implications of the findings: HSP90 inhibitor controls the development of endometriosis by repressing transcriptional activity of ER. HSP90 inhibitor could provide a valuable tool for better understanding of estrogen signaling, as well as for potential clinical use against estrogen-related diseases of women, including endometriosis.
Trial registration number: not applicable

P-307 Pharmaceutical targets of endometriosis for medical treatment: a systematic review

S.W. Hung[1], R.Z. Zhang[1], C.C. Wang[1]

[1]The Chinese University of Hong Kong, Department of Obstetrics & Gynaecology, Hong Kong, Hong Kong

Study question: Is there any targeted therapy available for treatment of endometriosis?
Summary answer: Approaches through specific-target, multi-targets, or a combination hold their promises to treat endometriosis and manage the complexity of pathophysiology.
What is known already: Growth and development of the endometriotic cells in ectopic sites can be promoted by multiple pathways, including proliferation, anti-apoptosis, migration, invasion, immune escape, inflammation, oxidative stress, angiogenesis, and disrupted autophagy. Endometriosis causes a negative impact on life quality, productivity and infertility. Current medical treatments for endometriosis are rather empirical and incurable. Endometriosis surgery is often performed to improve infertility. Effective medication for specific molecular and signalling pathways is limited.
Study design, size, duration: We systematically reviewed literatures that focused on pharmaceuticals targeting specific molecular and signalling pathways in endometriosis. Selected publications included both animal and human studies; in-vivo or in-vitro. We gathered high quality research studies of 150 publications to summarise the results.
Participants/materials, setting, methods: Literature search was performed using PubMed, Medline and Google Scholar for original articles that were written in English and Chinese. PRISM flowchart and Endnote were used for better management of the searches. We assessed the study quality by critically apprising their appropriateness to the research objective and outcome reproducibility. We presented the data narratively to update the research progress on the medical treatment in endometriosis.

Main results and the role of chance: Akt, ERK, MAPK, MTor, NF-κB, P13K, ROCK, ROS, TNF, Wnt, VEGF, estrogen, cytokines and their upstream and downstream molecules are the key aberrant signalling and regulatory pathways promoting growth and development of endometriotic cells and tissues. Pharmaceuticals targeting these molecules were identified, amongst which Western medicines focus on pain relief and anti-proliferation, such as hormonal (e.g. Dienogest, Aromatase inhibitors) targets on ER stress, estrogen receptors, or TNFα to inhibit NFκB; as well as non-hormonal (e.g. Pentoxifylline, Sunitinib) targets on VEGF and VEGFR for anti-angiogenesis. Natural products and Chinese Medicines aim to reduce chronic pain, resolve infertility and improve quality of life with few side-effects. They mainly regulate blood flow through targeting on superoxide anion and catalase as radical scavengers for anti-oxidation (e.g. EGCG, Glycyrrhizae Radix, Ligusticum Rhizoma) and cytokines and TNFα for anti-inflammation (e.g. Genistein, Angelicae Sinensis Radix, Bupleuri Radix). Chinese Medicine decoctions often contain many individual herbs, so multiple targeting on several pathways with synergistic efficacy and better outcomes.
Limitations, reasons for caution: Non-hormonal treatments are mostly under clinical trials or only studied in in-vitro or animal model. There are lack of experimental and clinical evidences to support its effectiveness and safety of TCM and natural products in alleviating the pathogenesis of endometriosis, when it is compared to western medicine.
Wider implications of the findings: New drugs to treat endometriosis and disease related symptoms and complications, with high efficacy, reduced off targets and other side effects, can be further developed based on knowledge of molecular targets. A detailed protein-protein network helps with target deconvolution for therapeutically known compounds.
Trial registration number: NA

P-308 Do PGT-M patients have a higher prevalence of thin endometrial lining and is this explained by prior prolonged hormonal contraceptive use?

I. Homminga[1], E. Ter Meer[1], H. Groen[1], A. Cantineau[1], A. Hoek[1]

[1]University of Groningen-University Medical Center Groningen, Obstetrics and Gynecology, Groningen, The Netherlands

Study question: Is thin endometrial lining on the day of hCG triggering more prevalent in PGT-M patients than in non-PGT patients, and related to differences in previous hormonal contraceptive use?
Summary answer: Endometrial lining <8mm is more prevalent in PGT-M patients compared to non-PGT patients, and this is related to prolonged hormonal contraceptive use up until IVF-treatment.
What is known already: Thin endometrial lining has been associated with lower pregnancy rates in multiple studies. We seemed to notice an increased prevalence of thin endometrial lining in patients attending our clinic for pre-implantation genetic testing for monogenetic disease (PGT-M). We hypothesized this could be due to a prolonged use of hormonal contraceptives up until the start of the PGT-IVF/ICSI treatment, which is typical for this patient group, as they usually want avoid spontaneous pregnancies. Though it is well known that endometrial thinning occurs during the use of e.g. oral contraceptives, little is known about a possible lingering of this effect after cessation.
Study design, size, duration: A retrospective cohort study was performed, including all PGT-M patients attending the University Medical Centre Groningen, between 2009 and 2018. For each PGT-M patient, two non-PGT IVF/ICSI patients (indication male factor, tubal factor or unexplained subfertility) were included, matched for age and treatment period. Prevalence of thin endometrium (<8mm) on the day of hCG triggering was compared between PGT-M and non-PGT patients. Hormonal contraceptive use (both duration and cessation period) was compared between both groups.
Participants/materials, setting, methods: 122 PGT-M patients and 240 non-PGT patients were included. Only first ovarian hyperstimulation IVF/ICSI cycles were included. Patients with endometriosis, PCOS or uterine abnormalities were excluded. Data on history of hormonal contraceptive use prior to the treatment was obtained from patient questionnaires, both duration (years) and cessation period were included. Cessation categories were <1 year (late cessation) or >1 year (early cessation) before treatment. Endometrial thickness was measured on day of HCG triggering.
Main results and the role of chance: Thin endometrium (< 8 mm) on the day of hCG triggering was found significantly more often in the PGT-M group, compared to the non-PGT group: 32% (95%CI: 23%-40%) versus 11% (95%CI: 7%-15%). As expected, more patients in the PGT-M group ceased their hormonal contraception late: 64% (95%CI: 55%-73%) versus 2% (95%CI: 0%-4%) in the non-PGT group. Average duration of hormonal contraceptive use was longer in the PGT-M group than in the non-PGT group (10,6 years SD 4,3 versus 9,3 years SD 4,5, p=0,02). To determine which factors were significant independent predictors of thin endometrium, a multivariate logistic regression analysis was performed including the following variables: PGT-M yes/no, duration of hormonal contraceptive use (years), late cessation yes/no, age, BMI, parity, previous curettage and number of dominant follicles. Only late cessation (OR: 5,1, 95%CI:1,5 – 16,7) and duration of hormonal contraceptive use (OR 1,1, 95%CI: 1,0-1,3) remained significant independent predictors. The odds ratio for PGT-M to predict a thin endometrium changed from 3.8 (95%CI:2,2-6,7) in an univariable analysis to 1,1 (95%CI: 0,3-3,3) in the multivariable analysis, suggesting that the difference in prevalence of thin endometrium between PGT-M and non-PGT patients could be attributed mainly to differences in prior contraceptive use.
Limitations, reasons for caution: The study is retrospective, using self-reported data. Different types of hormonal contraceptives were reported (e.g. levonorgestrel IUD, oral combined contraceptives) which possibly exert different effects on the endometrium, however, study size was too small to make separate analyses.
Wider implications of the findings: This study provides further insight to a possible contributor to the occurrence of thin endometrium: prior hormonal contraceptive use. Future studies should provide more information on its clinical relevance, to determine whether PGT-M patients can be reassured or should be advised to stop hormonal contraceptives in advance of their treatment.
Trial registration number: not applicable

P-309 High pregnancy rate with customized embryo transfer after endometrial receptivity assessment using a transcriptomic approach in patients candidate for eggs donation program

D. Haouzi[1], F. Entezami[2], A. Ferriere-Hoa[3], C. Mauries[3], A. Gala[3], E. Vintejoux[3], C. Brunet[3], C. Vincens[3], S. Bringer-Deutsch[3], S. Brouillet[3], S. Hamamah[3]

[1]INSERM U1203, IRMB- Hôpital St-Eloi- CHRU Montpellier, MONTPELLIER, France ;
[2]American Hospital of Paris, IVF department, Neuilly-Sur-Seine, France ;
[3]Arnaud de Villeneuve hospital- CHU Montpellier, ART/PGD department, Montpellier, France

Study question: The aim of this study was to optimize pregnancy outcome using customized embryo transfer according to the evaluation of endometrial receptivity of patients included in eggs donation program.
Summary answer: Individual evaluation of endometrial receptivity allows a customized embryo transfer (cET) according the endometrium receptivity day and improves pregnancy outcome in oocyte donation program.
What is known already: Many approaches for human endometrial receptivity including microarray has been previously reported. However, efficiency of the tests according to the clinical results is still debated. The aim of this study is to evaluate the endometrial receptivity using a transcriptomic approach in eggs donation program. This approach consists for screening 11 specific genes of the receptivity window.
Study design, size, duration: Endometrial biopsies are performed during the implantation windows 5-9 days after progesterone administration under hormone replacement therapy. Then, the transfer strategy consists in performing cET of blastocysts according the endometrium receptivity day identified using the Win-Test. Therefore, frozen day 2/3 embryos were transferred 72/48 hours before this specific receptivity day, respectively. When the endometrial sample was defined as non-receptive, a second evaluation was performed later, according to transcriptomic result.
Participants/materials, setting, methods: 45 patients in eggs-donation program due to an advanced age (n=36) or premature ovarian failure (n=9) were included. RNAs from biopsies were extracted and the Win-Test gene expression was assessed by qRT-PCR. Positive pregnancy test was defined as at least two consecutive positive b-hCG serum concentration. Clinical pregnancy, implantation rate and live birth rate were recorded after cET according to the transcriptomic results.
Main results and the role of chance: Analyses of endometrial receptivity status (n=108 biopsies) in patients in oocyte donation program (age mean

± SD: 41.2 ± 3.8 years) revealed a strong inter-patient variability of the moment of the opening of the receptivity window within the implantation window. Majority of patients (84%) present a delay of their receptivity window compared to the classical timing for blastocyst transfer (16% at Pg+5/Pg+6). This delay was mainly between 1 (40%) to 2 days (33%), or more (11%). Then, a cET can to be perform during a subsequent cycle according the endometrium receptivity day and in the respect of the synchronization of the fœto-maternal dialogue. Using this strategy, the positive b-hCG and clinical pregnancy rate per patient were 73.3% and 60%, respectively. The implantation and live birth rates after cET were 50% and 48.9%, respectively.

Limitations, reasons for caution: The benefits of this strategy will be analyzed in a large cohort of patients in eggs/embryos donation program

Wider implications of the findings: This finding demonstrated that customized embryo transfer according to the specific cycle day where endometrium is receptive improves both implantation rate and live birth rate in patients in oocyte donation program.

Trial registration number: ID: NCT04192396

P-310 Increased expression of fucosyltransferase 4 (FUT4) mRNA in eutopic endometrium is a specific and sensitive marker of endometriosis

J. Malejczyk[1], M. Żeberkiewicz[1], A. Hyc[1], A. Iwan[1], A. Zwierzchowska[2], E. Barcz[2], A. Ścieżyńska[1]

[1]Medical University of Warsaw, Department of Histology and Embryology, Warsaw, Poland ;
[2]Medical University of Warsaw, 1st Department of Obstetrics and Gynaecology, Warsaw, Poland

Study question: Are the levels of fucosyltransferase 4 (FUT4) mRNA in the eutopic endometrium associated with endometriosis?

Summary answer: *FUT4* mRNA expression is significantly increased in the eutopic endometrium from women with endometriosis and may serve as a diagnostic marker of endometriosis.

What is known already: Retrograde flow of shed endometrial cell may play a role in development of endometriosis. It is postulated that survival of endometriotic cells in the peritoneum is partially related to their decreased apoptosis and increased invasiveness. In particular, development of endometriotic lesions may be related to epithelial precursor/stem cells characterized by expression of stage specific embryonic antigen 1 (SSEA-1/CD15). Expression of SSEA-1 is related to activity of FUT4.

Study design, size, duration: This control-case study involved endometrial and endometrioid cyst samples collected by aspiration biopsy or laparoscopic surgery from 86 women with and without endometriosis.

Participants/materials, setting, methods: The study was conducted at a university research institution. *FUT4* mRNA were examined in eutopic endometrium tissue samples from 58 women with endometriosis (mean age 32.4 years) and eutopic endometrium from 28 control women (mean age 36 years) by means of quantitative reverse-transcription polymerase chain reaction (qRT-PCR).

Main results and the role of chance: Expression of *FUT4* mRNA in eutopic endometrium from women with endometriosis and controls did not differ in relation to phase of the menstrual cycle. The relative levels of *FUT4* mRNA were significantly increased in eutopic endometrium from endometriosis patients as compared to control women ($P<0.0001$). ROC analysis of *FUT4* mRNA expression in eutopic endometrium showed high statistical significance (AUC = 0.90, 95%CI = 0.81-0.99, $P<0.0001$) thus indicating endometrial *FUT4* mRNA to be a specific marker of endometriosis. Expression of FUT4 mRNA in eutopic endometrium was correlated with endometriosis severity ($r_s=0.5579$, $P<0.0001$). There were no differences in endometrial *FUT4* mRNA expression regarding endometriotic lesion location and patients' infertility status.

Limitations, reasons for caution: The study was performed on a limited group of patients and controls. The results should be confirmed by a replicate study on different patients' cohorts.

Wider implications of the findings: The present results strongly suggest that expression of *FUT4* mRNA in eutopic endometrium is a specific marker suitable for the low-invasive diagnosis of endometriosis. It is possible that FUT4 activity plays a role in development and persistence of endometriotic lesions and may potentially be a therapeutic target for endometriosis.

Trial registration number: not applicable

P-311 Expression of non-classical Human Leukocyte Antigen (HLA)-G and -F in the endometrium in relation to immune cell infiltration in women experiencing recurrent implantation failure (RIF)

H. Papuchova[1,2,3], M. Hviid Saxtorph[2,4], T. Hallager[2,5], I. Engberg Jepsen[2,4], G. Persson[1,2], J.O. Eriksen[2,5], L. Larsen Grupe[2,5], N. Macklon[2,6], T.V. Hviid[1,2,3]

[6]London Women's Clinic, London Women's Clinic, London, United Kingdom

Study question: Does HLA-F and HLA-G expression correlate with the infiltration of CD56+, CD16+, FOXP3+ or CD163+ immune cells in endometrial biopsies from women with RIF?

Summary answer: Endometrial HLA-G expression of women experiencing RIF is correlated with immune cell infiltration (CD16+ and CD56+). HLA-F expression is correlated with anti-inflammatory macrophage infiltration (CD163+).

What is known already: HLA class Ib have a prominent immunomodulatory role at the fetal-maternal interface, promoting immune tolerance of fetal antigens. HLA-G-positive trophoblasts are in a close contact with decidualized endometrium during pregnancy, and HLA-G expression in the endometrium has been identified as prognostic for achieving pregnancy. Evidence of HLA-F expression in the endometrium and its interactions with immunoglobulin-like transcript (ILT) receptors expressed on Natural Killer (NK) cells, T cells and macrophages have been elucidated. These interactions between endometrial HLA class Ib and immune cells could have a determinant immunosuppressive function required for successful embryo implantation.

Study design, size, duration: Endometrial biopsies were obtained from all participants in an estrogen/progesterone substituted cycle. Samples were collected after five days of progesterone treatment. In total, 86 women with RIF and 37 controls attending a fertility clinic were recruited between November 2017 and September 2019. The patients were divided into four groups based on the infertility cause: unknown, female factor, male factor and both male and female factor. Preliminary data are presented including 51 women experiencing RIF.

Participants/materials, setting, methods: Immunohistochemical procedures were automatically performed on an Autostainer on paraffin-embedded sections using anti-human antibodies for HLA-F, HLA-G, CD56, CD16, CD163 and FOXP3 with corresponding technical staining controls. Randomized and blinded analysis were performed using Tissue IA image analysis software (Digital Image Hub). Algorithms were developed for the above-mentioned antibodies. HLA-F and HLA-G expression were studied by flow cytometry on fresh endometrial samples. Statistical analysis based on Spearman correlation was performed using SPSS version 25.

Main results and the role of chance: HLA-F and HLA-G membrane expression on endometrial cells were confirmed by flow cytometry analysis on freshly isolated endometrial stromal cells from endometrial biopsies. Using immunohistochemistry, the preliminary results show that the percentage of HLA-G-positive cells in the endometrial glands was positively correlated with the percentage of CD16-positive cells per analyzed area ($p<0.05$). As well as the semi-quantitative HLA-G H-score (staining intensity score) was positively correlated with percentage of CD16-positive cells within the analyzed area ($p<0.05$). Moreover, in a patient subgroup with no female factor identified, both percentage of HLA-G-positive cells and HLA-G H-score were positively correlated with percentage of CD16-positive, CD56-positive and CD163-positive cells per analyzed area (all $p<0.05$). Interestingly, all three HLA-F variables (number of positive cells per mm^2, percentage of positive cells per analyzed area and H-score) in both endometrial glands and stroma were positively correlated with anti-inflammatory macrophages per mm^2 and their percentage per analyzed area (identified by CD163, $p<0.01$ and $p<0.005$ for glands and stroma respectively). The number of HLA-F-positive cells per mm^2 and HLA-F score were also negatively correlated with the number of regulatory T cells per mm^2 (identified by FOXP3, all $p<0.05$).

Limitations, reasons for caution: The data presented are preliminary data based on 51 women out of 123 included in the study. Correlations indicate the relationship between two variables; however, influences of other variables should be taken into consideration. No corrections for multiple comparisons were performed because the character of the study is primarily exploratory.
Wider implications of the findings: In the current preliminary analysis, we show interesting trends indicating links between NK cell, regulatory T cell and macrophage markers with HLA class Ib molecules of potential importance for establishing fetal-maternal tolerance at implantation and in early pregnancy.
Trial registration number: not applicable

P-312 16s sequencing of vaginal microbiota in patients undergoing frozen embryo transfer following IVF

K. Neumann[1], A. Masuch[2], S. Graspeuntner[3], L. Kirchhoff[3], A. Schultze-Mosgau[2], M. Depenbusch[2], J. Rupp[3], G. Griesinger[2]

[1]University Hospital of Schleswig-Holstein- Luebeck- Schleswig-Holstein- Germany, Department of Gynecological Endocrinology and Reproductive Medicine, Lübeck, Germany ;
[2]University Hospital of Schleswig-Holstein- Luebeck- Schleswig-Holstein- Germany, Department of Reproductive Medicine and Gynecological Endocrinology, Luebeck, Germany ;
[3]University Hospital of Schleswig-Holstein- Luebeck- Schleswig-Holstein- Germany, Department of Infectious Diseases and Microbiology, Luebeck, Germany

Study question: Does 16s sequencing of vaginal microbiota predict the outcome of a frozen embryo transfer cycle? Does the phase of the menstrual cycle impact these microbiota?
Summary answer: Vaginal microbiota can contribute to pregnancy prediction which seems to be independent from the phase of the menstrual cycle during which sampling was done.
What is known already: Recent studies have shown conflicting data on an association of certain vaginal microbiota with the outcome of a fresh cycle of in vitro fertilization (IVF) (Koedooder et al. 2019, Haahr et al. 2019). These studies, however, analyzed fresh embryo transfer cycles only and did not account for intra-individual variation, e.g. the impact of the sampling time-point within the menstrual cycle.
Study design, size, duration: Prospective, clinical cohort study of patients undergoing a frozen embryo transfer cycle (spontaneous or programmed) following IVF. Sample collection has started in 5/2018 and is still ongoing. The study was prospectively registered (clinicaltrials.gov ID: NCT03507673).
Participants/materials, setting, methods: Vaginal swabs were collected on day of planning of embryo transfer (in the late follicular phase day 13 – 15 of the menstrual cycle), on day of embryo transfer (i.e. after 2 to 6 days of progesterone administration) and on day of pregnancy test (10 – 14 days after embryo transfer). 16s ribosomal RNA sequencing was used for longitudinal investigation of vaginal microbiota which were classified according to previous reported outcome criteria.
Main results and the role of chance: 16s sequencing of the first collected sample from the end of the follicular phase (n=56) of the frozen embryo transfer cycle revealed a statistically significant reduction in species richness (p=0.011) and in the chao 1 index (p=0.0045) for patients achieving a positive pregnancy test (n=22) versus patients having a negative test (n=34). In patients having a sample available for analysis from all three time-points (n=13), a tendency towards an increased relative read count for Lactobacillus crispatus for patients achieving a positive pregnancy test vs. patients having a negative test was observed. Additionally, a decreased alpha-diversity was observed for patients with a positive pregnancy test. These differences were observed independent from the phase of the menstrual cycle during which sampling was performed; however, statistical significance was not reached yet for this subgroup. Surprisingly, n=3 asymptomatic patients undergoing infertility treatment were diagnosed with a relative chlamydial abundance. None of these patients having a positive relative chlamydia read could achieve a pregnancy.
Limitations, reasons for caution: This study is ongoing, a higher number of patients are needed for robust conclusions. Additionally, no stratification of subgroups (e.g. age, protocol of frozen embryo transfer cycle, etc.) or differentiation of previously reported community state types of bacteria have been conducted so far.
Wider implications of the findings: Vaginal microbiota seems to be associated with the outcome of a frozen embryo transfer cycle. This association might be independent from the phase of the menstrual cycle. Asymptomatic chlamydial infections detected by 16s sequencing in patients undergoing IVF needs further investigation.
Trial registration number: clinicaltrials.gov ID: NCT03507673).

P-313 Prevalence of T-shape uterus among porous women based on Congenital Uterine Malformations by Experts (CUME) criteria

A. Seyhan[1], S. Ertas[1], B. Urman[1]

[1]American Hospital, Reproductive Endocrinology and Infertility, Istanbul, Turkey

Study question: What is the prevalence of T-shape uterus among parous women based on CUME criteria?
Summary answer: Parous women who conceived spontaneously have a low prevalance of T-shape uterus.
What is known already: Both prevalence of T shape uterus in parous women and its effect on reproductive/obstetric outcome is unknown.
Study design, size, duration: Prospective cohort study including 238 reproductive age group of women in who conceived spontaneously and had at least one live birth. Participants were recruited from a contraception clinic between January 2017 and December 2019.
Participants/materials, setting, methods: Participants underwent 3D transvaginal ultrasound in the late luteal phase of menstrual cycle. The ESHRE/ESGE classification of congenital anomalies of the female genital tract was used for the description of abnormal findings. The diagnosis of T-shape uterus was based on the definition ofCUME criteria.The following measurements were taken In the coronal view; 1)lateral indentation depth, 2) lateral indentation angle, 3) T-angle. Uterine cavity volume was measured by Virtual Organ Computer-aided AnaLysis (VOCAL™) program.
Main results and the role of chance: The mean (± standard deviation) age was 35.7±5.9 years. Mean parity was 1.88 (min 1 max 7) and time to pregnancy (TTP) was between 1- 12 months. Mean antral follicle count was 12.2±9.5 and 10.5 % had at least one ultrasound feature of adenomyosis. Nine patients (3%) were diagnosed with congenital uterine abnormality of which 5 (2.1%) had partial septate uterus, 2 (0.8%) had a hemiuterus and 1 (0.4%) had a Tshape uterus and 1 had borderline T-shape uterus.

Overall mean uterine volume, lateral indentation depth, lateral indentation angle and T-angle was 4 ±2.3 ml, 2.95±,1.16mm, 154.7 ±9.9°and 73.5±9.9°respectively. Six women fulfilled one criterion and 1 patient met 2 criteria with lateral indentation depth of 8.4mm and lateral indentation angle of 128°. The women with T shaped uterus had uterine volume, lateral indentation depth, lateral indentation angle and T-angle of 2.62 ml, 7mm, 124°and 38°respectively. Her TTP was 7 months and she had given birth to a 3450 gr child at 39.
Limitations, reasons for caution: The prevalence of T-shape uterus in a population of parous women who conceived spontaneously is very low. The management of this condition can be determined following comparative studies showing the prevalance among parous, recurrent miscarriage and infertilite patients.
Wider implications of the findings: If women with infertility and recurrent misccariage are shown to have higher prevalance of T shape uterus, possible benefit of surgical management may be claimed.
Trial registration number: 2018.052.IRB1.008

P-314 Is endometrial gene expression profile affected in women with endometriosis? a meta-analysis

E. Vargas[1], E. García-Moreno[2], A. Salumets[3], F.J. Esteban[1], S. Altmäe[4]

[1]University of Jaen, Department of Experimental Biology, Jaen, Spain ;
[2]Puerta del Mar University Hospital, Immunology Unit, Cadiz, Spain ;
[3]Competence Centre on Health Technologies, Competence Centre on Health Technologies, Tartu, Estonia ;
[4]University of Granada, Department of Biochemistry and Molecular Biology, Granada, Spain

Study question: Do women with endometriosis have a different endometrial gene expression profile at the time of embryo implantation than healthy women?

Summary answer: This meta-analysis identified no single genes to be differentially regulated in endometriosis, while apoptosis, immune response and wound healing pathways seem to be dysregulated.
What is known already: ~50% of women with endometriosis suffer from infertility. Some studies suggest impaired endometrial receptivity in these women,while other studies claim no impact of endometriosis in endometrial receptivity. The studies analysing endometrial gene expression profiles in endometriosis have been performed in small sample size with low statistical power. We set out to systematically gather published studies comparing endometrial gene expression signatures in women with endometriosis vs. healthy women. Based on the obtained data we conducted meta-analysis of differentially expressed genes in order to raise the analysis power and thus clarify whether endometriosis have an impact on endometrial receptivity at molecular level.
Study design, size, duration: A systematic literature search was performed until 16th of January 2020 aiming to identify studies assessing the mid-secretory endometrial gene expression profile, i.e. transcriptome of women with endometriosis vs. healthy controls during the window of implantation. The eligible studies were further explored to extract the differentially expressed gene lists and the associated fold changes and we then performed a meta-analysis using the robust rank aggregation (RRA) method to screen for highly representative genes.
Participants/materials, setting, methods: The systematic literature search was conducted following the PRISMA criteria and included Pubmed, Cochrane, Google Scholar and Web of Science. A meta-analysis was performed on the selected studies to extract the differentially expressed genes described during the mid-secretory phase in women with endometriosis vs. healthy women using the RRA method. In total endometrial transcriptome data of 128 women (84 patients and 44 controls) were analysed in our meta-analysis.
Main results and the role of chance: Within the systematic literature search, 7 studies were eligible for the quantitative meta-analysis gathering transcriptome data in total from 128 women of the mid-secretory phase of the menstrual cycle. It is the first time when such a number of women have been analysed in order to assess the impact of endometriosis on endometrial transcriptome profiles. The transcriptome data from 128 women covered a total number of 1100 differentially expressed transcripts (644 up-regulated and 456 down-regulated), whose relevance was interrogated using the RRA method. After stringent multiple correction, our meta-analysis did not detect any significantly differentially expressed genes in the mid-secretory endometrium of patients vs. controls. However, when analysing the molecular pathways involved in the identified gene lists, we found that apoptosis, immune response and wound healing pathways were dysregulated among women with endometriosis.
Limitations, reasons for caution: Most of the studies included into the meta-analysis are relatively small, using different platforms for measuring gene expression together with the low number of samples which might contribute to a bias.
Wider implications of the findings: The current meta-analysis supports the hypothesis that a single gene is not dysregulated in endometriosis, rather is a cohort of genes that lead to dysregulation of specific molecular pathways.
Trial registration number: NA

P-315 The intra- and interobserver reproducibility of pelvic ultrasound for the detection and measurement of endometriotic lesions

E. Bean[1], P. Chaggar[1], N. Thanatsis[1], W. Dooley[1], C. Bottomley[1], D. Jurkovic[1]

[1]University College London Hospital, Women's Health, London, United Kingdom

Study question: What is the interobserver and intraobserver reproducibility of pelvic ultrasound for the detection of endometriotic lesions?
Summary answer: Pelvic ultrasound is highly reproducible for the detection of pelvic endometriotic lesions
What is known already: Transvaginal ultrasound has been widely adopted as the first-line assessment for the diagnosis and assessment of pelvic endometriosis. Severity of endometriosis as assessed by ultrasound has been shown to have good concordance with laparoscopy (kappa 0.79). The reproducibility of transvaginal ultrasound for assessment of ovarian mobility and pouch of Douglas obliteration using the 'sliding sign' has already been described in the literature. However, there is no available data in the literature to demonstrate the intraobserver repeatability of measurements for endometriotic cysts and nodules.
Study design, size, duration: This was a prospective observational cross-sectional study conducted over a period of 12 months. We included 50 consecutive women who were all examined by two operators (A and B) during their clinical attendance.
Participants/materials, setting, methods: The study was carried out in a specialist endometriosis centre. We included all consecutive women who had ultrasound scans performed independently by two experienced operators during the same visit to the clinic. The outcomes of interest were the inter- and intraobserver reproducibility for the detection of endometriotic lesions. We also assessed repeatability of the measurements of lesion size.
Main results and the role of chance: There was a good level of agreement between operator A and operator B in detecting the presence of pelvic endometriotic lesions (k = 0.72). There was a very good level of agreement between operators in identifying endometriotic cysts (k = 0.88) and a good level of agreement in identifying endometriotic nodules (k = 0.61). The inter- and intraobserver repeatability of measuring endometriotic cysts was excellent (intraclass correlation (ICC) ≥ 0.98). There was good interobserver measurement repeatability for bowel nodules (ICC 0.88), but the results for nodules in the posterior compartment were poor (ICC 0.41). The intraobserver repeatability for nodule size measurements was good for both operators (ICC ≥ 0.86).
Limitations, reasons for caution: There was insufficient data to perform a separate analysis for nodule size in the anterior compartment. All examinations were performed within a specialised unit with a high prevalence of deep endometriosis. Our findings may not apply to operators without intensive ultrasound training in the diagnosis of pelvic endometriosis.
Wider implications of the findings: These findings are important because ultrasound has been widely accepted as the first line investigation for the diagnosis of pelvic endometriosis, which often determines the need for future investigations and treatment**.** The detection and measurement of bowel nodules is essential for anticipation of surgical risk and planning surgical excision.
Trial registration number: Not applicable

P-316 Incidence of the Low Anterior Syndorme (LARS) after Colorectal Surgery for Deep Endometriosis: an International Multicentric Study

A. Bokor[1], G. Hudelist[2], B. Dauser[3], R. Brubel[1], J.J. Tuech[5], H. Roman[4]

[1]Semmelweis University, Dept.OB/GYN, Budapest, Hungary ;
[2]Hospital St. John of God Vienna- Austria, Gynecology, Vienna, Austria ;
[3]Hospital St. John of God- Vienna- Austria, Department of General Surgery, Vienna, Austria ;
[4]Centre d'endométriose Clinique Tivoli-Ducos Bordeaux- France, Endometriosis Centre, Bordeaux, France ;
[5]Department of surgery, Rouen University Hospital F-76000, France

Study question: Is there a difference between the incidence of the Low Anterior Syndrome (LARS) after segmental resection or transanal disc excision performed for the treatment of colorectal deep endometriosis (DE).
Summary answer: LARS is not more frequent after nerve and vessel spearing segmental resection (NVSSR) when compared to a more conservative approach, the Rouen-technique disc excision.
What is known already: Several studies show a significant drop in pain scores and improved fertility outcomes in women following surgical resection of colorectal endometriosis. However, there is inceasing evidence that intermediate and long-term bowel dysfunction may occur as a consequence of radical surgery for rectal DE. Typical symptoms include constipation, feeling of incomplete evacuation, clustering of stools and urgency. This is described in the colorectal surgical literature as LARS. Previous studies demonstrated statistically significant differences in functional outcomes in favour of the conservative surgical approach, i.e. resection of endometriotic tissue with preservation of the luminal structure of the rectal wall.
Study design, size, duration: A total of 205 patients, operated before the 1st of January 2018, were enrolled in this study. One hundred and thirty-nine patients with nerve and vessel sparing segmental resection (NVSSR) from the University Hospital Rouen, France (n=52); Semmelweis University Budapest, Hungary (n=50) and Hospital of St.John of God Vienna, Austria (n=37) as well as 66 patients operated at the University Hospital Rouen, France using the Rouen-technique disc excision (RTDE) were included.
Participants/materials, setting, methods: All patients underwent low rectal resection with a resection line lower than 7cm from anal verge.

Gastrointestinal functional outcomes of the two procedures were compared using the validated LARS questionnaire.

The median follow-up time was 46±11 months. As a secondary outcome, the surgical sequelae and fertility results were examined. Statistical analysis was done using Fisher's Exact and Pearson Chi Square test.

Main results and the role of chance: We found no statistically significant difference between the incidence of the LARS (31.7% and 37.9% respectively) among patients operated using RTDE when compared to women treated by NVSSR (p=0.4). The occurence of LARS was positively associated with the use of protective ileo-or colostomy (p=0.02). A higher rate of severe complications was observed in RTDE (19.7%) compared to patients who underwent NVSSR (9.0%, p=0.029).

Limitations, reasons for caution: Since digestive complaints may also be present presurgically, evaluation of digestive complaints should have been recorded pre- and post surgery as well.

Although this study has important limitations due to its retrospective design, it highlights important factors that affects outcomes in patients undergoing colorectal resection for the treatment of DE.

Wider implications of the findings: LARS is not more frequent after NVSSR when compared to a more conservative approach RTDE.

The findings of this study may help guide treatment strategies aimed at providing patients with colorectal DE an optimal surgical therapy. To confirm our findings prospective studies are required.

Trial registration number: NA

P-317 Increased rate of spontaneous miscarriages in women affected with adenomyosis associated with endometriosis

B. Pham[1], M. Bourdon[1], L. Marcellin[1], C. Maignien[1], C. Chapron[1], P. Santulli[1]

[1]Hopital Cochin Port-Royal, Gynecology and reproductive medecine, Paris, France

Study question: Among women with a radiological diagnosis of adenomyosis, are spontaneous miscarriages higher in women with endometriosis when compared with endometriosis-free controls?

Summary answer: Endometriosis-affected women display a significantly higher rate of previous spontaneous miscarriages than endometriosis-free controls in a population of adenomyosis affected women.

What is known already: Endometriosis and adenomyosis are common, estrogen-dependent, inflammatory disorders in women of reproductive age. Those diseases could be responsible for pain and fertility alteration. Endometriosis and adenomyosis are associated in a large part of women. In endometriosis, an association with an increased incidence of miscarriage was demonstrated compared to endometriosis-free women. The association between adenomyosis and miscarriages has also been shown. When endometriosis and adenomyosis are associated, we do not know what is their share of responsibility in the occurrence of miscarriages.

Study design, size, duration: An observational study nested in a cohort of women aged between 18-42 years who had undergone surgical exploration for benign gynecological conditions or who underwent assisted-reproductive-technology at our institution between May-2005 and May-2018. Only women who presented adenomyosis lesions visualized at uterine-MRI were retained for this study. Women who had never been pregnant before were excluded. The control-group included patients presenting adenomyosis without lesions of endometriosis and the study-group patients with adenomyosis associated with endometriosis.

Participants/materials, setting, methods: Data were collected preoperatively using a structured questionnaire. Among women who previously conceived, the type and number of the different previous first trimester pregnancies outcomes were studied. Previous history of miscarriage was studied according to the phenotype of adenomyosis (focal and/or diffuse lesions) and the phenotype of endometriosis (superficial, ovarian and/or deep infiltrating lesions).

Main results and the role of chance: 214 pregnancies in 'Adenomyosis associated with endometriosis' group and 53 pregnancies in 'Adenomyosis-affected women without endometriosis' group were analysed. Previous miscarriage rate was significantly higher in adenomyosis affected women with endometriosis compared to the controls (61/214 [28.5%] vs. 6/53 [11.3%], respectively; p = 0.009). After multivariable generalized estimating equation logistic regression model, adjusted on adenomyosis and endometriosis phenotypes, the association with endometriosis in women affected with adenomyosis significantly increase the risk of miscarriage (OR=3,198, 95% CI [1,1-9,65]). The risk was significantly higher in case of deep infiltrated endometriosis (OR 4,37, 95% CI [1,32-14,53]).

Limitations, reasons for caution: The exclusive inclusion of patients from our referral center could constitute a possible selection bias, as those women may have suffered from particularly severe forms of adenomyosis and/or endometriosis.

Wider implications of the findings: We reported in this study that endometriosis associated with adenomyosis is associated with higher previous spontaneous miscarriage rate as compared to women with isolated adenomyosis. This study opens the doors to future, more mechanistic studies to establish the exact link between endometriosis/adenomyosis and spontaneous miscarriage rates.

Trial registration number: not applicable

P-318 Alteration in gene expression of H19 lncRNA and IGF2 in endometrial tissues of women with endometriosis

S. Kamrani[1,2], E. Amirchaghmaghi[3,4], K. Ghaedi[1,5], M. Shahhoseini[2,6,7]

[7]Department of Reproductive Epidemiology Research Center- Royan Institute for Reproductive Biomedicine- ACECR- Tehran- Iran, Department of Reproductive Epidemiology Research Center, Tehran, Iran

Study question: Is gene expression profile of *H19 lncRNA* and *IGF2* different in endometrial tissues of women with endometriosis in compare to normal endometrium?

Summary answer: Decreased *H19* and *IGF2* expression was showed in eutopic and ectopic endometriual tissues of women with endometriosis.

What is known already: Endometriosis is one of the most common diseases in female reproductive system. Several factors, including genetic and epigenetic factors are suggested to be involved in its pathogenesis. Adhesion and proliferation of endometrial tissue, are essential elements in the pathogenesis of endometriosis. Thus growth factors such as insulin-like growth factor-2 (IGF2) may be involved as inducers of cellular proliferation. *IGF2* gene is among the most regulated genes in endometriosis that play important roles in regulating growth and differentiation of endometrial cells. Another factor is imprinted lncRNA H19. It is known to be involved in the regulation of cell proliferation and differentiation.

Study design, size, duration: In this case-control study, 5 endometriotic lesions (ectopic), 5 endometrial samples (eutopic) of women with endometriosis and 10 endometrial control samples were analysed. Control samples were obtained from women who had no evidence of endometriosis during laparoscopy in Royan Institute. Ectopic samples were obtained during laparoscopy surgery. Control and eutopic endometrial samples were obtained by pipelle. All women signed the informed consent form and did not receive any hormonal treatments during the last three months.

Participants/materials, setting, methods: After endometrial tissues collection, RNA extraction and cDNA synthesis were done. Real-time PCR

technique was used for quantitative gene expression of H19 lncRNA and IGF2. Gene expression data were analyzed based on $2^{-\Delta\Delta CT}$ to estimate the relative fold change value. One-Way ANOVA was used for data analysis. P value less than 0.05 was considered statistically significant.
Main results and the role of chance: Gene expression profile of H19 and IGF2 was decreased in eutopic and ectopic endometrial lesions compared with control samples. These decreases were not statistically significant (p>0.05). In addition, gene expression levels of these genes were lower in ectopic lesions in compare to eutopic samples in endometriosis women. These differences were not significant.
Limitations, reasons for caution: The main limitations of this study is the small sample size. For getting more information, we are going to study these genes in a large number of women with and without endometriosis.
Wider implications of the findings: It seems altered gene expression of H19 and IGF2 could play role in the development of endometriosis, because of their roles in regulatory pathways of cellular proliferation. After increasing sample size, epigenetic analysis will be performed on the samples.
Trial registration number: -

P-319 Increased expression of CREM is associated with decreased binding of its inhibitor (ICER) to the promoter region of CYP19 aromatase gene in endometriosis

S. Kalantari[1,2], A. Saadat Varnosfaderani[1,2], F. Ramezanali[3], E. Amirchaghmaghi[3,4], M. Shahhoseini[5,6,7]

[1]Reproductive Biomedicine Research Center- Royan Institute for Reproductive Biomedicine- ACECR., Department of Genetics, Tehran, Iran ;
[2]Faculty of Basic Sciences and Advanced Technologies in Biology- University of Science and Culture, Department of Cell and Molecular Biology Science, Tehran, Iran ;
[3]Reproductive Biomedicine Research Center- Royan Institute for Reproductive Biomedicine, Department of Endocrinology and Female Infertility, Tehran, Iran ;
[4]Cell Science Research Center- Royan Institute for Stem Cell Biology and Technology- ACECR, Department of Regenerative Biomedicine, Tehran, Iran ;
[5]Reproductive Biomedicine Research Center- Royan Institute for Reproductive Biomedicine- ACECR, Department of Genetics, Tehran, Iran ;
[6]School of Biology- College of Science- University of Tehran, Department of Cell and Molecular Biology, Tehran, Iran ;
[7]Royan Institute for Reproductive Biomedicine- ACECR, Reproductive Epidemiology Research Center, Tehran, Iran

Study question: Is there any association between gene expression of CREM and binding of its inhibitory isoform ICER to CYP19 promoter II (PII) in women with endometriosis?
Summary answer: Overexpression of CREM was detected in the ectopic endometrium and the binding of ICER to CYP19 promoter II in eutopic tissues was decreased.
What is known already: Endometriosis is an estrogen-dependent disease. The synthesis of estrogen depends on the expression of the aromatase enzyme (CYP19 gene). cAMP response element modulator (CREM) is a member of the bZIP family of transcription factors that has an important role in the regulation of aromatase gene expression. Inducible cAMP early repressor (ICER) is one of CREM inhibitory isoforms that represses cAMP-induced transcription.
Study design, size, duration: Endometriotic biopsies (ectopic), endometrial samples (eutopic) of women with endometriosis and endometrial control samples were collected. Control samples were obtained from women who had no evidence of endometriosis during laparoscopy. Ectopic biopsies from endometriosis women were obtained through laparoscopy while eutopic samples and control endometrial samples were collected by pipelle. Twelve endometrial samples from each group were used for gene expression analysis of CREM, while 6 control and 5 eutopic samples used for ChIP assay.
Participants/materials, setting, methods: Total RNA extraction and cDNA synthesis were done. Real-time PCR technique was used for quantitative gene expression of CREM. One-way ANOVA was used for data analysis. For protein-DNA interaction analysis, soluble chromatin was extracted and chromatin immunoprecipitation (ChIP) coupled with Real-time PCR was performed to quantify the binding of ICER to CYP19 promoter II in control and eutopic endometrial samples.
Main results and the role of chance: Gene expression level of CREM was statistically increased in ectopic lesions compared with control (P=0.001) and eutopic (P=0.007) samples. Increased expression of the CREM gene was also detected in eutopic endometrial samples compared to controls, while this difference was not statistically significant (P>0.05). In addition, the binding of ICER to CYP19 promoter II was statistically decreased in eutopic samples compared to the control endometrial group (P=0.005).
Limitations, reasons for caution: Larger sample size for the confirmation of these data is needed. Epigenetic evaluation of ectopic endometrial tissues especially in CYP19 promoter II is recommended.
Wider implications of the findings: The overexpression of CREM in the endometriosis tissue samples and decreased binding of the inhibitory isoform of CREM (ICER) to the CYP19 prompter II may contribute to the pathogenesis of endometriosis via its regulatory role in the expression of estrogen biosynthesis enzymes.
Trial registration number: not applicable

P-320 Oral dydrogesterone compared to intravaginal micronized progesterone for endometrial preparation in frozen-thawed embryo transfer cycles: preliminary results of a randomized controlled trial

M. Cavagna[1], L.C. Mattos de Macedo[1], S. Rolim[2], A. Dzik[1], N. Donadio[1], H.S. Marçon[1], M.D. Vasconcelos[1], B. Merquires de Araujo[1], S.M. Franceschini Cinquetti[1], A. Mantovani Fonseca[1], A.R. Rocha[1]

[1]CRSM Hospital Perola Byington, Human Reproduction, Sao Paulo, Brazil ;
[2]Faculdade de Ciências Médicas da Santa Casa de Sao Paulo, Obstetrics and Gynecology, Sao Paulo, Brazil

Study question: Can we achieve similar reproductive outcomes assessed by ultrasound scan at 12 weeks of gestation using oral dydrogesterone or vaginal micronized progesterone for endometrial preparation in frozen-thawed embryo transfer (FET)?
Summary answer: At present, our preliminary results are suggesting that reproductive outcomes of FET are similar with both methods of progesterone supplementation (oral dydrogesterone versus vaginal progesterone).
What is known already: In recent investigations, it has been demonstrated that oral dydrogesterone for luteal phase supplementation in fresh embryo transfer is as effective as micronized progesterone regarding reproductive outcomes. Nevertheless, nothing is known about FET cycles.
Study design, size, duration: We are performing a prospective randomized study comparing the use of oral dydrogesterone and intravaginal micronized progesterone for endometrial preparation in FET cycles.
Participants/materials, setting, methods: So far, 44 patients were randomly selected to receive either oral dydrogesterone, 40 mg/daily (DDG group, n=22) or vaginal micronized progesterone, 800 mg/daily (VMP group, n=22), following endometrial preparation with transdermal estradiol. Patients who did not reach an endometrial thickness ≥ 7 mm or who developed a dominant follicle were excluded of the study. The main outcome was a viable ongoing pregnancy at 12 weeks of gestation assessed by ultrasound scans.
Main results and the role of chance: The median age of the patients was 34 years (DDG group) and 32 years (VMP group). The median endometrial thickness on the day of progesterone administration was 8.7 mm in DDG group and 9.2 mm in VMP group. In DDG group, one embryo transfer was performed in 50% (n=11) of patients, two embryos were transferred in 40.9% (n=7) of patients and three embryos were transferred in 9.1% (n=2) of patients. In VPM group, one embryo transfer was carried out in 36.4% (n=8) of patients and two embryos were transferred in 63.6% (n=14) of patients. Blastocyst stage transfer was performed in 81.8% (n=18) in DDG group and in 54.5% (n=12) in VMP group. A positive pregnancy test performed 14 days after FET was achieved in 45.5% (n=10) in both groups. Ongoing pregnancy at 12 weeks of gestation was observed in 36.4% (n=8) in DDG group and in 40.9% (n=9) in VMP group.
Limitations, reasons for caution: The investigation is ongoing and these are preliminary data. The number of patients is still small and the data must be confirmed with larger number of patients and analysis of the reproductive outcomes. At the present moment, no statistical analysis was performed and live-birth rate was not still assessed.
Wider implications of the findings: The use of oral dydrogesterone may be a more patient-friendly approach for endometrial preparation in FET, avoiding undesirable side effects and discomfort resulting from vaginal administration and providing similar reproductive outcomes.
Trial registration number: UTN:U1111-1247-1845 – Registro Brasileiro de Ensaios Clínicos

P-321 Intrauterine Granulocyte-Colony Stimulating Factor (IU G-CSF) to improve the suboptimal endometrium: Is it worth a try?

S. Ahuja[1], Z. El Mahdi[1], V. Shaikly[1], M. Ranieri[1], M. Taranissi[1]

[1]Assisted Reproduction and Gynaecology Centre, Assisted Conception, London, United Kingdom

Study question: Does intrauterine instillation of G-CSF improve the endometrial thickness in women with a sub-optimal endometrium (< 7 mm) going through an embryo transfer cycle?
Summary answer: In this retrospective study of 32 women, the endometrium improved to over 7 mm in 71.8 % of cases following IU G-CSF.
What is known already: The thin endometrium is a challenge to treat in assisted conception. Interventions to improve the endometrium include hysteroscopy to diagnose and treat intrauterine pathology, estrogen tablets/patches, sildenafil citrate orally/vaginally, vitamin E and l-arginine. Surrogacy is a last resort in women where the endometrial factor shows no improvement, using the above strategies. G-CSF is a cytokine reported to improve the thin endometrium and implantation. There are few published studies that have reported a positive impact of IU G-CSF on thin endometrium. This study adds to the existing literature.
Study design, size, duration: We report a retrospective study of 32 women who were identified to have a sub-optimal endometrium of < 7 mm during the treatment cycle over a period of 18 months. All the women were additionally on sildenafil citrate, aspirin and clexane to improve the endometrium. The women were counselled regarding the options of trying IU-GCSF versus cycle cancellation versus proceeding with the transfer if the endometrium was considered sub-optimal but suitable.
Participants/materials, setting, methods: Patients were selected for the intervention if their endometrium was below 7 mm in late stimulation (1-2 days before HCG trigger) or in the late estrogenic phase (day 10-12) in a medicated frozen embryo replacement cycle with sufficient serum estrogen levels. Following informed consent, 30MU in 1 ml G-CSF was instilled into the uterus. The endometrium was rechecked after 48 hours. A second dose was repeated if the endometrium was still sub-optimal.
Main results and the role of chance: Of the 32 patients, age 30-45 years, who received IU G-CSF, 20 women were having fresh and 12 women were having frozen embryo transfer cycles. 7 patients had a history of uterine pathology. The mean increase in endometrium was 1.23 mm with a range of 0 -3.7 mm. The endometrium increased to > 7 mm in 71.8 % of cases. The transfer was cancelled in 2 cases due to no change in the endometrium (6.6%). There were 8 pregnancies-3 have had livebirths, one of which was a set of twins, and one of them is about 30 weeks pregnant. 4 women had 1st trimester miscarriages. Only 1 woman complained of bone pain for about 1 week post IU G-CSF and her pregnancy sadly ended in a miscarriage.
The women in this study comprised of patients with complex fertility problems and previous treatment failures. Therefore, the positive and negative outcomes could have been due to other confounding actors such as embryo quality in the cycle rather than just the impact of the G-CSF on implantation.
Limitations, reasons for caution: The findings of this small retrospective study with no matched control, limit the conclusions that can be drawn. Furthermore, the women included in the study had complex fertility problems that could have contributed to the success/failure of the cycle independent of endometrium thickness.
Wider implications of the findings: Treating the sub-optimal endometrium is one of the most challenging situations in assisted conception. This study supports the evidence that IU G-CSF may have a positive impact. However, further research is required to establish its benefits and safety, as an option for patients before they consider alternative options like surrogacy.
Trial registration number: Not Applicable

P-322 Role of platelet rich plasma (PRP) in improving endometrial receptivity: A systematic review and meta-analysis.

H.S. Naseem[1], M. Lokman[1], F. Soxibova[2], L. Mohiyiddeen[1], Y. Abdallah[1]

[1]Manchester University NHS foundation Trust, Reproductive Medicine, Manchester, United Kingdom ;
[2]Medical University Sofia, Medical school, Bulgaria, Bulgaria

Study question: Does PRP improve outcome of assisted conception in women with unexplained recurrent implantation failure (RIF) or thin endometrium?
Summary answer: The use of PRP in women with unexplained RIF and thin endometrium has shown significant increase in chemical and clinical pregnancy rates through assisted conception.
What is known already: PRP is the concentrate obtained by centrifugation of the patient's own whole blood. Platelets have granules containing numerous proteins, several growth factors, and cytokines. In ex-vivo studies, activated PRP has been shown to promote the migration of endometrial stromal fibroblasts, endometrial mesenchymal stem cells and bone marrow-derived mesenchymal stem cells. This has formed the basis for in vivo use of autologous PRP to promote endometrial regeneration.It is also theorized that another mechanism of PRP action is via anti-inflammatory processes involved in receptivity of the endometrium and trophoblasts placentation. This would suggest that PRP could improve implantation and clinical outcomes.
Study design, size, duration: This is a systematic review of available literature including case series, cohort studies and randomised controlled trials (RCTs) on the role of PRP in improving endometrial receptivity in assisted conception. The databases were searched from inception to 2019. We then performed a meta-analysis, which comprised of four prospective RCTs comparing use of PRP intrauterine infusion or no treatment in women with unexplained RIF or thin endometrium. There are 330 patients included in the meta-analysis.
Participants/materials, setting, methods: This is a systematic review of available literature including case series, cohort studies and randomised controlled trials (RCTs) on the role of PRP in improving endometrial receptivity in assisted conception. The databases were searched from inception to 2019. We then performed a meta-analysis, which comprised of four prospective RCTs comparing use of PRP intrauterine infusion or no treatment in women with unexplained RIF or thin endometrium. There are 330 patients included in the meta-analysis.
Main results and the role of chance: The systematic review of current literature suggests a benefit of PRP intrauterine infusion in improving assisted conception outcomes. We performed a meta-analysis of available RCTs. Our inclusion criteria for the meta-analysis were: i) a prospective randomized controlled trial comparing PRP intrauterine infusion to controls in assisted conception, ii) participants were characterized as having thin endometrium or RIF, and iii) all patients had a negative hysteroscopy to rule out uterine factors.
134 relevant studies were identified. 92 were excluded as they did not meet the inclusion criteria. 30 studies were reviewed for full text and 4 were included in the meta-analysis.

The chemical and clinical pregnancy rate was reported in all 4 trials. The chemical pregnancy rate from pooled data showed a significant difference in favour of PRP treatment with odds ratio of 2.14 (OR: 2.14, 95% CI: 1.49 – 3.07; P<0.0001). Similarly, the clinical pregnancy rate from pooled data showed that there was a significant difference between the two groups (OR: 2.58, 95% CI: 1.75 - 3.78; P <0.0001).

Two trials reported on change to endometrial thickness and miscarriage rate. No significant difference was found for change of endometrial thickness or miscarriage rate, between the two groups.
Limitations, reasons for caution: The sample size in each RCT was relatively small and there was a lack of standardization in the PRP preparation. No trial reported measures to avoid performance or detection bias. These factors will impact the strength of evidence available.
Wider implications of the findings: These results support the evolving role for PRP in improving endometrial receptivity in clinical practice. Nevertheless, multi-centre RCTs with larger sample sizes are still needed to further evaluate the effectiveness of this intervention.
Trial registration number: Not Applicable

P-323 Prevalence of chronic endometritis varies more by diagnostic method than by reproductive history

M. Scarrone[1], S. Bordoli[1], V. Vanni[2], L. Quaranta[3], F. Pasi[4], C. Patruno[2], G. Campo[2], V. Canti[5], A. Quartucci[2], M. Castiglioni[4], M. Candiani[4], E. Papaleo[3], P. Rovere Querini[1], P. Giardina[3]

[1]Vita-Salute San Raffaele University, Internal and specialistic medicine, Milan, Italy ;
[2]Vita-Salute San Raffaele University, IVF Unit, Milano, Italy ;
[3]IRCCS San Raffaele Hospital, IVF Unit, Milan, Italy ;
[4]IRCCS San Raffaele Hospital, Obstetrics and Gynecology, Milan, Italy ;
[5]IRCCS San Raffaele Hospital, Internal and specialistic medicine, Milan, Italy

Study question: Does prevalence of chronic endometritis (CE) vary by reproductive history or by diagnostic method used?
Summary answer: CE is equally represented in patients affected by different types of reproductive failure. The different methods used for the diagnosis strongly influence its prevalence.
What is known already: CE is an asymptomatic inflammation of the endometrium mainly caused by bacteria. CE diagnosis is non-standardized and can be based on immunohistochemistry (IHC) for stromal endometrial CD138+ plasma cells or on endometrial cultures/molecular diagnosis for non-cultivable microorganisms. CE might be associated with impaired receptivity and reproductive failure, thus emerging as a potential factor in the pathogenesis of unexplained infertility, repeated implantation failure (RIF) and recurrent pregnancy loss (RPL). CE prevalence is inconsistent among studies, possibly due to different diagnostic methods and vaginal contamination of cultures.
Study design, size, duration: We performed a prospective study of patients referred to the hysteroscopic service of the San Raffaele Hospital (Milan, Italy) between May 2018 and December 2019 for diagnostic hysteroscopy and CE diagnosis as a second-level investigation for unexplained infertility (n=15), RIF (n=28) or RPL (n=44). We stratified CE prevalence by diagnostic method in addition to reproductive history.
Participants/materials, setting, methods: Patients underwent endometrial culture and concomitant vaginal and cervical cultures to account for possible contamination during sampling. A subgroup of n=43 samples were also subjected to immunohistochemistry for CD138+ plasmacytes. Diagnosis of CE was done in the presence of either a) positive endometrial culture/molecular bacterial DNA amplification or b) >=5 CD138+ plasmacytes in 20 high-power fields. Affected patients were treated with targeted antibiotic therapy and re-tested with endometrial culture to assess CE regression.
Main results and the role of chance: N=50 out of 87 cultures resulted positive (57.5%). In only 2 out of 50 cases, the same pathogen was isolated in both endometrial and vaginal cultures - with a concordance rate of 4% - suggesting that vaginal contamination is infrequent. IHC was positive in 12 out of 43 cases (27.9%). Concordant results between culture and IHC were observed in 25 cases, with a matching accuracy of 58,1%. Cases with contradictory results mostly showed positive bacterial cultures but negative immunohistochemical analysis (n=16 out of 18, 88.9%) while only n=2 out of 18 (11.1%) resulted positive at IHC but negative at culture. Of the n=22 affected patients who have completed treatment and control cultures at the time of data analysis, n=9 resulted negative (40.9%), n=6 (27.3%) tested positive for the same pathogen whereas n=7 (31.8%) tested positive for a different pathogen. We observed similar prevalence of CE among groups of patients stratified by reproductive history as defined by RIF (n=17/28, 60.7%), RPL (n=23/45, 52.1%) or unexplained infertility (n=10/15, 66.7%).
Limitations, reasons for caution: The currently small sample size is the main limitation of our study. Further prospective data collection and inclusion of pregnancy outcomes will be of interest.
Wider implications of the findings: Endometrial cultures are frequently positive in patients with reproductive failure. Our study shows that vaginal/cervical contamination has marginal role in this finding. However, only 58.1% of culture-positive patients show the presence of plasmacytes. Whether bacteria mediate endometrial dysfunction in the absence of plasmacytes-mediated inflammation needs further investigation.
Trial registration number: not applicable

P-324 The importance of timing in detection of asymptomatic CD138 diagnosed chronic endometritis

J. Odendaal[1,2], K. Fishwick[1], Q. Hussain[1], J. Thornton[1], K. Larsen[1], P. Vrljicak[1], E. Lucas[1], J.J. Brosens[1,2], S. Quenby[1,2]

[1]University of Warwick, Division of Biomedical Sciences, Coventry, United Kingdom ;
[2]University Hospitals Coventry and Warwickshire, Biomedical Research Unit, Coventry, United Kingdom

Study question: How does the expression of CD138 alter across the menstrual cycle?
Summary answer: CD138 is normally expressed, at mRNA and protein level, in glands and stroma during the proliferative phase but expression decreases markedly during the luteal phase.
What is known already: Asymptomatic chronic endometritis (CE), diagnosed by the presence of CD138-positive stromal cells on immunohistochemistry (IHC), has been associated with recurrent implantation failure (RIF) and recurrent pregnancy loss (RPL). CE can be treated with antibiotics and has been linked with dysbiosis of the vaginal and endometrial microbiome. CD138 (syndecan 1) is a selectively expressed heparan sulphate proteoglycan and putative cell surface marker of plasma cells. However, CD138 expression occurs in non-immune cells and has been associated with proliferation, apoptosis and angiogenesis. The cycle-dependency and cellular distribution of CD138 expression in the endometrium has not yet been analysed comprehensively.
Study design, size, duration: Observational cohort study of (i) 27 proliferative and 29 luteal phase endometrial samples and 3 paired proliferative/luteal phase endometrial samples; (ii) interrogation of published single-cell RNA-seq data derived from 6 midluteal endometrial biopsies (GSE127918).
Participants/materials, setting, methods: Timed endometrial biopsies were obtained from local biobanks from control and recurrent reproductive failure patients. Endometrial *SDC1* (CD138) transcript levels were quantified by RT-qPCR and cellular distribution examined by single-molecule in-situ hybridization (smISH). Temporo-spatial expression of CD138 at protein level was examined by IHC followed by digital image analysis and deconvolution for quantification. Dual staining with Ki67 was performed to delineate CD138-positive proliferating cells. Single-cell transcriptomics data were interrogated to examine cell type-specific *SDC1* expression.
Main results and the role of chance: Whole tissue RT-qPCR demonstrated non-immune *SDC1* expression across the menstrual cycle with no significant difference in transcript levels across cycle phases. Analysis of midluteal scRNA-seq data showed enriched *SDC1* mRNA expression in endometrial epithelial cells, although transcripts were also detectable in stromal, immune and endothelial cell populations. The cellular distribution of *SDC1* transcripts was confirmed by smISH. IHC of proliferative endometrium demonstrated very high stromal CD138 expression (>200 CD138-positive stromal cells/10mm^2) in 26/27 samples. Expression was significantly reduced in luteal samples (Mann Whitney U-Test; P<0.005). This transition was also demonstrated across the paired proliferative/luteal samples. Dual IHC demonstrated a mean co-localisation of 30% of CD138-positive stromal cells with the proliferation marker Ki67 across the menstrual cycle, suggesting that CD138 is not merely marking proliferating cells. H-scoring of the glandular endometrium demonstrated a similar drop in expression from the proliferative to luteal phase (Mean H-Score 197.51 vs. 104.56; Student T-test; P<0.05).
Limitations, reasons for caution: The marked reduction in CD138 immunoreactivity upon transition from the proliferative to luteal phase was not reflected by a corresponding decrease in *SDC1* mRNA levels in whole biopsies. This discrepancy is likely due to post-transcriptional regulation of CD138 however, further work is required to elucidate this.
Wider implications of the findings: Detection of CD138-positive stromal cells is used increasingly for the diagnosis of CE. It is important that CD138 is assessed in the luteal phase to prevent over-diagnosis, that non-immune cell expression is acknowledged, and its clinical importance evaluated.
Trial registration number: Not applicable

P-325 Presence of focal adenomyosis lesion based on MRI is associated with infertility issues

L. Melka[1], M. Bourdon[1], J. Oliveira[1], J. Cormier[1], L. Marcellin[1], C. Maignien[1], C. Bordonne[2], A.E. Millischer[3], G. Plu-Bureau[1], P. Santulli[1], C. Chapron[1]

[1]Université de Paris- Faculté de Médecine- Paris- France, clinician, Paris, France ;
[2]Université de Paris- Faculté de Médecine- Paris- France, Radiology, Paris, France ;
[3]Centre de Radiologie Bachaumont- IMPC- Paris- France, radiology, paris, France

Study question: Is there an association between adenomyosis and infertility, according to the adenomyosis phenotype as diagnosed by magnetic resonance imaging (MRI)?
Summary answer: In the study population, the presence of focal adenomyosis was associated with primary infertility.
What is known already: Adenomyosis is characterized by the presence of endometrial glands and stroma deep within the myometrium. This disease exhibits various clinical presentations notably infertility, which prevalence and causes are still unknown. In addition, various forms have been described, including focal

(Foc-ADE) and diffuse adenomyosis (Dif-ADE), and several evidences suggest that those two forms could be considered as distinct entities, which could make the analysis of adenomyosis-related infertility even more difficult. As a matter of fact, the association between the distinct adenomyosis phenotypes (focal and/or diffuse forms) and infertility has not yet been investigated.

Study design, size, duration: This was a cross-sectional study using data prospectively collected in all non-pregnant patients aged between 18 and 42 years, surgically explored for benign gynecological conditions at our institution between May 2005 and May 2018. For each patient, a standardized questionnaire was completed during a face-to-face interview conducted by the surgeon during the month preceding surgery. Only women with uterine MRIs performed by a senior radiologist during the preoperative work-up were retained for this study.

Participants/materials, setting, methods: A uterine-MRI was performed in 496 women operated for a benign gynecological disease. Among them, 248 women did not present adenomyosis lesions and 248 women had a radiological diagnosis of adenomyosis. According to MRIfindings, women were diagnosed with Foc-ADE and/or Dif-ADE forms. Three groups were compared: the non-infertile women group (n=361), the 'primary infertility' group (n=84) and the 'secondary infertility' group (n=51). Univariate and multiple analysis were performed to determine primary and secondary infertility-associated factors.

Main results and the role of chance: The presence of focal adenomyosis was significantly associated with primary infertility. Diffuse adenomyosis was not found to be associated with infertility, whether at the primary or at the secondary stage. The distribution of other benign gynecological diseases, notably endometriosis or leiomyomas, was not significantly different between the groups. After a multinomial regression model including notably the women's age and the presence of endometriosis or leiomyoma, the presence of focal adenomyosis was identified as an independent associated factor of primary infertility (1.9; 95% CI: 1.1 - 3.3).

Limitations, reasons for caution: Inclusion of only surgical patients may constitute a possible selection bias. In addition, it cannot be excluded that other non–explored causes of infertility were present among the infertile women-group.

Wider implications of the findings: This study opens the door to future clinical and basic studies aiming at better characterizing focal adenomyosis and its infertility-related physiopathology

Trial registration number: NA

P-326 The correlation between gene expression in endometrial cells and the formation of pinopodes

I. Ilyin[1], O. Parnitskaya[2], N. Kazachkova[3], J. Gontar[3], Y. Gerevich[1], E. Kapustin[1], N. Buderatskaya[2], S. Lavrynenko[2], Y. Lakhno[3]

[1]Medical Centre IGR, ART department, Kyiv, Ukraine ;
[2]Medical Centre IGR, Embryology, Kyiv, Ukraine ;
[3]Medical Centre IGR, Diagnostic Laboratory, Kyiv, Ukraine

Study question: Do different patterns of gene expression affect morphology of the endometrial tissue in natural or stimulated cycles?

Summary answer: A specific pattern of gene expression contributes to the formation of a certain endometrial morphology, such as the appearance of pinopodes.

What is known already: Well known that recurrent implantation failure is tightly related with endometrial cells function. Endometrial structure and receptivity are result of gene expression in certain period of menstrual cycle. Many investigations indicated main genes of endometrial receptivity regulation in samples of infertile women. But it is equally important to understand how genes are expressed in the known morphology of endometrial tissue in fertile young women, such as oocyte donors in the natural menstrual cycle and during ovarian stimulation. Since there is an opinion that hormonal stimulation is ahead of the endometrium development in comparison with the natural cycle.

Study design, size, duration: The study was performed in the Medical Centre IGR from March 2018 to December 2019. It involved 42 endometrial samples obtained from 32 oocyte donors whose mean age was 27.9±2.8 (range 22-32 years). The parts of tissue sample were examined for detection of pinopodes, tissue structure and expression of following genes generally upregulated during receptive phase (URG) *PAEP,GPX3, TAGLN,EDNRB, CLU, HABP2,LMOD1, IMPA2, GAS, FXYD2* and such downregulated genes (DRG) as *HLA-DOB, CTNNA2, CAPN6, MAP2K6, NDRG2,SORD*.

Participants/materials, setting, methods: The whole endometrial tissue sample was received by pipelle biopsy from 32 women on the mid-luteal phase of the natural menstrual cycle or on the day of oocyte pick up. Each biopsy was separated into three parts:one was fixed in 10% formaldehyde for histopathological analysis, the other piece was fixed in 2.5% glutaraldehyde for scanning electron microscopy (SEM) and the third part in PBS was taken for gene expression detection using qPCR analysis.

Main results and the role of chance: Of 42 samples 33 were obtained from women in the natural menstrual cycle and 9 samples were taken after oocyte retrieval, moreover 9 women also had been sampled in the natural cycle prior to ovarian stimulation start. The expression of URG in edometrium cells was higher in stimulated cycles (n=7), but statistically it wasn't significantly different (SSD) (p>0,05), the expression pattern of the DRG was the same in natural and stimulated cycles. Histopathological analysis of each sample also was similar and showed type of tissue structure appropriate early secretion.

According to the results of SEM, all samples were divided into 3 groups: (A) no signs of pinopodes formation (n=31), (B) increased number of ciliary cells without pinopodes formation (n=9) and (C) the presence of pinopodes in the samples (n=2). Group A had pattern with very low expression of URG and higher DRG. Group B samples demonstrated higher expression of URG and high expression of some DRG. And group C samples showed high level expression of URG and low expression of DRG similar to expression profile during receptive phase; that showed a SSD calculated by Chi-square on levels of gene expression relative to groups A and B (p<0,001).

Limitations, reasons for caution: Tracking changes in endometrial morphology using SEM and specific genes expression is a useful tool in predicting of embryo implantation. But these indicators are very variable depending on the individual characteristics of the patient as well as the selected drugs and dosages correctness in the cycles of ovarian stimulation.

Wider implications of the findings: A study of the morphology and gene expression of endometrial samples obtained from donor is the basis for assessing the status of the endometrium in patients with infertility, which allows us to more accurately understand the problem of implantation failure and adjust treatment in the right direction

Trial registration number: Not applicable

P-327 Bowel endometriosis-related infertility: assisted reproductive technology (ART) outcomes are favorable in women with no prior history of surgery for endometriosis

C. Maignien[1], P. Santulli[1], M. Bourdon[1], L. Marcellin[1], K. Pocate-Cheriet[2], J. Gonnot[1], V. Blanchet[1], C. Chapron[1]

[1]Assistance Publique-Hôpitaux de Paris AP-HP- Centre Hospitalier Universitaire CHU Cochin, Department of Gynaecology Obstetrics II and Reproductive Medicine, Paris, France ;
[2]Assistance Publique-Hôpitaux de Paris AP-HP- Centre Hospitalier Universitaire CHU Cochin, Department of Reproductive Biology, Paris, France

Study question: To evaluate the ART cumulative live birth rates (CLBR) in a cohort of bowel endometriosis (OSIS) patients with no prior history of surgery for OSIS

Summary answer: ART CLBR are excellent (67.3%) in bowel OSIS patients with no prior history of surgery. No bowel complications occurred during ovarian stimulation or pregnancy

What is known already: Bowel OSIS-related infertility is a therapeutic challenge, with 2 main treatment modalities: surgery and ART, each with different risks of complications. Numerous reports have been published about ART pregnancy rates after bowel surgery, but data are currently lacking on ART outcomes in bowel OSIS affected-women who reverted to ART first. Moreover, the determinant factors of pregnancy chances in this specific population remain unclear

Study design, size, duration: Observational cohort study on 101 consecutive bowel OSIS patients without a prior history of surgery for OSIS, who underwent IVF-ICSI treatment at Cochin-Port-Royal Hospital between January 2013 and December 2018. Diagnosis of OSIS was based on published imaging criteria using transvaginal sonography and magnetic resonance imaging. Patients with a prior history of surgery for OSIS were excluded

Participants/materials, setting, methods: The main outcome measure was CLBR. Miscarriage rates, perinatal outcomes and bowel complications were also studied. We compared the characteristics of women who became pregnant and those who did not, using univariable and multivariable analysis, to identify determinant factors of fertility outcome

Main results and the role of chance: One hundred and one bowel OSIS patients underwent 176 ART cycles. The mean number of deep infiltrating endometriosis lesions per patient was 3 ± 0.9, with a mean number of bowel lesions

of 1.3 ± 0.6. Seventy-three percent of the patients had associated endometriomas, and 88.1% had associated adenomyosis. Overall, the cumulative live birth rate was 67.3%. No bowel complication occurred during ART cycles or pregnancies. Regarding perinatal outcomes, cesarean sections were performed in 38.2% of the pregnancies; there were 7.4% preterm births (< 37 WG) and 10.3% low birthweight (< 2500 g). Using multivariate analysis, AMH levels <2 ng/mL ($p < 0.001$) and antral follicle count < 10 ($p = 0.006$) were the only factors associated with negative ART outcomes

Limitations, reasons for caution: The diagnosis of OSIS was based on imaging rather than surgery. This limitation is however inherent to the design of the studies on OSIS patients reverting to ART first

Wider implications of the findings: CLBR are excellent in bowel endometriosis patients undergoing ART first, with low risks of complications. Low ovarian reserve seems to be the main prognostic factor of ART CLBR. These data urge the clinician to carefully weight the pros and cons before systematically referring infertile bowel OSIS patients to radical surgery

Trial registration number: NA

P-328 Deep endometriosis with digestive involvement : Comparison of the surgical strategy and ATR

R. Goldstein[1], S. Bendifallah[2], S. Touleimat[3], H. Roman[3], F. Krief[4], M. Ballester[5], E. Darai[1,2], 2. Bendifallah.S([1]

[4]Hôpital Jean verdier, Department of gynecology-obstetricics, Bondy ;
[5]Hôpital Diaconesse, Department of gynecology-obstetricics, Paris ;
[6]Hôpitaux de Saint Maurice, Department of gynecology-obstetricics, Saint Maurice

Study question: To compare the fertility results of two therapeutic strategies for colorectal endometriosis associated-infertility :surgery followed by spontaneous conception+ / - IVF (In vitro fertilization) versus IVF in first intention.

Summary answer: For women with colorectal endometriosis associated-infertility, first-line surgery seems to be a good option, especially for patients with good prognostic factors.

What is known already: surgery for deep endometriosis improved fertility. Regarding endometriosis with digestive involvement, data in the literature are scarce. Their is no consensus for the management of those patients. . Regarding endometriosis with digestive involvement, data in the literature are scarce. Their is no consensus for the management of those patients.

Study design, size, duration: Retrospective cohort study conducted in hospital Tenon in Paris and in the University hospital of Rouen, two referral centers in endometriosis. Patients: 159 patients were inclued between January 2010 and December 2016

Participants/materials, setting, methods: The patients were matched after using a propensity score (PSM). The propensity score was developed using a logistic regression model, with the following covariates : age, anti-mullerian hormone (AMH) and the presence of adenomyosis.113 patients were included in the surgery first group and 46 patients in the IVF first group. Patients follow-up was done for a period of at least 24 months after surgery or the first IVF cycle.

Main results and the role of chance: After PMS, The pregnancy rate was 76% (86/113) in the primary surgery group (including 33.7% (29/86) after spontaneous conception and 66.3% (57/86) after IVF), versus 30.4% (14/46) in the IVF first group. The live birth rate was 50.4% (57/113) in the primary surgery group (including 45.6% (26/57) after spontaneous conception and 54.4% (31/57) after IVF), versus 23.9% (11/46) in the IVF first group. Overall the 182 cycles performed, the cumulative rates of live birth after the first IVF cycle in the surgery first group compared to the IVF first group were 29.6% versus 15.2%, for the second cycle 44.2% versus 28.6% and for the third cycle 69.6% versus 40.5%.For patients oriented towards spontaneous conception attempt after surgery, the pregnancy rate was 69% (29/42) and the live birth rate 61.9% (26/42), with a median time of 6 months [IQR: 5-11 months] for pregnancy. Pregnancy and live birth rates were significantly higher in the surgery first group compared to the IVF first group, especially for the subgroup of patients with good prognostic factors (AMH> 2 ng / mL, age <35 years and no adenomyosis).

Limitations, reasons for caution: retrospective study, selection bias (Two referral centers of endometriosis surgery), difference between the 2 groups (3 for 1 pairing after PSM)

Wider implications of the findings: Pregnancy and live birth rates were significantly higher in the surgery first group compared to the IVF first group, especially for the subgroup of patients with good prognostic factors (AMH> 2 ng / mL, age <35 years and no adenomyosis).
This study highlights a good live birth rate after surgery for the spontaneous pregnancy, with a median time of 6 months.

Trial registration number: not applicable

POSTER VIEWING SESSION
ETHICS AND LAW

P-329 Analysis of the outcomes chosen by european patients for their surplus embryos, taking into account all possible options available in Spain

M. Lopez-Teijon[1], V. Walker[1], C. Castello[1], B. Marques[1], S. Novo[1], F. Garcia[1], A. Garcia-Faura[1]

[1]Institut Marques, Reproductive Medicine Service, Barcelona, Spain

Study question: What outcome do patients choose for their surplus frozen embryos?

Summary answer: Only 13,3% of patients who have surplus embryos make an active choice about their final outcome. 86,7% don't respond, or keep the embryos for themselves.

What is known already: Fertility clinics continue to accumulate frozen embryos. Deciding what to do with surplus embryos can be difficult for patients and can create significant emotional conflict.
It's not that patients have an irresponsible attitude towards their embryos; rather it appears to be the long-reaching implications that their decision might have. Patients don't want to give the embryos to other women for fear their children might one day meet their siblings; they don't want to destroy them because it makes them feel bad, and they don't want to donate them to research because they are frightened of what might be done to them.

Study design, size, duration: In accordance with Spanish law, patients sign a consent form confirming their desired outcome for their surplus embryos. All options are open to them, and every 2 years after freezing the patients receive a letter asking them to reconfirm or alter their previous decision.
We assessed the informed consents from 7607 patients doing IVF (own eggs and donor eggs) between 2012 and 2016 with surplus frozen embryos. Patient follow-on replies up to 2018 were analysed.

Participants/materials, setting, methods: Patient consent forms and replies were analysed and the chosen outcome for the embryos noted. We compared the replies given by patients from different european countries and also the decisions made by patients regarding embryos made from their own gametes or from donor gametes.

Main results and the role of chance:

1. B. 41% wished to maintain the embryos for their own use. 90% of these patients had completed their family, they didn't want any more children but they still preferred to keep their surplus embryos.
   C. 2% destroyed the embryos
   D. 3% gave them away to others
   E. 3% donated them to research

There were no significant differences in the results according to the biological origin of the embryos. There were though notable differences between the options chosen by patients from countries in close geographical proximity, which highlights the idiosyncrasies of each culture.

Ireland: A 45%, B 45%, C 1,5%, D 7%, E 1,5%
UK: A 63%, B 29%, C 3%, D 3%, E 2%.
Germany: A 36%, B 51%, C 6,5%, D 6%, E 0,5%.

France: A 61%, B 25%, C 7%, D 4%, E 3%.
Spain: A 56%, B 33%, C 2%, D 3%, E 6%.

Limitations, reasons for caution: The study did not differentiate between replies from couples or single patients. Therefore in the majority of cases it is a joint decision made by the couple, and maybe if just one partner was asked to decide the results would have been different.
Wider implications of the findings: When couples finish their reproductive project their surplus embryos create a problem they do not know how to resolve.

If they don't answer the letters sent to them, embryos are considered abandoned. Spanish law allows fertility clinics to choose the outcome for these embryos, that can include entering the embryo-adoption program.
Trial registration number: not applicable

P-330 Import/export of cryopreserved gametes and embryos between European centers: what should be done, which forms, which protocols, which responsibilities: an Italian experience

[15]SIERR, Italian Society of Embryology- Reproduction and Research, Italy, Italy

Study question: is standardization of National and International procedures and forms for cryopreserved samples transfer sufficient to meet quality, traceability and safety requirements?
Summary answer: Indications on shipping between tissue institutions and legal responsibilities are important points and a working protocol with shared transport forms has been defined.
What is known already: In Italy, the transport of cryopreserved biological material is dealt exhaustively by several Legislative Decree (No. 191/2007;16/2010 and D Lgs 10 October 2012) which transpose European Directives. Given the nature of their application, the transport of reproductive cells has peculiar quality and safety requirements that must be applied univocally, minimizing the chance of error. In order to standardize the transborder shipping procedure to meet the quality, traceability and safety criteria for cells and tissues, it is appropriate to establish a unified process using the same tools, forms and communication channels.
Study design, size, duration: The Italian Society of Embryology, Reproduction and Research (SIERR) has defined a working protocol with shared forms in order to distribute them nationally and internationally. This is necessary in light of the increasingly widespread movement of biological samples between the various countries.
Participants/materials, setting, methods: A working group has been created by SIERR. This "FOCUS Group" was constituted by representatives from Italian ART centres and Sperm Banks who worked together to define joint procedural steps and create specific forms to support movement of cryopreserved samples.
Main results and the role of chance: The FOCUS Group identified the critical steps in the communication procedures between centres and created the related forms: patient authorisation, request from the recipient centre, critical checks carried out by both sending and recipient centres, start of samples transfer, collection, transport and taking responsibility of the biological material, acknowledgment of samples arrival, acknowledgement of any adverse event occurred.
Limitations, reasons for caution: SIERR will evaluate the validity of these modules through several pilot SIERR affiliated ART centres in order to evaluate the concrete application and usefulness of the forms.
Wider implications of the findings: Transfer of cryopreserved samples between centers implies effective and appropriate on time communication in order to establish the approaches of transport itself, in terms of ethical, legal and practical management. It is increasingly essential to share a homogeneous procedure that guarantees the management of cryopreserved gametes and embryos.
Trial registration number: not applicable

P-331 PGT-A in any Egg Donation

A. Anastasi[1], F. Capodanno[1], S. Rossi[1], A. Gallinelli[1]

[1]AUSL di Ferrara - Ospedale del Delta di Lagosanto, Centro di Fisiopatologia della Riproduzione Umana, Ferrara, Italy

Study question: Why Pre implantation Genetic Test for Aneuploid diseases (PGT-A) should be routinely performed in Egg Donation (ED)?
Summary answer: Only euploid embryos should be routinely transferred after ED. Following a stressful and expensive ED, embryo transfer with euploid-blastocyst should be strongly recommended.
What is known already: Data from EIM for ESHRE, suggest that 39 Countries and 1.279 Institutions perform ART, with a total of 56.516 ED. No informations about ED following embryo-transfer with euploid-embryos are available. Even if egg-donors are young, aneuploidy increases in women older than 26. A slightly increased prevalence of embryo aneuploidy is reported in young patients, with >40% aneuploidy in women 23 years and less. Aneuploidy can not be excluded in young egg donors.
IVF Centers discourage PGT-A following ED, without any scientifically reason. We speculate that PGT-A in ED is not perfomed with the questionable aim to guarantee fresh and following frozen-embryo-transfer.
Study design, size, duration: To perform PGT in all ED, offering to the patients the higher chances to transfer an euploid embryo. It would be advisable to set a duration of 2 years in order to evaluate the cost-effective of this approach.
Participants/materials, setting, methods: The are 39 Countries and 1.279 Institutions offering ART services, 56.516 treatment cycles with egg donation (ED) where the study could be conducted.
Main results and the role of chance: The main goal is to establish a clinical setting that it offer to the couples submitted to ED the highest chances to transfer one euploid embryo, optimizing the costs of the procedure. The second objective is the cost-effective evaluation of the policy we suggest: cost-effectiveness analysis is an hot topic in the debate about clinical application of PGT-A, but we assume that the high cost of new techniques for the genetic screening such as the Next Generation Sequencing (NGS), could be surely covered by high number of couples seeking PGT after ED. Recent studies suggest a positive cost-effective ratio only in women older than 35 years old. However, no data are available regarding cost-effectiveness of PGT-A in younger patients or in those submitted to ED. In our view, PGT-A could allow to optimize the cost of ED, allowing to the couples to pay for euploid embryos, and not for the aneuploid ones. The question we should make us in term of costs is the following: how much any aneuploid embryo cost respect to any euploid one?

The unique way to support couples hopeful having euploid gametes is PGT-A, especially in ED where financial and psychological investment of infertile women are consistent.
Limitations, reasons for caution: PGT-A following ED could flow in the indiscriminate employment of this technique, with a consequent uncontrolled business.

PGT-A following ED is difficult to adopt because of financial, social and organizational reasons.
Wider implications of the findings: Optimization of financial and psychological investment of couples submitted to ED.
To get more data about aneuplody frequency in egg donors.
Trial registration number: not applicable

P-332 Ethical concern regarding the assisted reproduction techniques: a qualitative interview study with professionals, patients, donors and general population

J. Guijarro[1], R. Nuñez-Calonge[2]

[1]Hospital Virgen de la Luz- Cuenca, Obstetricia y Ginecología, Cuenca, Spain ; [2]Duncan, Ethics and reproduction, Madrid, Spain

Study question: Is there a different ethical consideration regarding the assisted reproduction techniques of professionals compared to patients, donors and general population?
Summary answer: There is a different moral consideration towards the problems derived from assisted reproduction techniques, being higher in physicians and laboratory personnel and lower in donors.
What is known already: Assisted reproduction techniques (ART) have opened numerous ethical questions different from religious or legal approaches, involving not only the professionals who perform them but also patients and donors. Additionally, many ethical challenges generated by new scientific developments in this field generate widely differing opinions.

To date, there are no studies comparing the concerns of the different moral agents involved in these processes and whether the ethical issues raised are the same in all these groups.
Study design, size, duration: The plan was set-up as an electronic qualitative survey study and took place between September and December 2018.
Participants/materials, setting, methods: Data were collected from 123 voluntarily participating assisted reproductive centres (including clinicians, embryologists, nurses and administrative staff) and 110 non-professionals (oocyte and sperm donors, patients and general population). Participants filled out an anonymous questionnaire asking for their socio-demographic characteristics and 100 questions based on the main ethical problems. After a depuration process by means of Factorial Analysis a definitive questionnaire with 41 items was obtained.
Main results and the role of chance: Based on the interviews, we articulated four main topics describing participants views regarding the ethical aspects of assisted reproduction: solidarity, morality, religiosity and confidence. Comparing the average of scores in the four issues according to the professional relationship with assisted reproduction it was concluded that the professional / non-professional dichotomy is the one that occupies more extreme values: the professionals display a greater preoccupation by the morality, a greater confidence and a more restrictive attitude, without influence by religiosity. Conversely, non-professionals present a more solidary and mistrustful profile, with greater disregard for moral issues. Within the group of professionals, doctors have a greater moral concern than the rest and a less supportive attitude.

People without a direct relationship with reproduction have a more supportive and distrustful profile, similar to the patients, but clearly present a greater indifference for moral problems. Donors are the group that presents less concern for ethical or moral aspects and greater confidence in medical decisions.
Limitations, reasons for caution: The non-existence of religious differences in the surveyed population may have led to a bias in some answers.

A possible effect of social desirability in the answers by the patients should be considered.
Wider implications of the findings: The differences in systems of values demonstrate the need to have a thorough discussion on the specific meaning of the ethics terms.

The personal profile can be useful in clinical practice when dealing with the patient in an individualized manner.
Trial registration number: Not applicable

P-333 Artificial womb technology and the ethics of prenatal medicine

S. Segers[1]

[1]Bioethics Institute Ghent - Ghent University, Department of Philosophy and Moral Sciences, Gent, Belgium

Study question: How would artificial womb technology affect how obligations towards the future child and obligations towards the expecting mother are balanced against each other?
Summary answer: Artificial womb technology could facilitate prenatal interventions and may exacerbate potential conflicts between directive treatment recommendations and the pregnant woman's autonomous decision to the contrary.
What is known already: Current developments in artificial womb technology have rekindled the expectation that human ectogenesis may come within reach. As yet, the ethics debate has largely focused on the link with abortion, how this technology may provide an alternative for surrogacy or uterus transplantation and how it could remedy gender inequity and enhance reproductive autonomy. So far, the morally relevant connection between ectogenesis and the fetus as a beneficiary of treatment is largely overlooked. Ectogenesis could provide easier access to the fetus and thus contribute to the allocation of a patient status to the fetus.
Study design, size, duration: A literature study of the scientific literature was performed to inventory the state-of-the-art of artificial womb technology and a literature study of the respective bioethical literature was performed to inventory the main ethical arguments. Next, ethical problems in prenatal medicine were conjoined with normative argumentation to arrive at substantiated ethical judgements with regards to the ethics of ectogenesis and decision making in prenatal medicine.
Participants/materials, setting, methods: Literature study, conceptual analysis, normative analysis.
Main results and the role of chance: Suggestions have been made that ectogenesis could make it easier for clinicians to fix fetal defects by allowing to treat the fetus outside the woman's body, inside the artificial womb. Combined with social expectations about maternal responsibilities, this may put pressure on pregnant women to undergo prenatal interventions for the benefit of the future child. However, despite an expected better fetal accessibility, concerns for the pregnant woman's wellbeing still remain in case of surgical removal and physical translocation of the fetus to the artificial uterus. While a pregnant woman may have obligations of beneficence towards the fetus, she may nevertheless refuse interventions, not only because of the value of autonomy, but also that of bodily integrity. An argument can be made that a focus on fetal beneficence should not disregard potential cases of autonomy violation as connected with a person's life goals and personal interests (like the woman's wish to carry the fetus in the womb to birth). As such, ectogenesis aided fetal treatment could induce higher tensions between a clinician's obligations towards the pregnant woman and the future child. It is defended here that ectogenesis would not circumvent the key ethical concerns that come with in utero fetal treatment.
Limitations, reasons for caution: Human ectogenesis is still hypothetical, especially the variant where the offspring's development happens from conception to birth completely outside a woman's uterus. This paper focuses on partial ectogenesis, meaning that 'ectogenesis' will generally refer to the transfer of a partially developed fetus to an artificial womb for further development.
Wider implications of the findings: The availability of ectogenesis aided fetal treatment could open the door for routine directive counselling for fetal benefit. With the advent of artificial womb technology, it is timely to inquire whether actual clinical codes of practice are sufficiently fine-grained to provide ethical guidance to the future practice of prenatal medicine.
Trial registration number: BOF19/24J/066

P-334 The ethical implications of the framing of egg donation on Belgian fertility clinic websites

L. Jacxsens[1], C. Coveny[2], L. Culley[3], T. Goethals[1], C. Herbrand[4], S. Lafuente[5], V. Pavone[6], G. Pennings[7], V. Provoost[7], C. Weis[3], N. Hudson[3]

[1]Ghent University, Bioethics Institute Ghent, Ghent, Belgium ; [2]Loughborough University, Department of Social Sciences, Loughborough, United Kingdom ; [3]De Montfort University, Centre for Reproduction Research, Leichester, United Kingdom ; [4]De Montfort University, Centre for Reproduction Research, Leicester, United Kingdom ; [5]Goethe-Universität Frankfurt am Main, Faculty of Social Sciences, Frankfurt am Main, Germany ; [6]Consejo Superior de Investigaciones Cientificas, Institute of Public Goods and Policies, Madrid, Spain ; [7]Ghent University, Bio-ethics, Ghent, Belgium

Study question: How is egg donation framed on the websites of fertility clinics in Belgium and what are the ethical implications of this framing?
Summary answer: Donors were presented as mothers under 37; recipients as heterosexual couples with a medical need. Overall, egg donation was framed as a medical act.

What is known already: How information is presented or framed can significantly influence the interpretation and decisions of the reader. Therefore, the framing of egg donation in information for prospective donors is ethically important. In the literature, the most important ethical debates concerning egg donation deal with the topics of commercial egg donation, postmenopausal pregnancies and anonymity. Studies (mostly conducted in the United States) have shown that the framing of gamete donation is gendered and that altruism seems to play an important role. This is the first frame analysis of the Belgian context.
Study design, size, duration: This study is part of the ESRC-funded 'EDNA' project that aims to explore the social, political, economic and moral configuration of egg donation in the United Kingdom, Belgium and Spain. In this study we only focused on Belgium.
Participants/materials, setting, methods: We analysed the websites of all 18 Belgian fertility clinics that perform egg donation. Frame analysis and content analysis were used. The websites of clinics in Flanders and Wallonia were analysed separately.
Main results and the role of chance: On Belgian clinic websites egg donation is presented as a service that suffers from scarcity in donors. Images found on clinic websites were mainly in the style of commercial advertisement images, with the exception of a small number of websites where 'scientific' images were used. Overall, the donor was presented as someone who is (preferably) a mother, younger than 37 years, and highly motivated, typically because she donates to or for (in the case of cross donation) family or friends. The recipients were framed as heterosexual couples who are in need of eggs due to medical reasons. In general, egg donation was framed as a medical act. Information relating to risks mainly dealt with physical aspects whilst psychological risks were less frequently mentioned. Minor risks (such as temporary physical discomfort) and more serious risks (e.g. ovarian hyperstimulation syndrome) received equal coverage. All websites where compensation was mentioned made it clear that this is not a payment and only one website mentioned the amount of compensation. On the Flemish websites expressions of clinic preference for anonymous donation were present whereas this was not found on the Walloon websites.
Limitations, reasons for caution: Clinic websites are the first step in a process of information provision that continues in the clinic. The current analysis is limited to one country. In a further phase, these data will be combined with data from the two other countries (UK and Spain) involved in the EDNA-project
Wider implications of the findings: The presentation of donor or recipient profiles is ethically important since people who do not relate to these profiles might feel excluded, thus dismissing egg donation as an appropriate practice. The framing of risks has ethical implications for the donors' informed consent.
Trial registration number: ES/N010604/1

P-335 Relational autonomy in postmortem sperm retrieval and donation

H. Mertes[1]

[1]*Bioethics Institute Ghent BIG Ghent University, Department of Philosphy and Moral Sciences, Gent, Belgium*

Study question: Should relational autonomy be the standard instead of personal autonomy in the case of postmortem sperm retrieval and donation?
Summary answer: As genetic material 'belongs' to several family members and the disadvantages of the procedure fall disproportionately on family members, a relational approach should be pursued.
What is known already: Recently, a study was published pleading to include the option of postmortem sperm donation in organ donor programmes in order to increase the availability of donor sperm. This is technically feasible and if one relies on the analogy with organ donation, one could argue that it is the deceased's right to decide how his tissues are used after passing away. At the same time, several legal cases have been brought forward in which family members request control over reproductive material of a deceased person, some of which were successful.
Study design, size, duration: This is a normative analysis in which (a) different arguments from the literature and from legal cases are inventoried, compared and scrutinized; (b) the analogy with posthumous organ donation is dismantled, looking for semantic and structural (in)consistencies and (c) an exploration is made of how the concept of relational autonomy might be operationalized in this case and whether this would lead to better or worse outcomes for the different stakeholders.
Participants/materials, setting, methods: Literature research; normative analysis
The method that is used to bring empirical data (as found in literature research) and normative ethics together is the 'Wide Reflective Equilibrium', the most commonly used method in bioethics.
Main results and the role of chance: Personal autonomy is a very highly valued principle within biomedical ethics, yet it has been criticized for ignoring the fact that people are essentially relational, interconnected beings, that people's identities are shaped by those with whom they interact and that one person's decisions have implications for others. Feminist scholars have therefore introduced the concept of relational autonomy, which emphasizes the importance of input from the web of people a patient is connected with in medical decision making. While one should be very wary of this concept being abused to sideline autonomous choice, posthumous sperm donation may be one case in which a relational approach can be well defended. In first instance, this is because genetic material is concerned, over which people can be said to have shared 'ownership', rather than individual ownership (and thus decisional authority). Secondly, the benefits for the donor are dubious, whereas the donor's action can cause significant distress and grievance in his family. Also, the benefits for the recipients are of a different order than in the case of organ donation. Sharing the decisional authority between family members therefore seems appropriate.
Limitations, reasons for caution: What does not follow from this reasoning is that family members would have decisional authority over posthumous sperm retrieval and use in the absence of advance directives by the deceased. In this case the family would seek a benefit at the expense of the deceased's autonomy, instead of avoiding harm.
Wider implications of the findings: Although personal autonomy is and should be a central concept in reproductive ethics, incorporating relational autonomy can lead to new perspectives on how to deal with reproductive decision making.
Trial registration number: N/A

POSTER VIEWING SESSION
IMPLANTATION AND EARLY PREGNANCY

P-336 Anterior gradient protein 3 and S100P levels in the reproductive tract mucosa may play an important role in human fertility

N. Tempest[1,2], **E. Batchelor**[2], **J. Drury**[2], **D. Hapangama**[1,2]

[1]*Liverpool Women's Hospital, Obstetrics and Gynaecology, Liverpool, United Kingdom ;* [2]*University of Liverpool, Department of Women`s and Children`s Health- Institute of Translational MedicineLiverpool, Liverpool, United Kingdom*

Study question: Do women with implantation problems have altered levels of two endometrial calcium binding proteins (Anterior grade protein 3 (AGR3) and S100P) when compared with women of proven fertility?
Summary answer: Significantly higher AGR3 and S100P immunostaining was observed in cilia of luminal epithelium (LE) of women with implantation problems compared with women of proven fertility.
What is known already: Calcium signalling pathways are of vital importance to embryo implantation. Calcium-binding proteins such as S100P, Anterior gradient protein 2 (AGR2) and Anterior gradient protein 3 (AGR3) participate in these pathways. AGR2 and S100P have previously been shown to be involved in endometriosis and endometrial cancer and S100P demonstrates highest endometrial levels during the window of implantation (WOI). Endometrial expression and the functional relevance of AGR3 is unknown, but it may play an important role in the regulation of ciliary beat frequency, thus in the LE of the endometrium may play an important functional role in embryo transfer and fertility.
Study design, size, duration: This observational study examined luteinising hormone timed human endometrial samples taken in the WOI from 53 women (10 recurrent miscarriage (RM), 13 recurrent implantation failure (RIF), 30 control). The women underwent gynaecological procedures at a UK tertiary referral centre. The women did not have any known endometrial pathology and had not been on hormone treatment for 3 months prior to the procedure.

Participants/materials, setting, methods: Immunohistochemistry was used to confirm the presence of and immuno-staining patterns of AGR3 and S100P in human endometrium during the WOI. Immuno-reactivity was analysed with a quick score that quantified immunostaining in the different endometrial areas at the cellular level.

Main results and the role of chance: In total, 53 patients (10 RM, 13 RIF, 30 control) with an average age of 39 years were included in the study. The women in the RM group had an average of 4 previous miscarriages, while women in the RIF group had an average of 8 previous failed embryo transfers and the control group on average had 2 previous children.

The epithelial cell sub-region and subcellular location of S100P immunoreactivity was different in the healthy fertile controls when compared with the RM and RIF samples. Nuclear S100P was seen in control samples whereas RM/RIF samples showed no evidence of nuclear S100P immunoreactivity in the WOI. Cilia of the LE of the RM/RIF samples demonstrated significantly higher ($p<0.01$) S100P immuno staining when compared with the control samples.

Similar differences were observed in AGR3 immunoreactivity of the ciliated LE cells, where significantly higher immune-scores were demonstrated by RM/RIF samples ($p<0.01$).

This observed higher immunoreactivity for 2 calcium binding proteins in the LE cilia of women with a history of reproductive failure suggests their inaccurate subcellular location associated pathophysiology for these conditions. The nuclear localisation of S100P may allow transcriptional regulatory function that is necessary for implantation of a viable pregnancy.

Limitations, reasons for caution: This study employs only immunohistochemistry and although we have confirmed gene expression with qPCR no functional studies have been conducted to confirm a role of the 2 calcium binding proteins in the implantation process.

Wider implications of the findings: We describe the presence of epithelial AGR3 in the human endometrium and demonstrate differential AGR3 and S100P in the WOI in women with a history of reproductive failure. These proteins may have a functional role in fertility. Further work is thus warranted to assess their utility as a diagnostic/therapeutic targets.

Trial registration number: NA

P-337 Placental disorders of pregnancy and In-Vitro Fertilization – does placental histological examination explain the excess risk?

H. Ganer Herman[1], L. Tamayev[2], O. Feldstein[2], M. Bustan[2], Z. Rachmiel[2], L. Schreiber[3], A. Raziel[1], B. Jacob[2], M. Kovo[2]

[1]Edith Wolfson Medical Center, In Vitro Fertilization, Holon, Israel ; [2]Edith Wolfson Medical Center, Obstetrics and Gynecology, Holon, Israel ; [3]Edith Wolfson Medical Center, Pathology, Holon, Israel

Study question: Assessment of clinical characteristics of in vitro fertilization (IVF) pregnancies complicated by fetal growth retardation (FGR) and preeclampsia (PE), and the correlation to histopathological placental findings.

Summary answer: Neonatal outcome is relatively favorable in placental diseases in IVF pregnancies. Placental villitis is more common in IVF pregnancies, pointing to an additive immunological etiology.

What is known already: Assisted reproduction is correlated with an increased risk for FGR and PE, independent of the higher incidence of risk factors among IVF patients. FGR and PE, termed "the placental diseases of pregnancy", share a common pathogenesis of ischemia, with a higher rate of vascular mal-perfusion placental lesions. Villitis of unknown etiology is an additional placental finding in FGR, assumed to reflect an immunological pathogenesis.

Study design, size, duration: This was a retrospective cohort of 1114 deliveries during an 11-year period.

Participants/materials, setting, methods: The study was performed in a tertiary hospital. The cohort included deliveries with a diagnosis of FGR and/or PE, with a singleton live birth at 22 weeks of gestation or more, whose placentas were sent to histological examination. We compared obstetric, neonatal and placental characteristics between IVF conceived pregnancies and controls.

Main results and the role of chance: A total of 1114 deliveries with a diagnosis of placental related pregnancy complications were included - 105 conceived with IVF (IVF group) and 1009 non-IVF conceived (control group). Patients in the IVF group were older, and of lesser parity and gravidity. The rate of diabetes mellitus and chronic hypertension was significantly higher among IVF patients, and the rate of smokers significantly lower. Patients in the IVF group delivered at a significantly earlier gestational age, 36.6 ± 3.2 vs. 37.3 ± 2.9 weeks, p=0.02. A trend for a higher rate of cesarean delivery was noted in the IVF group, 69.5% vs. 60.7%, p=0.07, while birth weight was non-significant between the groups. A significantly higher rate of neonates in the control group experienced an adverse neonatal outcome. No difference in placental mal-perfusion lesions was demonstrated between the groups. However, a significantly higher rate of villitis of unknown etiology (VUE) was demonstrated in the IVF group, 16.1% vs. 8.3%, p=0.007. A sub-analysis of stimulated cycles, frozen embryo transfer cycles and controls, demonstrated a significantly higher rate of VUE among stimulated cycles as compared to controls (21.0% vs. 8.3%, p=0.006), with no significance between stimulated and frozen cycles, or frozen cycles and controls.

Limitations, reasons for caution: Despite a departmental protocol necessitating placental examination in complicated pregnancies, the study cohort probably represents more severe cases of FGR and PE, for which placental examination was performed. In addition, certain data was unavailable and underpowered for sub-analysis, such as IVF cycle characteristics (stimulated/frozen).

Wider implications of the findings: PE and FGR are common among IVF pregnancies, although neonatal outcome is more favorable in this group. Placental examination demonstrated a higher rate of VUE in IVF pregnancies, pointing to an additional immunological pathogenesis, thus contributing to our knowledge regarding the excess risk for placental disorders in IVF pregnancies.

Trial registration number: N/A

P-338 Proteomic characterization of endometrium in IVF-ET patients with repeated implantation failure

C. Wang[1], H.Y. Zhang[1], Z.J. Cheng[1], Y. Feng[1], W.J. Zhou[1], M.Y. Jiang[1], Y. Zhou[1], X.Y. Fei[1]

[1]Hangzhou Women's Hospital Hangzhou Maternity and Child Health Care Hospital, Reproductive Medicine Center, Hangzhou, China

Study question: Repeated implantation failure (RIF) seriously affects the clinical pregnancy rate of in vitro fertilization-embryo transfer (IVF-ET) treatment, while the pathogenesis of RIF was still unknown.

Summary answer: We highlighted antithrombin-III and corticosteroid-binding globulin as RIF-related proteins by screening the RIF patients' endometrium proteins.

What is known already: Assisted reproductive technology has developed for more than 40 years, but there is no significant breakthrough in pregnancy rate. RIF is a difficult problem in IVF-ET treatment. The uterine environment, especially the endometrial receptivity during the implantation window, has a great influence on the pregnancy of such patients.

Study design, size, duration: In this study, we collected the endometrium of IVF-ET patients in our hospital during 2016 to 2019. According to the pregnancy outcomes, we finally gained 40 RIF cases. According to the patients' age, infertile factors, and visiting time, we matched our RIF cases with 40 pregnant cases.

Participants/materials, setting, methods: All the female patients were aged under 40. We performed iTRAQ-2D LC-MS/MS between RIF and pregnant group. Clinical data were analyzed using paired t test.

Main results and the role of chance: Fifty-five higher expressed proteins (> 1.50 times, $P < 0.05$) and 27 lower expressed proteins (< 0.67 times, $P < 0.05$) were found significant changed by iTRAQ-2D LC-MS/MS in RIF patients. Furthermore, the most different categories: negative regulation of hydrolase activity, blood particles, and enzyme inhibitor activity were found in the biological process, cell composition and molecular function through GO analysis with hypergeometric test. We also found that the differential proteins were mostly in the immune system, and mRNA translation through KEGG analysis, while most of them were enriched in the primary immunodeficiency. At last, we discovered that these RIF-related proteins were clustered mostly in the post-translational modification, protein turnover, chaperones; transduction, ribosome structure and biogenesis; and function unknown using the EggNOG database. The most repeated proteins were antithrombin-III and corticosteroid-binding globulin, in the different categories we found by GO analysis, which related to hypercoagulable state and lower progesterone level, respectively. However, we found higher level of D-Dimer and lower level of progesterone in RIF patients with no significant differences ($P > 0.05$).

Limitations, reasons for caution: Most of the proteins that screened by iTRAQ-2D LC-MS/MS were lack of commercialized ELISA Kit or antibody, and

we could only compare paired RIF and pregnant cases' clinical data to reveal the hypercoagulable state and lower progesterone level of RIP patients. More cases of clinical data were needed.
Wider implications of the findings: Our results might give a new sight into the implantation-related molecular, moreover, also provides a new experimental basis to understand the pathogenesis of RIF.
Trial registration number: Project supported by the Medicine and Health Science Technology project of Zhejiang province,China(2017KY550), the Natural Science Foundation of Zhejiang province,China (LQ18H040009).

P-339 Circ-CCNB1 inhibits trophoblast cells proliferation and inasion by sponging miR-223 to regulate SIAH1 during embryo implantation

D. Wang[1], L. Xie[1], M. Jin[1], Y. Zhou[1], A. Liu[1]

[1]School of Medicine- Zhejiang University, Reproductive endocrinology, Hangzhou, China

Study question: Whether circRNAs regulate trophoblasts function and the tentative molecular mechanisms in aberrant implantation environment remains unknown.
Summary answer: circ-CCNB1 regulates trophoblast cell proliferation and invasion through sponging miR-223 to increase SIAH1 expression and inhibit CCNB1 nuclear translocation.
What is known already: Ectopic pregnancy (EP) has been recognized as a model to investigate the signaling and pathways regulated by trophoblast cells during embryo implantation. Circular RNAs (circRNAs) have been reported to exert important regulatory effects on trophoblasts function and embryo development.
Study design, size, duration: To study the tentative molecular mechanisms in the occurrence of EP, five trophoblast cells samples from EP and five trophoblast cells samples from normal pregenancy were used to analyze the differential expression of circRNAs by high-throughput sequencing. To determine the effect of circ-CCNB1 on trophoblast cells function, JEG-3 and HTR-8 cells were transfected with overexpression of circ-CCNB1 vectors or empty vectors for 24 h or 48 h *in vitro*.
Participants/materials, setting, methods: Through high-throughput sequencing, we found the decreased expression of (circRNA CyclinB1) circ-CCNB1 in the patients with EP. Subsequently, overexpression of circ-CCNB1 vectors, CCK-8, transwell, immunofluorescence, quantitative PCR, western blot, RNA pull-down and dual-luciferase reporter assays were used to investigate the effect of circ-CCNB1 on the function of trophoblast cells.
Main results and the role of chance: *In vitro* study demonstrated that overexpression of circ-Ccnb1 slightly inhibited JEG-3 cell proliferation and significantly inhibited HTR-8 cell proliferation after 24h and 48h treatment. Moreover, transfection of circ-Ccnb1 overexpression vectors lead to a significant decrease of cell invasion in JEG-3 and HTR-8 cells. Furthermore, miR-233 was predicted and demonstrated to interact with circ-Ccnb1 in trophoblast cells. We found miR-233 mimics treatment decreased the expression levels of circ-Ccnb1, whereas miR-233 inhibitor significantly enhanced the expression levels of circ-Ccnb1 in trophoblast cells. Meanwhile, miR-233 inhibitor treatment suppressed cell proliferation and invasion in HTR-8 cells. Interestingly, we found miR-233 dramatically increased cyclin related genes CCNB1, Thymidine kinase (TK1) Krüppel like factor-4 (KLF4) and nuclear factor kappa B (NF-κB) expression levels, while significantly decreased the expression levels of E3 ubiquitin ligase, seven in absentia homolog-1 (SIAH1) and F-box and WD-40 domain protein 7 (FBXW7), and apoptotic factor caspase-3. SIAH1 was testified to be directly targeted by miR-233, which could be activated by circ-Ccnb1 treatment in trophoblast cells. In addition, we also found circ-Ccnb1 increased CCNB1 expression levels and suppressed CCNB1 nuclear translocation in HTR-8 cells.
Limitations, reasons for caution: The investigation of the molecular mechanism of circ-CCNB1 regulating trophoblast cells function was limited in trophoblast cells *in vitro*. It's necessary to testify this mechanism in the EP animal models in future.
Wider implications of the findings: These results demonstrated an important molecular mechanism of circ-CCNB1 regulating trophoblast cell proliferation and invasion through sponging miR-223 to increase SIAH1 and inhibit CCNB1 nuclear translocation, which might provide a novel pathophysiological characteristic during embryo implantation.
Trial registration number: 20180192

P-340 Can AUTOLOGOUS PLATELET RICH PLASMA treatment improve pregnancy outcome in ivf/et cases : a case control study done at Teerthanker Mahaveer Medical College & RC

P. Singh[1]

[1]TMMC&RC, OBS & GYNAE / IVF, MORADABAD, India

Study question: Can AUTOLOGOUS PLATELET RICH PLASMA treatment improve pregnancy outcome in ivf/et cases ?
Summary answer: the use of autologous PRP holds promise in the treatment of women with suboptimal ET and vascularity for embryo transfer.
What is known already: Poor endometrium is a cause of treatment faliure in majority of cases of assisted reproduction .refractory endometrium is seen in many cases which does not respond to various treatments e.g. vaginal silnafil , esrtogen,androgens,low dose aspirin etc.to overcome this refractory endometrium PRP treatment was found effective .
Study design, size, duration: CASE CONTROL STUDY
18 MONTHS
168 PATIENTS WERE INCLUDED IN STUDY.
Participants/materials, setting, methods: Intrauterine instillation of autologous PRP was done in 168 women,101 did not received aprp treatment due to various reasons,taken as controls between 22 and 45 years, over 18 months, with suboptimal endometrial growth, and patients with repeated cycle cancellations, in addition to vaginal sildenafil ,Estradiol valerate etc . Embryo transfer was performed when the endometrium reached an optimal pattern in terms of thickness, appearance, and vascularity.
Main results and the role of chance: The mean pre-PRP endometrial thickness (ET) was 3.5 mm which significantly increased to 7.18 mm post-PRP. There was a significant increase in vascularity, seen by the number of vascular signals seen on Power Doppler, reaching the zones 3 of the endometrium. The positive beta Human Chorionic Gonadotropin (hCG) rate was 70.93% and the clinical pregnancy rate was 42.31%. A total of 47 delivered healthy babies ,11 women are in the second trimester, 12 are in the first trimester with a healthy intrauterine pregnancy, one patient had an ectopic gestation, 22 had missed abortions.
Limitations, reasons for caution: Small sample size
Wider implications of the findings: Patients with refractory endometrium ,especially in younger age groups seems to be benifitted by this technique.
Trial registration number: NA

P-341 Impact of uterine contractility on pregnancy success rate during in-vitro fertilisation: assessment by quantitative ultrasound imaging

C. Rees[1], C. Blank[1], N. Kuijsters[2], Y. Huang[2], F. Sammali[2], H. Van Vliet[1], P. De Sutter[3], M. Mischi[2], B.C. Schoot[1]

[1]Catharina Hospital Eindhoven, Obstetrics and Gynaecology, Eindhoven, The Netherlands ;
[2]Eindhoven University of Technology, Signal Processing Systems, Eindhoven, The Netherlands ;
[3]Ghent University Hospital, Reproductive Medicine, Ghent, Belgium

Study question: Can assessment of uterine activity in patients with successful in-vitro fertilisation (IVF) versus patients with unsuccessful IVF treatment be used to predict success of embryo implantation?
Summary answer: Measuring uterine contractility prior to embryo implantation in IVF patients is able to predict chance of pregnancy with 93.8% accuracy.
What is known already: During the menstrual cycle, the natural contraction pattern of the uterus is affected by changes in hormones. Abnormal uterine contraction activity is known to influence the outcome of fertility treatment. Recently, an automated measurement tool to characterise these movements has been developed, but has not yet been widely applied to patients receiving fertility treatment.
Study design, size, duration: A single-centre prospective study included 16 IVF/ICSI patients between January 2017 and July 2018. Participants underwent three quantitative 2D-transvaginal ultrasound measurements prior during three phases of IVF treatment: follicle stimulation (FS), one hour before embryo transfer (ET1), and five to seven days after ET (ET5-7).
Participants/materials, setting, methods: A dedicated speckle tracking algorithm was implemented to extract frequency and amplitude-related features

of uterine motion in relation to ongoing implantation at 6 weeks up to 11 weeks pregnancy. Machine learning and random forest models were used to create a prediction model based on uterine motion characteristics prior to ET in order to suggest a subsequent chance of pregnancy.

Main results and the role of chance: Overall, frequency and amplitude of uterine significantly decreased during the phases of the IVF/ICSI treatment showing FS as the most active phase followed by ET1 and ET5-7. Women with successful implantation/pregnancy showed significantly higher uterine contraction frequency compared to those without in all phases. Conversely, uterine contraction amplitude was significantly lower (p = 0.037) in women at ET5-7 in case of with ongoing implantation/pregnancy. Analysing uterine contraction frequency and coordination prior to ET was able to predict chance of pregnancy after ET with a sensitivity of 85.7%, specificity of 100% and an accuracy of 93.8%.

Limitations, reasons for caution: The small sample size limits statistical power of this study. Research should be continued with larger patient cohorts to confirm the results. Additionally, not all uterine motion characteristics were taken into account, in future research the full characterisation of the uterine activity during IVF treatment should be completed.

Wider implications of the findings: This study is a first step to objectively and non-invasively assess uterine contraction characteristics during IVF cycles, and introduces a new method to predict chance of IVF success. In future, it may boost IVF success rates by for example introducing specific uterine motion modulators prior to ET.

Trial registration number: NL5035

P-342 Oral Dydrogesterone vs. Micronized Vaginal Progesterone(MVP) Gel for Luteal Phase Support (LPS) in Frozen-Thawed Single Blastocyst Transfer in Good Prognosis Patients

G. Özer[1], K.B. Yuksel[1], O.S. Yucel Cicek[2], S. Kahraman[1]

[1]Istanbul Şişli Memorial Hospital, Memorial Hospital- ART and Reproductive Genetics Center- Istanbul., Istanbul, Turkey ;
[2]Kocaeli University School of Medicine, Department of Gynecology and Obstetrics, Kocaeli, Turkey

Study question: Is oral dydrogesterone an effective option for luteal phase support in modified natural cycle frozen -thawed embryo transfers (mNC-FET) when compared to MVP gel?

Summary answer: In mNC-FET cycles, oral dydrogesterone provides an effective option compared to MVP gel with similar ongoing pregnancy rates and with fewer intolerable side effects.

What is known already: Administration of progesterone for LPS could be oral, intramuscular, vaginal and subcutaneous with each route having various bioavailability, side effects and tolerability profiles. The optimal form of progesterone supplementation has not been determined from available data. Since bioavailability of oral micronized progesterone is <10 % and is related to drowsiness, flushing, and nausea, it is not commonly used for LPS. However, dydrogesterone, which is an optical isomer of progesterone, has better bioavailability and progestogenic activity and causes endometrial transformation at a dose of 10–20 fold lower than that of oral micronized progesterone.

Study design, size, duration: This was a randomized, single center, parallel controlled trial conducted at Istanbul Memorial Hospital IVF and Reproductive Genetics Centre, Istanbul, Turkey between January and August 2019. A total of 134 women, aged below 38, were assigned randomly in a ratio of 1:1, based on a computer-generated list to receive oral dydrogesterone (n=67) or MVP (n=67) for LPS in mNC-FET cycle.

Participants/materials, setting, methods: The exclusion criteria were a history of ≥2 unsuccessful cycles and early pregnancy losses, uterine malformation, severe endometriosis, azoospermia and women with endocrine or metabolic disorders

The primary outcome was ongoing pregnancy rate (OPR). Secondary outcomes were clinical pregnancy and miscarriage rates, patients' satisfaction and tolerability of oral and vaginal progesterone. A questionnaire was developed to compare side effects and satisfaction profiles. Data was collected through telephone interviews on the day of pregnancy test.

Main results and the role of chance: There was no significant difference in demographic features such as female age, body mass index, AMH levels and fresh cycle characteristics including the number of retrieved oocytes, mature oocytes, ICSI-fertilized oocytes, the number of vitrified blastocysts and endometrial thickness on the day of recombinant-hCG between two groups (p>0.05).

When we compared the results of mNC-FET cycles, OPR was 68.7% in MVP gel and 71.6% in dydrogesterone group, respectively (p=0.706). Biochemical - clinical pregnancy rates and biochemical - clinical miscarriage rates were also comparable between two groups (p=0.382, p=0.547, p=1.0, p=1.0 respectively).

A significantly higher patient tolerability score was present in the dydrogesterone arm (4,13±0,97 vs 3,43±1,17, p=0.001).

Vaginal discharge (76,9% vs. 12,3%, p=0.001), vaginal irritation (44,6% vs. 1,6%, p=0.001) and interference with coitus (50% vs. 1,6%, p=0.001) were significantly higher in MVP gel compared to dydrogesterone group. On the other hand, mastalgia (36,9 % vs. 4,6%, p= 0.001), headache (13,8% vs. 0%, p=0.003), dizziness (9,4% vs. 0%, p=0.013), flatulence (32,8% vs. 12,3%, p=0.005) and somnolence (38,5% vs. 1,5%, p=0.001) were also significantly higher in the dydrogesterone group compared to MVP gel.

Limitations, reasons for caution: In order to avoid any possible selection bias, which can result from compromised clinical features, only good prognosis patients with top and good blastocysts were included in the study.

Wider implications of the findings: When choosing the form of progesterone supplementation, effectiveness of treatment, as well as side effects, patients' preference and convenience should be considered. Dydrogesterone, as an alternative oral preparation for LPS, constitutes an effective option, especially for patients suffering from side effects of vaginal progesterone.

Trial registration number: NCT04124913

P-343 Embryos versus endometrium: who is to blame for the impaired implantation rate in morbidly obese women?

I. Antonova[1], T. Milachich[1], I. Bochev[1], M. Yunakova[2], M. Magunska[2], A. Shterev[2]

[1]SAGBAL "DR. SHTEREV" EOOD, Embryology, Sofia, Bulgaria ;
[2]SAGBAL "DR. Shterev" EOOD, Ivf, Sofia, Bulgaria

Study question: What is the major reason for the reduced implantation and clinical pregnancy rates in cases with obese women who have undergone ART treatment?

Summary answer: Our results suggest that the endometrial receptiveness is adversely affected by higher proportions of the body fat and leads to difficulties in pregnancy achievement.

What is known already: Obesity has become one of the greatest public health challenges of the last few decades. Its prevalence has tripled in many countries of the WHO European Region since the 1980s, and the numbers of those affected continue to rise at an alarming rate. Overweight female patients undergoing fertility treatment face many complications. Obesity drastically increases gonadotrophin consumption and is linked with lower embryo implantation and higher miscarriage rate as well. Elevated body mass index (BMI) is associated with complicated obstetric anamnesis such as risk of pre-eclampsia and gestational diabetes.

Study design, size, duration: This is retrospective analysis from hospital database for 5-year period. This study includes 3599 fresh cycles using own gametes and additional group of 343 patients with donor oocytes as a control group. For the purpose of the investigation, all patients were divided into 4 groups according the international BMI WHO classification: underweight (BMI<18.49) group A (n=336); normal range (BMI 18.5-24.9), group B (n=2291); overweight (BMI 25-29.9), group C (n=639) overweight and D obese (BMI>30) (n=333).

Participants/materials, setting, methods: In order to establish possible impact of excess weight on oocyte and embryo quality, we compared average number of the retrieved oocytes, fertilization rate, embryo quality at day 3 and blastocyst rate between the groups. For the examination of the linkage between obesity and endometrial receptivity, we measured main outcomes such as pregnancy and implantation rates and compared the results with a control donor-oocyte recipient group.

Chi-squared analysis was used to compare results.

Main results and the role of chance: All four groups were homogeneous according the average number of the retrieved oocytes (5.97 vs 6.11 vs 5.99 vs 6.25; p: NS) and regarding the fertilization rate: 73.5% for group A, 74.4% Group B, 73.6% group C and 73.3% for group D respectively.

At cleavage stage we measured the embryo quality in groups and they showed similar proportions of good, fair and bad embryos. Day 5 blastocyst rate was slightly higher in normal BMI group B 45%), but not significant referred to other groups (A - 42% vs C - 42% vs D - 40%).

After clinical pregnancy rates (CPR) measurement groups A and B appeared comparable results (34.6% vs 35.7%). In overweight group (C) CPR was lower, but not significantly (31.5%); (P = 0.0895). Statistical difference was found in obese group D where CPR dropped to 28.9% (P = 0.0392). In the control group of 343 patients using ovum donation the results were even more demonstrative where CPR was 56% for underweight women (n=33); 52.8% for normal range (n=208); 50% in overweight (n=70) and only 17.4% in the obese group (n=32) .

Limitations, reasons for caution: This is observational retrospective study and it is limited by the subgroups size. More detailed studies are required to achieve a deeper understanding and to shed light into the finer aspects of this complicated implantation process.

Wider implications of the findings: Our survey shows that the endometrium receptiveness is the one that is negatively influenced by excess fat cells. This could be a good predictive model for implantation capability as there is a clear cut-off range in BMI values. Weight-loss concealing before fertility treatment could be beneficial for the successful outcome.

Trial registration number: not applicable

P-344 Endometrial steroid metabolism (intracrinology) in relation to pregnancy outcome in women undergoing IVF/ICSI

L. Brentjens[1], J. Den Hartog[1], B. Delvoux[1], M. Häkkinen[2], J. Koskivuori[2], P. Koskimies[2], S. Auriola[2], N. Van Hoogenhuijze[3], H. Torrance[3], F. Broekmans[3], SCRaTCH-2 study group(4), R. Van Golde[1], A. Romano[1]

[1]Maastricht University Medical Centre - GROW Maastricht University, Obstetrics & Gynaecology, Maastricht, The Netherlands ;
[2]University of Eastern Finland, School of Pharmacy, Kuopio, Finland ;
[3]Universitair Medisch Centrum Utrecht, Divisie Vrouw en Baby - Gynaecologie & Voortplantingsgeneeskunde, Utrecht, The Netherlands ;
[4]Amsterdam Medisch Centrum, F. Mol, Jeroen Bosch Ziekenhuis

Study question: Does the endometrial steroid profile (estrogens, progestogens, androgens and corticosteroids) differ between receptive and non-receptive endometrium?

Summary answer: The levels of steroids were similar in the endometrium of women who did and did not achieve a clinical pregnancy through IVF/ICSI.

What is known already: Implantation failure of high-quality embryos is a main concern in IVF/ICSI treatment. We previously reported that in IVF/ICSI patients, blood sex-steroid concentrations do not reflect their corresponding concentrations in endometrial tissue. This is in line with the concept that blood steroids (and precursors) are locally converted to bioactive metabolites and vice versa, leading to a specific intra-tissue steroid milieu. The endometrium regulates local steroid concentrations by expressing steroid-metabolising enzymes, or 'intracrinology'. Studies indicate that alterations in intracrinology might modulate endometrial receptivity. We hypothesize that the endometrial steroid profile during the window of implantation differs between pregnant and non-pregnant IVF/ICSI patients.

Study design, size, duration: Case-control study of 40 patients that were recruited in the SCRaTCH study (NTR 5342), a randomised trial exploring whether 'endometrial scratching' in patients with a previous IVF/ICSI cycle failure affects pregnancy outcome in a subsequent IVF/ICSI cycle. For the present investigation, 20 endometrial biopsies from women who became clinically pregnant after fresh embryo transfer were compared with 20 endometrial biopsies of women that did not conceive after fresh embryo transfer.

Participants/materials, setting, methods: Endometrial biopsies and serum were obtained at LH+ 5-8 days (urinary test) in a natural cycle. In their next cycle, subjects underwent IVF/ICSI with fresh embryo transfer. Cases (negative pregnancy test, n=20) and controls (clinically pregnant, n=20) were selected and matched for primary vs. secondary infertility, embryo quality and age. Steroid concentration was determined in endometrial 'scratched' tissue homogenates and serum (liquid chromatography mass spectrometry). Statistics was computed with Pearson Correlation and unpaired Student's *t*-test.

Main results and the role of chance: Steroids were measured in 40 endometrial biopsies and 16 serum samples. Median estrone level was 0.23 pmol/g in tissue and 0.29 pmol/mL in serum. Median estradiol level was 0.37 pmol/g in tissue and 0.45 pmol/mL in serum. Tissue progesterone (P4) median was 51.32pmol/g; P4 in serum was above quantification limit (33.3pmol/mL). With regard to androgens, median androstenedione level was 2.02pmol/g in tissue and 6.06pmol/mL in serum, whereas the median testosterone level was 0.34pmol/g and 0.86pmol/mL in tissue and serum, respectively.

Among corticosteroids, median 11-deoxycortisol level was 0.32 pmol/g in tissue and 0.64 pmol/mL in serum. Androsterone in tissue was below quantification limit (<3.26pmol/mL) and median serum level was 0.60 pmol/mL.

No statistically significant differences were found in steroid **tissue** concentrations between cases and controls. Mean **serum** 11-deoxycortisol levels were higher in women who conceived compared with those who did not (1.38±1.24 vs. 0.45±0.23 pmol/mL, p=0.04). The opposite was seen for androsterone, whose mean serum levels were lower in women who conceived compared with women who did not (0.47±0.23 vs 0.72±0.10 pmol/mL, p=0.02).

Tissue and blood concentrations were not correlated for estrogens, indicative of local steroid metabolism of these steroids, but they were significantly correlated for most progestogens, androgens and corticosteroids.

Limitations, reasons for caution: Even though cases and controls were matched for several important variables, it cannot be excluded that other maternal factors or embryo aneuploidy could have led to implantation failure, as there is heterogeneity in IVF/ICSI treatment indication in the (small) group of not-pregnant women.

Wider implications of the findings: Further clarification of the complex interplay between endometrial steroidogenesis, the tissue availability of steroidogenic enzymes, and that of the steroid hormone receptors in women with multiple failed IVF/ICSI cycles is necessary to unravel a possible role in the implantation process.

Trial registration number: NTR5342

P-345 Impaired myeloid-derived suppressor cells are associated with recurrent implantation failure

H. Jiang[1], Y. Cao[1], K. Wang[1], K. Bi[1], Z. Lu[1], P. Guo[1], C. Li[1]

[1]the First Affiliated Hospital of Anhui Medical University, Obstetrics and Gynecology, Hefei, China

Study question: Studies have reported that myeloid-derived suppressor cells (MDSCs) contribute to maintain pregnancy. The aim of this case–control study was to test whether there is a dysregulation of peripheral MDSCs in recurrent implantation failure (RIF).

Summary answer: This study indicated that the dysregulation of MDSCs might impaired maternal-fetal immune balance thus result in RIF.

What is known already: Recurrent implantation failure (RIF) is diagnosed when women experienced 3 or more frozen or fresh cycles with being transferred high-quality embryos and failed to obtain a clinical pregnancy. Myeloid-derived suppressor cells (MDSCs) represent a heterogeneous cell group with attributes in myeloid origin, immature state, and immunosuppressive function.

Study design, size, duration: In our study, We collected 26 RIF cases and 30 controls 2019. Then we completed the experiments in two months.

Participants/materials, setting, methods: 26 RIF patients and 30 controls were recruited. Flow cytometry was applied to characterize polymorphonuclear (PMN)-MDSCs, monocytic-MDSCs (M-MDSCs), effector T cells (Teffs) and regulatory T cells (Tregs) in blood. ELISA was used to define MDSCs correlative cytokines and chemokines in serum from all patients.

Main results and the role of chance: Compared with controls, RIF patients showed significant reductions of blood PMN-MDSCs, M-MDSCs, Tregs and NO production by PMN-MDSCs, whereas the expression of ζ chain on $CD4^+$T cell receptor (TCR) and $CD8^+$TCR displayed a remarkable upregulation in RIF patients. Moreover, RIF patients presented a lower concentrations of serum chemokine (C-C motif) ligand (CCL) 5 and transforming growth factor (TGF)-β than those from controls. Furthermore, the level of TCR ζ chain on $CD4^+$ and $CD8^+$Teffs was negatively correlated not only with the percentage of PMN-MDSCs, but also with the amount of NO produced by PMN-MDSCs. The frequency of PMN-MDSCs had positive correlations with the concentration of CCL5 and TGF-β.

Limitations, reasons for caution: Consistent with previous observations, results showed Treg failure in patients with RIF. However, the proportion of Treg in this study is independent of the proportion of MDSC. This may be because hormones can also induce Tregs.

Wider implications of the findings: our study discovers the role of MDSCs and their related mediators in RIF. Therefore, targeting these cells could provide new treatment methods in the future.

Trial registration number: 1808085QH273

P-346 Validation of an in vitro model to study the interactions between endometrial cells, uterine natural killer cells and embryonic signals during human implantation.

A. Almansa[1], C.S. King[2], P. Brighton[2], G. Tiscornia[1], G. Hartshorne[2], J. Muter[2], M. Barragan[1], J. Brosens[2], R. Vassena[1]

[1]Clinica Eugin, Eugin, Barcelona, Spain ;
[2]Warwick Medical School, University of Warwick University Hospital Coventry and Warwickshire, Covnetry, United Kingdom

Study question: What is the effect of human embryo conditioned media obtained from blastocysts of different quality on uterine natural killer (uNK) cell activity during implantation?
Summary answer: Conditioned medium from blastocysts that failed to give rise to biochemical pregnancy diminished uterine NK mediated clearance of senescent endometrial cells *in vitro*.
What is known already: Embryo implantation is a regulated process involving synchronous communication between the embryo, endometrium and immune system. Recent studies demonstrate the emergence of acute cellular senescence during decidualization. Senescent cells irreversibly exit the cell cycle and remain biologically active, but may be detrimental to endometrial function if left unchecked. uNKs infiltrate the endometrium and are present in high numbers during implantation where they neutralize senescence by selectively targeting and eliminate the senescent decidual cell population. Here we validate a model for the uNK clearance of senescence, and apply it to investigate interactions between different endometrial cell types involved in this process.
Study design, size, duration: Basic research study. We co-cultured decidualized human endometrial stromal cells (EnSCs) from 5 women with human uNK cells in the presence embryo-conditioned media (ECM) obtained from cultured human embryos that were transferred as part of IVF treatment. Transferred embryos were grouped depending on whether they resulted in a positive biochemical pregnancy or not. Non-conditioned culture media was used as control. The effect of conditioned media on uNK cell clearance was measured.
Participants/materials, setting, methods: EnSCs were cultured from 5 different endometrial biopsies. uNK were isolated by MACS targeting CD56, and purity and viability assessed by flow cytometry. Stromal cells were decidualised for 6 days with 8-bromo-cAMP and medroxyprogesterone acetate, before uNKs were added. After 2 days of co-culture, levels of senescence associated-β-Galactosidase (SA-β-Gal) and senescent-specific genes *DIO2* and *CLU* were used as direct indicators of uNK clearance. Effects of ECM were assessed by inclusion at day 6.
Main results and the role of chance: uNK cells isolated from endometrial biopsies were round, granulated and stained positively for CD56. Characterization by flow cytometry revealed high purity (83.5%) and viability (87.4%). As expected, we observed the emergence of decidual senescence in EnSCs by increased SA-β-Gal, and expression of *DIO2* and *CLU*. The addition of uNK cells in co-cultures effectively eliminated cellular senescence by significantly reducing SA-β-Gal (p=0.038), *DIO2* (p=0.046) and *CLU* (p=0.021). Markers for non-senescent, mature decidual cells (*SCARA5* and *CXCL14*) were unaffected. This demonstrates the specific uNK-mediated targeting and elimination of senescent decidual cells. The effects of embryo-derived signals on uNK function were assessed by inclusion of ECM at day 6. Exposure to non-conditioned media, or media from embryos that resulted in positive biochemical pregnancies had no effect on uNK cell mediated senescence clearance. However, on evaluation of SA-β-Gal we detected a significant loss of clearance activity when the system was cultured with ECM from embryos that failed to establish pregnancies (p=0.015). We propose that embryonic signals from poor quality embryos inhibit uNK function. This demonstrates our model can detect uNK cell biological activity in response to embryo-derived stimuli and could be useful as an improved model to help understand human implantation
Limitations, reasons for caution: This study was conducted with biopsies from a limited number of patients; higher numbers of samples will need to be characterized to confirm our findings. Furthermore, our model lacks the endometrial epithelial component involved in apposition of the embryo to the endometrium.
Wider implications of the findings: This newly developed model will allow us to better characterize the interactions between immune cells, endometrium and the implanting embryos. This will provide further insights into human embryo implantation, and potentially lead to novel markers or predictors of implantation failure.
Trial registration number: NA

P-347 Patients with repeated implantation failure and Natural Killer cells immaturity: the efficiency of the endometrial scratching strategy

F. Lamazou[1], P. Oger[1], P. Meicler[1], G. Kerbrat[1], G. Soudre[1], E. Genauzeau[2], V. Maget[1], X. Guettier[1], L. Delaroche[2], N. Ledee[3]

[1]RAMSAY SANTE Hôpital Privé de Parly 2, Reproductive Medecine, Le Chesnay, France ;
[2]Centre de Biologie Medicale Hôpital Prive de Parly 2, ART laboratory, Le Chesnay, France ;
[3]MatriceLab innove pépinière paris santé cochin hôpital cochin paris, ART Center, Paris, France

Study question: Is the scratching an efficient treatment for patients with history of repeated implantation failure (RIF) associated with a uterine Natural Killer (uNK) cells immaturity?
Summary answer: The endometrial scratching performed in the mid luteal phase may increase live birth rates in patients with RIF and uNK cells immaturity
What is known already: Twenty to 25% of RIF patients have been described to have uNK cells immaturity. When performed in the mid-luteal phase, the endometrial scratching stimulates the local expression of IL-15 in the mid-luteal phase of the following cycle. The IL-15 secretion allows the uNK cells maturity which is essential for an effective implantation since they regulate local angiogenesis and invasion of spiral arteries.
Study design, size, duration: This is a single-center observational study performed from January 2016 to March 2019. The institutional review board approved this study and the patients'consent to the use of their data was prior obtained.
Participants/materials, setting, methods: Patients with RIF history (>4 top blastocysts) and normal explorations were proposed an endometrial biopsy to analyse their uterine immune profile. The endometrial immune profile documented the ratio of IL-15/Fn-14 mRNA and the IL-18/TWEAK mRNA ratio. Patients with an uNK cells immaturity were included. A scratching in the mid-luteal phase was performed before a new fresh or a frozen-thawed blastocyst transfer in the following cycle. The main endpoints were the implantation and live birth rates.
Main results and the role of chance: Sixty-nine RIF patients with an uNK cells immaturity on their uterine immune profile were included in this study. They were 35.1 ± 1.2 [LD1] years old and had a median AMH level of 2.6 ng/ml [1,2-4.2]. Forty-four patients (64%) received an endometrial scratching in the mid-luteal phase followed by an embryo transfer. The mean number of blastocysts transferred was 2.2 [1-2]. The implantation rate was 40% and 54.4% of these couples achieved a live birth. The rate of spontaneous abortion reached 11.2%.
Limitations, reasons for caution: Despite the bias inherent to a retrospective study and the small number of patients included, these preliminary encouraging results call a prospective randomized controlled trial with a higher number of patients.
Wider implications of the findings: This study suggests that the uterine immune profile can select a population for who the endometrial scratching can be an efficient strategy in RIF situation with an uNK cells immaturity to improve the implantation and live birth rates.
Trial registration number: non applicable

P-348 The remaining cell-free DNA from noninvasive preimplantation genetic test (NIPGT-A) could be used to identify single nucleotide polymorphisms (SNPs) related to the implantation process.

J.G. Franco Jr., M.D.[1,2], L.D. Vagnini[2], C.G. Petersen[1,2], A. Renzi[2], M. Canas[2], B. Petersen[1,2], A.L. Mauri[1,2], M. Mattila[1], J. Ricci[1], A. Nicoletti[1], C. Zamara[1], A.H. Oliani[3], F. Dieamant[1,2], R. Baruffi[1,2], J.B.A. Oliveira[1,2]

[1]Centre for Human Reproduction Prof. Franco Jr, Research, Ribeirao Preto, Brazil ;
[2]Paulista Center for Diagnosis Research and Training, Research, Ribeirao Preto, Brazil ;

[3]Sao Jose do Rio Preto School of Medicine FAMERP, Research, Sao Jose do Rio Preto, Brazil

Study question: Could the remaining cell-free DNA from the same sample used for NIPGT-A diagnosis also identify SNPs related to the embryonic implantation process?
Summary answer: Regardless of the cell-free DNA concentration after the amplification process used by NIPGT-A technology, the success rate of genotyping was 75%.
What is known already: NIPGT-A is a new technology that uses cell-free DNA present in the spent culture medium of human blastocyst, which reflects its ploidy status. This DNA is an important source of information for the embryo. Since there is a gene pattern signature of endometrial receptivity, several SNPs such as those found in the LIF, VEGF, TP53 and MMP9 genes have been used as markers of the implantation process. However, there are no reports on the possibility of identifying SNPs in embryos using remaining cell-free DNA in culture medium.
Study design, size, duration: This prospective cohort study included 23 samples of remaining cell-free DNA obtained in culture medium on day 5 after embryo culture during NIPGT-A technique (Yikon Genomics). A total of 13 patients participated in this study after the couple's informed consent.
Participants/materials, setting, methods: Cell-free DNA evaluation used the amplified DNA obtained after NIPGT-A technique (Yikon Genomics) and quantified by Qubit fluorometer (Thermo Fisher Scientific). SNPs were evaluated by real-time polymerase chain reaction (PCR) using individual TaqMan® SNP genotyping assays (Thermo Fisher Scientific) for each SNP (LIF rs929271, TP53 rs1042522, VEGF rs3025010, MMP9 rs17576) and TaqPath™ ProAmp™ Master Mix (Thermo Fisher Scientific), following the manufacturer's instructions, on a StepOnePlus™ Realtime PCR System (Thermo Fisher Scientific).
Main results and the role of chance: All cell-free DNA samples in the culture medium had at least one SNP identified regardless of their quantification (Table 1). It was observed that of all 92 genotyping reactions performed, 69 were properly amplified, leading to an accuracy of 75%.
Limitations, reasons for caution: Clinical validation studies are underway to determine the predictive value of this methodology.
Wider implications of the findings: This study showed a novel system (NIPGT- A/SNPs) for embryo tracking. The studied SNPs involved in the implantation process were successfully amplified and genotyped with the remaining cell-free DNA of culture medium after NIPGT-A. In the future, NIPGT-A/SNPs dual evaluation could be an additional tool for embryo selection
Trial registration number: Not Applicable

P-349 Serum beta human chorionic gonadotropin (β-hCG) levels 13 to 14 days after embryo transfer (ET) and the predictability of pregnancy outcome in IVF cycles

L. Luque[1], N. Ruiz[2], Á. Linares[3], J. Bartolomé[3], J.A. Ortíz[3], R. Bernabéu[4]

[1]Instituto Bernabeu Albacete, Reproductive Medicine, ALBACETE, Spain ;

[2]Instituto Bernabeu Albacete, Embriologist, Albacete, Spain ;

[3]Instituto Bernabeu Albacete, Embriologist, Albacete, Spain ;

[4]Instituto Bernabeu, Reporoductive Medicine, Alicante, Spain

Study question: Is the first β-hCG value predictive of pregnancy outcome in IVF cycles?
Summary answer: Pregnancy viability can be predicted by the levels of early β-hCG in IVF cycles.
What is known already: There is an international agreement to consider> 5 mUI / ml of β-hCG in blood as the positive predictive value after 10-15 days post-transfer, this being the standardized reference level for a pregnancy diagnosis. The subsequent evolution is very variable according to the initial value. Levels past 50 mIU / ml are considered to have a good prognosis. Low levels are related, in most cases, with non-evolutionary pregnancies. There is a growing interest in establishing ranges that can be related to the subsequent evolution of pregnancy.
Study design, size, duration: Retrospective evaluation of a cohort of women with a positive result of serum β-hCG in IVF-ET cycles in a private fertility center. The sample includes 196 cycles performed between July 2017 and January 2020. The study explores the correlation between positive early serum β-hCG (mUI/ml) and pregnancy outcome in terms of: biochemical pregnancy (BP), early pregnancy loss (EPL), ongoing pregnancy (OP) and live birth (LB) rate.
Participants/materials, setting, methods: Women who carried out β-hCG determination in blood 13/14 days post egg retrieval in fresh and frozen transfer, respectively. Blood levels were measured using enzyme-linked fluorescent immunoassay (ELFA), with Minividas from Biomérieux analyzer. Own and donor egg cycles were included. The link between variables of IVF-cycle and serum β-hCG was evaluated using U-Mann-Whitney or Kruskal-Wallis. The β-hCG value as a predictor of the clinical results of IVF was evaluated by a binary logistic regression (SPSSv20.0).
Main results and the role of chance: The mean patient age was 39.1 years. Average blood levels of β-hCG were 201.74 ± 339.26 mIU/mL. The total clinical rates were: 28.1% BP, 33.7% EPL, 71.9 OP y 42.9 % LR. Statistically significant differences were found between β-hCG levels in fresh embryo cycles (170.6) and frozen (228.7) (p=0.006). No statistically significant differences were seen between β-hCG values in own egg cycles or donor (p=0.954) nor with natural endometrial preparation or with transdermal estrogen or oral and vaginal progesterone in frozen transfers (p=0.099). No link was found between β-hCG levels and the day of embryo development. With regards to clinical prognosis, a direct relation was found between β-hCG levels and rates of BP(OR=0.981, IC 95% [0.974-0.988], p<0.001), OP (OR=1.02, IC 95% [1.012-1.027], p<0.001) y LB ido vivo (OR=1.003, IC 95% [1.001-1.005], p<0.001). Confounding variables were introduced to avoid bias: maternal age, cycle of own or donor egg, endometrial thickness, natural or HRT cycle, number of embryos transferred and fresh or frozen embryos. When analyzed in quartile the value of β-hCG,

the rate of LB was: first quartile (hCG38.5) 6.5%, second (hCG: 35.5-120-8) 47.4%, third (120.8-214.5) 54.1%, fourth (>214.5) of74.3% (p<0.001).
Limitations, reasons for caution: Larger prospective studies including homogeneous cohorts are needed in order to corroborate our initial results.
Wider implications of the findings: Early serum β-hCG values constitute a potential biomarker for pregnancy outcome in assisted reproduction IVF cycles.
Trial registration number: Not applicable

P-350 Endometrial assessment and personalised plan in the treatment of patients with unexplained repeated embryo implantation failure: initial outcomes from a dedicated Implantation Clinic

M. Rahmati[1], A. Ripanelli[1], M. Ollila[1], S. Nair[1], A. Gill[1], R. Balet[1], E. Kuan[1], K. Ahuja[1], N. Macklon[1]

[1]London Women's Clinic, Reproductive Medicine, London, United Kingdom

Study question: Can targeted treatment based on endometrial assessment produce satisfactory outcomes in women who have suffered unexplained repeated embryo implantation failure?
Summary answer: A personalised treatment plan based on endometrial diagnostics leads to good clinical outcomes and may represent an improvement on current largely empirical management approaches.
What is known already: Unexplained recurrent embryo implantation failure (RIF) represents a major challenge in reproductive medicine. The current management of RIF is largely based on empirical treatments aim at improving endometrial receptivity. However, the emergence of tests of different aspects of endometrial function provides the opportunity to direct therapies to address underlying pathologies.
Study design, size, duration: A prospective cohort follow up study analysed the endometrial testing results and clinical outcomes achieved from a referral clinic set up in June 2018, dedicated to the investigation and treatment of patients with unexplained repeated embryo implantation failure, who had at least three high quality blastocysts transferred without success.
Participants/materials, setting, methods: Timed endometrial biopsy was performed after 5 days of luteal support in a hormone substituted cycle. Biopsies were subject to endometrial dating by gene expression (ERA test, iGenomix, Valencia) and to endometrial immune profiling including the recruitment and activation of the uterine Natural Killer cells (MLI test, Matrice Lab Innove, Paris). Based on the results, a management plan focusing on optimizing endometrial preparation and embryo transfer was proposed to the referring clinician.
Main results and the role of chance: 170 patients were referred to our unit. 112 patients with an average of 4.3 blastocysts previously transferred underwent investigation. 91% of the patients tested revealed at least one abnormal test outcome. For 70% of the patients, the ERA test showed a non-receptive endometrium. For 75% of the patients, the MLI test found an endometrial immune dysregulation. No correlation was observed between the results of the two test profiles. The outcome of the first attempt implementing a personalised plan showed a pregnancy rate of 52% and an ongoing pregnancy rate of 37% after the first trimester, per transferred blastocyst. Those who did not achieve a subsequent implantation showed a higher prevalence of normal endometrial profiling compared to those who conceived on the implemented treatment plan.
Limitations, reasons for caution: In order to assess the added value of personalised a treatment plan, outcomes need to be compared prospectively with a matched control group who are managed without implementation of a personalised plan.
Wider implications of the findings: Our study suggests that treatment based on endometrial diagnostics might improve outcomes compared with empirical management. This approach provides the opportunity to carry out randomized controlled trials of targeted rather than blind interventions.
Trial registration number: Not Applicable

P-351 First clinical outcomes after personalized embryo transfer using the new endometrial receptivity test in recurrent implantation failure patients

Y. Ohara[1], H. Matsubayashi[1,2], K. Yamaguchi[1,2], K. Kitaya[2], M. Doshida[1], T. Takeuchi[1], T. Ishikawa[1,2]

[1]Reproduction Clinic Tokyo, Department of reproductive medicine, Tokyo, Japan ;
[2]Reproduction Clinic Osaka, Department of reproductive medicine, Osaka, Japan

Study question: Is the new ERPeak[SM] endometrial receptivity test useful for patients with recurrent implantation failure (RIF)?
Summary answer: A displaced window of implantation detected by ERPeak[SM] test was frequently observed in RIF patients. Personalized embryo transfer after ERPeak[SM] testing may improve pregnancy outcomes.
What is known already: Lack of synchronization between an embryo and the timing of endometrial receptivity is thought to be a cause of RIF. Therefore, correctly identifying the window of implantation (WOI) is essential for maximizing the effectiveness of assisted reproduction treatments. While the widespread endometrial receptivity assay (ERA) uses microarray analysis to determine the transcriptomic profile of 238 genes, the ERPeak[SM] test analyses 48 genes by RT-qPCR, a methodology that has been demonstrated to have the highest sensitivity, widest dynamic range and least bias for gene expression analysis. This is the first report of clinical outcomes using ERPeak[SM] testing for RIF patients.
Study design, size, duration: A retrospective review was performed for 137 patients who underwent ERPeak[SM] testing in our clinic between April and October 2019. A total of 119 patients under 45 years old, who had 2 or more failed embryo transfers and underwent personalized embryo transfer (pET) after ERPeak[SM] testing, participated in this study. A hormone replacement cycle had been performed for all patients. The first day of progesterone administration was defined as P+0.
Participants/materials, setting, methods: An endometrial biopsy was performed on day P+5 in an HRT cycle. After the ERPeak[SM] test result was given as receptive, pre-receptive or post-receptive, pET was performed in a subsequent cycle on the day where the ERPeak[SM] test indicated optimal receptivity. In receptive cases, we also considered embryonic developmental speed to set the day of transfer: blastocyst grade 3,4,5 and 6 were transferred on day P+5, P+5.5, P+6.0 and P+6.5, respectively.
Main results and the role of chance: Of 119 RIF patients (average age, 38.8 years), ERPeak[SM] testing showed a shifted WOI result in 50 patients (42.0%) and a receptive (R) result in 69 patients (58.0%). In the shifted WOI group, 66.0% (33/50) indicated a pre-receptive state and 34.0% (17/50) resulted in post-receptive state. After pET for shifted WOI patients, we found that the pregnancy rate and implantation rate were similar between shifted WOI and R patients (46.0% vs. 41.5% and 23.8% vs. 19.3%, respectively), which is consistent with previous studies of pET based on the ERA test. pET for shifted WOI patients showed similar pregnancy rate (42.9%, 47.4% and 47.1%) and implantation rate (20.0%, 28.6% and 21.9%) stratified by patients' age (<38, 39-41, 42-45 years old), respectively. Among R patients, 16 patients received pET in consideration with embryonic developmental speed and 53 patients without such consideration. the pregnancy rate and implantation rate of the former group were higher (62.5% vs. 41.5% and 34.5% vs. 19.3%) compared to the latter, although differences were not statistically significant.
Limitations, reasons for caution: There are several limitations, including small sample size and lack of control group to compare clinical outcomes among RIF patients who are not treated by pET with the ERPeak[SM] test. Embryos were selected for transfer by morphology alone, rather than chromosomal screening, which may have affected the clinical outcome.
Wider implications of the findings: A shifted WOI detected by ERPeak[SM] was frequently observed in RIF patients. pET for shifted WOI patients after ERPeak[SM] testing was consistent with ERA for pregnancy outcomes regardless of patients' age. pET for R patients in consideration with embryonic developmental speed may also improve pregnancy outcomes. Further studies are required.
Trial registration number: not applicable

P-352 Retrospective evaluation of diagnostic usefulness of endometrial lymphocyte subpopulations quantification: influence in endometrial receptivity and in pregnancy outcome in the setting of assisted reproduction techniques

D. Valero Hervás[1], J. Sarasa[2], M. Enciso[2], L. Agúndez[1], J. Aizpurua[3]

[1]iGLS, Immunology, Alicante, Spain ;
[2]iGLS, Research and Development, Alicante, Spain ;
[3]IVF Spain, Gynaecology, Alicante, Spain

Study question: Is the distribution of lymphocyte populations in the endometrium associated with endometrial receptivity and the appearance of early complications during pregnancy?
Summary answer: Endometrial lymphocyte populations are associated with endometrial receptivity status and can be a useful indicator for the early diagnosis of adverse reproductive outcomes.
What is known already: During pregnancy, a series of crucial adaptations occur in the maternal immune system, aimed at ensuring correct embryo implantation and development, while avoiding recognition of the embryo as foreign tissue that could lead to its rejection. Recent studies have shown that disturbances in this balance may lead to pregnancy complications, so the achievement of a successful pregnancy requires maternal and fetal cells coexistence in a tightly regulated balance. In this study, the different immune populations' profiles present in the endometrium and their association with different infertility conditions have been evaluated.
Study design, size, duration: This is a retrospective study analysing immune populations distribution in endometrial tissue and assisted reproduction techniques (ART) outcomes of patients undergoing immune status assessment under different clinical suspicions (recurrent implantation failure or/and miscarriage and primary infertility). Immune profiles were analysed in 239 patients between October 2018 and December 2019. These profiles were compared according to the day of the endometrial cycle in which the sample was obtained and the receptivity status measured by ER Map®.
Participants/materials, setting, methods: Patients referred for endometrial function evaluation were included in the study. Biopsy samples were obtained in hormone replacement therapy (HRT). ImMap® test consisting on the evaluation of the percentage of different Natural Killer (NK) cell phenotypes, Th1, Th2, Th17 and regulatory T lymphocytes, and B1a lymphocytes by means of flow cytometry was performed in all cases. The profiles identified were evaluated according to the available values of normality stated in the scientific literature.
Main results and the role of chance: Our study showed differences in population dynamics depending on the day of the cycle in which the biopsy was performed. The samples obtained between days P4+5 and P4+6 showed significant enrichment in NK cells compared to those taken further away from the theoretical implantation window (WOI) (T-test: 35.67% vs 26.37%; p=0.016). These differences were confirmed analysing exclusively those endometria classified as receptive using ER Map® technology (T-test: 36.02% vs 25.59%; p=0.039), and a decrease in the Tc cells was also identified (T-test: 54.97% vs 48.82%; p=0.042). Furthermore, the receptivity stratification also showed that the lack of this predominance of the NK cells is associated with a post-receptive endometrial state (T-test: 36.39% vs 11.47%; p=0.028). Similarly, a receptive endometrium would be characterized by a lower proportion of the lymphoid group characterized by CD45 (Man-Whitney test: p=0.0001), compared with those non-receptive. In the context of the clinical outcomes, the results show that in women with a WOI between P4+5 and P4+6 who suffered from early abortions, had a lower proportion of activated NK cells when compared to those women who did not develop any adverse effects (p=0.034).
Limitations, reasons for caution: Our study reveals differences in immune populations dynamics with potential usefulness in predicting pregnancy evolution. However, the context and type of sample evaluated hinders the establishment of normality ranges, so to understand the extent of its usefulness it would be necessary to carry out clinical trials including healthy controlled women.
Wider implications of the findings: The application of ImMap® assessment as a routine tool for identifying abnormal immune profiles would lead to the optimal and appropriate medical intervention, in order to prevent or minimize the appearance of adverse outcomes and improve effectively the ART outcomes, and the life-quality of couples with a reproductive desire.
Trial registration number: Not applicable

P-353 DNA extraction protocol optimized for low-biomass samples are essential for accurate profiling of the intra-uterine microbiota.

J. Centelles Lodeiro[1]

[1]*KU Leuven, VIB-KU Leuven Center for Microbiology, Leuven, Belgium*

Study question: Does the DNA extraction protocol affect the accuracy of low biomass intra-uterine microbiota profiling?
Summary answer: A DNA extraction protocol designed for low-biomass samples allows to increase intra-uterine microbiota profiles quality.
What is known already: In recent years, the view of a sterile uterus is being challenged, there is a growing interest in understanding the potential role of microbiota of the female upper reproductive tract in processes leading to a healthy pregnancy. Indeed, several publications have shown preliminary associations between the intra-uterine microbiota and the outcome of pregnancy. However, samples containing low microbial biomass, such as intra-uterine samples, are especially susceptible to contamination by DNA and/or cross-contamination between samples, which can easily dominate the obtained microbiota profiles and lead to erroneous interpretation of results.
Study design, size, duration: Bacterial DNA from intra-uterine biological replicate samples (n=38x2) was extracted using two methods: automated extraction using a standardized kit and manual extraction in a room specially designed to handle low-biomass samples. Technical and procedural negative controls were taken along the process (n=33).
Participants/materials, setting, methods: Intra-uterine samples were retrieved using embryo transfer catheters with a sterile bridging tube, flash-frozen in liquid nitrogen and stored at -80C. DNA was isolated using a Tecan Nucleic Acid Extraction-Platform (MagAttract PowerMicrobiome DNA/RNA kit [Qiagen]) or using a low-biomass-optimized manual extraction (Allprep DNA/RNA kit [Qiagen]). Microbiota profiles were obtained by 16S rRNA amplicon sequencing (V4) using the gold-standard DADA2 pipeline, and analysed using constrained principal coordinates analysis at genus level (cPCoA).
Main results and the role of chance: Biological replicate samples (N=38x2) of the intra-uterine microbiota were subjected to two extraction protocols to evaluate the importance of protocol optimization for these low-biomass samples. The extraction protocol explained 27% of the variation in intra-uterine microbiota profiles (n=76, db-RDA, R2=0.27, adjP=0.0002). Microbial diversity was higher with the DNA extraction protocol optimized for low-biomass samples as compared to the standard protocol (n=76, Simpson diversity index, Wilcoxon rank-sum, r=0.0028, P=3.61E-09). We tracked, in the negative controls of each protocol, a total of 119 genera as contaminants, 13 of which were common to both protocols. We thus identified 90 genera of trustworthy biological sampling origin (non-contaminants) in the standard protocol, compared to 136 in the optimized protocol. These genera were used to calculate the amount of sequencing data generated per biological sample that is of trustworthy origin. With the standard protocol, only 21% of the intra-uterine samples achieved the minimum threshold of 1000 trustworthy sequencing reads, while 79% of the biological samples passed that threshold with the optimized protocol.
Limitations, reasons for caution: The negative controls used in this analysis focused on the evaluation of contaminants during DNA extraction and sequencing. The addition of negative controls for the sampling procedure (empty sampling devices) would give additional information on potential DNA contaminants in devices used for sampling.
Wider implications of the findings: Applying 16S rRNA amplicon sequencing on low-biomass intra-uterine samples is a two-edged sword since its efficiency for detecting microbial DNA also makes it highly sensitive to contaminant DNA and to cross-contamination. Ignoring this drawback can lead to erroneous interpretation of microbiota profiles and their role in human reproductive health.
Trial registration number: NCT03105453

P-354 Placental morphology remains unaffected by addition of GM-CSF during pre-implantation development

V. Nordhoff[1], **L. Ogoniak**[1], **T. Pock**[1], **K. Schulte**[2], **S. Schlatt**[1], **M. Boiani**[3]

[1]*University Hospital of Muenster, Centre of Reproductive Medicine and Andrology, Münster, Germany ;*
[2]*University of Muenster, Central Animal Facility of the Faculty of Medicine, Münster, Germany ;*
[3]*University of Münster, Max Planck Institute for Molecular Biomedicine, Münster, Germany*

Study question: Does GM-CSF supplemented during pre-implantation development have an influence on fetal growth or placenta development?
Summary answer: GM-CSF had an effect on fetal weight but placenta morphology was not affected by different concentrations of GM-CSF.

What is known already: The growth factor granulocyte macrophage colony-stimulating factor (GM-CSF) is used in ART for preimplantation embryo cultivation to increase survival of embryos up to week 12, especially in women with previous miscarriages. Naturally, GM-CSF is produced by the endometrium during early gestation. The corresponding receptors can be found in the trophoblast cells of the early embryo. After implantation trophoblast cells establish the connection of the embryo with the maternal tissue and the placenta forms. The mature placenta consists of the fetal layers labyrinth and spongiotrophoblast and the maternal decidua.
Study design, size, duration: Female mice (B6C3F1, 5-10 weeks old) were superovulated by injection of 5 IU PMSG and 10 IU hCG and mated to males (C57BL/6J). Zygotes were isolated on day 0.5 post coitum, pooled and randomly allocated to KSOM(aa) with 0, 2 and 10 ng/mL mGM-CSF. Medium refreshment was applied on day 2.5. Embryos were transferred to foster mothers and the developing fetuses and placentas were dissected at day 13.5 of gestation.
Participants/materials, setting, methods: In total 48 placentas and fetuses could be collected of which 41 placentas were appropriate for analysis: 13 placentas in the control group (KSOM(aa)), 15 in the group with 2 ng/mL GM-CSF and 13 in the group with 10 ng/mL GM-CSF. Tissues were collected to measure fetus weight and length and placenta weight. Placentas were embedded, cut and stained by PAS-reaction. Area and diameter of the single placenta layers were measured from 6 sections each.
Main results and the role of chance: Fetal weight was significantly higher after culture in medium containing 2 ng/mL GM-CSF compared to the control medium (mean values: 0ng/mL=0.17g; 2ng/mL=0.21g; 10ng/mL=0.18g; P-value <0.05). No difference was found between placenta weight in different concentrations of GM-CSF (mean values: 0 ng/mL=0.115 g; 2ng/mL=0.122 g; 10ng/mL=0.122 g). Values for placenta layer areas and diameters were similar in each group, as well as the whole placental area (mean values: 0 ng/mL=10.01mm^2 g; 2ng/mL=10.49mm^2 g; 10ng/mL=10.65mm^2 g) and diameter (mean values: 0 ng/mL=2.05mm^2; 2ng/mL=2.19mm^2 g; 10ng/mL=2.29mm^2). A significant correlation was found between body length and weight of the fetuses (R2 = 0.3869). Additionally, fetus length and placenta weight were associated as was placenta area and placenta weight. Whole placenta area and also the single layers (labyrinth, spongiotrophoblast and decidua) and their proportions were similar among all groups.
Limitations, reasons for caution: A limitation of this study is the use of an animal model and the number of examined placentas. Data cannot be transferred 1:1 to the human situation. Further studies should investigate the effect of GM-CSF during several developmental steps in the development of either the embryo or the fetus.
Wider implications of the findings: GM-CSF had an influence on fetus weight but not on placenta weight or morphology. Although it seems that this growth factor has no major influence during culture, still our data create awareness for the general use of growth factors in ART culture media.
Trial registration number: not applicable

P-355 Evaluation of ER Map® test to predict endometrial transcriptomic signatures associated to different infertility conditions and ART outcomes.

J. Sarasa Marcuello[1], J. Aizpurua[2], B. Rodriguez-Estrada[1], I. Jurado[1], M. Ferrández[1], A.B. Climent[3], M. Enciso[1]

[1]iGLS, Research and Devolopment, Alicante, Spain ;
[2]IVF Spain, Reproductive Medicine, Alicante, Spain ;
[3]IVF Spain, Statistics, Alicante, Spain

Study question: Is it possible to identify endometrial transcriptomic signatures with clinical significance using the molecular tool ER Map®?
Summary answer: ER Map® gene expression analysis is able to predict infertility conditions and ART outcomes with clinical significance.
What is known already: Transcriptomic analyses have been proposed in many fields of medicine as powerful tools to identify pathological conditions. In reproductive medicine, gene expression analysis of endometrial tissue has been recognized as an effective approach for endometrial receptivity evaluation. ER Map® is a molecular diagnostic tool able to accurately predict the window of implantation (WOI) by analysing the expression profile of 40 genes by high-throughput RT-qPCR. Other conditions of altered endometrial function beyond receptivity could be responsible of failed ART results. In this study we aim to identify WOI transcriptomic signatures with clinical significance associated to different infertility conditions and ART outcomes.
Study design, size, duration: This is a retrospective study analysing transcriptomic signatures, infertility conditions and ART outcomes of 1095 patients undergoing endometrial receptivity assessment by ER Map® between March 2016 and January 2020. Results obtained when embryo transfers were scheduled on the moment of endometrial receptivity (WOI timeframe) were analysed. Prediction models of gene expression profiles of patients with different infertility conditions and ART outcomes were evaluated.
Participants/materials, setting, methods: A control group of healthy egg-donors and patients referred for ER Map® analysis for a variety of reasons including implantation failure (RIF) and recurrent miscarriage (RM) were included in the study. ER Map® gene expression analysis of endometrial biopsies obtained in HRT cycles at P4+5.5 was performed by qRT-PCR (Biomark-HD, Fluidigm). Transcriptomic profiles from donors, different infertility conditions (RIF, RM) and ART outcomes (successful implantation, biochemical pregnancy and clinical pregnancy) were evaluated by discriminant analysis.
Main results and the role of chance: We have identified WOI transcriptomic signatures predictive of recurrent miscarriage (RM) and implantation failure (RIF). In the RM group the overall accuracy prediction in the training set is 100%, all 37 RM patients and 9 controls were classified in their respective groups. Leave-one-out cross-validation presented a positive predictive value (PPV) of 86.67%. In the RIF group the overall accuracy prediction in the training set is 99.2%, only 2 out of 235 RIF patients were misclassified as controls. Leave-one-out cross-validation presented a PPV of 99.57%.
Analysis of ART outcomes in our cohort showed that 81.64% (894/1095) of patients achieved implantation, of which 9.96% (89/894) had a biochemical pregnancy and 73.52% (805/1095) continued to have clinical pregnancies. Analysis of the gene expression profiles allowed the identification of a WOI signature predictive of successful outcome (clinical pregnancy) and two WOI signatures predictive of negative reproductive outcomes (implantation failure and biochemical pregnancy). The group of samples identified to present a positive outcome signature had an implantation rate of 91.95%, a biochemical pregnancy rate of 3.43% and a clinical pregnancy rate of 88.52%. These rates are significantly different ($p<0.001$) than the ones obtained in the group of samples identified to present negative outcomes signatures.
Limitations, reasons for caution: ER Map® test can serve as a valuable tool to improve the diagnosis of endometrial function and anticipate ART outcomes in sub-fertile patients, however, other types of investigations aimed to determine the therapeutic options for patients at risk of negative reproductive outcomes will also be necessary.
Wider implications of the findings: The ability of ER Map® for the prediction of cases at risk of negative reproductive outcomes offers a comprehensive method for the diagnosis of endometrial function and infertility. This tool may open new research lines to understand endometrial pathology and develop new treatment strategies.
Trial registration number: Not applicable

P-356 Whole-genome sequencing of embryos from pregnancy loss identifies putatively detrimental genomic variants

[8]Igenomix, Igenomix, Marostica, Italy

Study question: Do whole-genome sequences of embryos from recurrent pregnancy loss clarify the impact of genetic variants of small-size and/or located in non-coding regulatory regions?

Summary answer: Whole-genome analysis of embryonic DNA from pregnancy loss successfully identifies putatively detrimental genomic variants

What is known already: Pregnancy Loss (PL), the spontaneous demise of pregnancy before 24 weeks of gestation, occurs in 10-15% of pregnancies. PL is often the result of chromosomal aneuploidies of the gametes but it can also have non-random genetic causes like small mutations (SNPs and indels), both de-novo or inherited from parents. Comparative genomic hybridization (CGH) detects variants of several thousand base pairs while targeted resequencing resolves point mutations. Both are currently the most accurate methods for the genetic analysis of PL, but are not sensitive to small variants (CGH), or do not target those located in non-coding regulatory regions (targeted resequencing).

Study design, size, duration: Our aim is to identify small-size genetic variants likely to cause PL using a predictive model integrating whole-genome sequence data with functional annotations and gene networks relevant to embryonic development. Seventy women, mostly European (82.7%) diagnosed with first (n=39, av.age 28.9) or recurrent (n=31, av.age 39.0) miscarriage were recruited by the University of Ferrara from 2017 to 2019. Ethical committee approval is from Emilia-Romagna CE/FE (#170475).

Participants/materials, setting, methods: Fetal DNA extracted from chorionic villi was used to exclude samples with aneuploidies using both CGH and shallow sequencing of random genomic regions. Euploid samples were whole-genome sequenced at high-coverage. Variants were called against the reference genome GRCh38 with Freebayes. Variants were annotated with a custom script that integrates information from Ensembl99 with publicly available manually curated lists of genes associated with embryonic development, miscarriages, lethality, cell cycle. The code is available on gitHub (ezcn/grep)

Main results and the role of chance: We understood the requirements to scale-up the project and obtained initial results from the analysis of these genomic sequences. We determined that shallow sequencing of random genomic regions is more efficient compared to CGH in detecting aneuploidies in samples with poor quality DNA. We estimated that 20% of collected samples are suitable for sequencing, the rest presenting aneuploidies or quality issues and maternal contamination. Sequenced samples have on average 4M high-quality variable sites that were annotated with information on gene content and functional consequences. In the autosomes 4.3k variants are ranked as having a high deleterious impact according to Ensembl, 69.1k moderate, and 111k low. After filtering based on the combination of several criteria, such as allele frequency in the general population, homozygosity, impact of the allele with consequences we identify a number of putatively detrimental mutations. Three samples carry two homozygous missense mutations in the same exon of the AHNAK2 cancer-related gene, which codes for a cytoplasmic nucleoprotein. Five samples share the same stop gain mutation in the RPTOR gene, a component of a signaling pathway that regulates cell growth and survival, and autophagy in response to nutrient and hormonal signals.

Limitations, reasons for caution: While encouraging, these first results needs to be corroborated with a more comprehensive analysis that fully implement a predictive model. Results will be validated in a biobank of embryonic sequence data from PL.

Wider implications of the findings: We demonstrated that whole-genome sequencing can help to clarify the causes of RPL. The pilot study described here has discovered plausible candidate RPL-associated variants and provides essential indications for the realization of a larger study.

Trial registration number: not applicable

P-357 Assessment of pH at the surface of the endometrium of the uterine fundus is a novel marker of chronic endometritis

T. Endo[1], T. Baba[2], E. Itabashi[3], H. Honnma[4], H. Henmi[5], U. Ikeda[5], T. Kiya[6], T. Saito[7], A. Azumaguchi[8], M. Fujii[3]

[6]ENA Aazabu ART Clinic, Obstetics and Gynecology, Sapporo, Japan ;
[7]Sapporo Medical University, Obstetriics and Gynecology, Sapporo, Japan ;
[8]Sapporo Endometrium Research, Obstetrics and Gynecology, Sapporo, Japan

Study question: Can assessment of pH at the surface of the endometrium of the uterine fundus distinguish the condition of chronic endometritis(CE) from the normal condition?

Summary answer: Assessment of the pH at the surface of the endometrium of the uterine fundus is thought to be an excellent novel marker of chronic endometritis.

What is known already: CE is a state of persistent inflamation in the endometrium caused by common bacterial pathogens. It is reported to be associated with reproductive failure. Endometrial plasma cells (CD138 immunostainined cells) are accepted as the standard criterion to establish a diagnosis of CE. Recently, sequencing of the 16S rebosomal RNA revealed that lactobacillus species are abundant in the uterine cavity in women without CE, and much less abundant in CE patients. However, the effects of lactobacillus in the endometrium are unknown. Uterine fluid pH in both CE and non-CE is reported to be around 7.2 (Moreno et al.,2016).

Study design, size, duration: We tried to determine whether assessment of the pH of the endometrium could be a new marker of chronic endotmetritis. Asymptomatic women (N=56) with recurrent implantation failure or recurrent miscarriage were recruited. Chronic endometritis was diagnosed using CD138 immunostaining, and the uterine microbioma by using sequensing of the 16S ribosomal RNA gene. We checked uterine pH in both CE and non-CE. This study was performed from June 1 until December 31,2019.

Participants/materials, setting, methods: Participants were recruited from the infertility clinic of Tokeidai Memorial Hospital. Plasma cells in the stroma of endometrium were indentified by means of immunohistochemistry staining. Sequencing of 16S rebosomal RNA gene in the endometrial fluid was done for detecting bacteria. Endometrial surface pH was examined directly at the endometrial surface using a Portable pH Meter (Japan Asch Inc., Japan) that has been utilized for the esophageal mucosa of esophagitis (Journal of Gastroenterology, Japan, 1990).

Main results and the role of chance: We tried to examine some markers of CE in a total of 56 patients with reproductive failure who gave informed consent. We first screened for CE using our criteria following 2 criteria reported by Liu et al.(Fertil Steril, 2019), >5.15 CD138 stained cell/10mm2 or <85% lactobacillus in the Endometrial Microbioma Test (Varinos Inc., Japan). The endometrial pHs of the follicular phase and luteal phase in non-CE were 5.34±1.00(mean±SD)(n=8) and 5.43±0.97(n=13), respectively. This difference was not significant. The endometrial pH of CE, 6.23±0.65(n=35), was significantly different from that of non-CE, 5.61±0.74 (n=21)(P<0.01). The endometrial pH of CE (CD138 cell number>5.15/10 mm2) was 6.39±0.58(n=18), which was also significantly different from that of non-CE(CD138 cell number <5.15/10mm2), which was 5.41±0.79 (n=20)(p<0.01). The endometrial pH of CE(lactobacillus<85%),was 6.67±0.39(n=17), whcih was significantly different from that of non-CE(lactobacillus >85%), which was 5.58±0.59 (n=15)(p<0.01).

Limitations, reasons for caution: As this study was performed in only 56 female patients with infertility or recurrent miscarriage, a larger number of patients need to be studied for precise evaluation of the usefulluness of the dendometrial pH.

Wider implications of the findings: The endometrial pH was usually acidic, unlike in from Mereno et al.'s report. The endometrial pH of CE was significantly higher than that of non-CE. The endometrial lactobacillus is associated with the endometrial surface pH. Therefore, endometrial pH is thought to be an excellent novel CE maker.

Trial registration number: R1919

P-358 Modelling embryo implantation in vitro using a three-dimensional co-culture system

C. Hill[1], D. Hapangama[1], M. Phelan[2]

[1]University of Liverpool, Women's and Children's Health, Liverpool, United Kingdom ;
[2]University of Liverpool, Institute of Integrative Biology, Liverpool, United Kingdom

Study question: Can we construct a 3D *in vitro* model of endometrial embryo implantation to study early human pregnancy establishment?

Summary answer: We were able to develop a 3D human endometrial co-culture model that accepted surrogate embryo implantation to simulate early human pregnancy.

What is known already: The human and non-human primate endometrium is unique amongst mammals in its ability to decidualise, shed and regenerate. Furthermore, the cellular architecture of human endometrium is found only in higher primates. These fundamental differences make it difficult to model early pregnancy establishment in routinely studied laboratory animals. Therefore, novel models of human embryo-endometrium interactions are needed to fully define the factors involved in successful implantation.
Study design, size, duration: A 3D *in vitro* model of the endometrium was established using endometrial epithelial cell line Ishikawa and a telomerase immortalised human endometrial stromal cell line embedded in a collagen hydrogel. The model was expanded to include primary human endometrial epithelial and stromal cells isolated from freshly collected endometrial biopsies from healthy women not on hormonal medication. Embryo implantation was simulated by attachement of Jeg3 trophoblast spheroids over a ten day period.
Participants/materials, setting, methods: Liverpool Women's Hospital is a tertiary referral centre affiliated to the University Hospital Research Centre. Samples of endometrium was harvested from women undergoing benign gynaecological procedures after obtaining informed consent. Surrogate embryo implantation in 3D culture models was assessed by immunohistochemistry. The metabolomic signature of early pregnancy was assessed by NMR analysis of conditioned medium from endometrium-embryo co-cultures.
Main results and the role of chance: We initially employed human cell lines to develop a 3D construct containing epithelial and stromal cells, and a variety of protocol optimisations were necessary to replicate the different cycle phases and decidualisation process of the endometrium. The optimised conditions for cell lines were further adjusted for primary cells, which demonstrated an enhanced capacity for self-organisation and remodelling of the collagen matrix. Successful decidualisation of the 3D constructs in the presence of oestrogen and progesterone was confirmed by ELISA and immunohistochemistry. Jeg3 spheroids were show to attach to the 3D constructs and interact with the epithelial and stromal elements. Preliminary analysis of the metabolome defined by NMR analysis of the co-culture conditioned medium identified metabolites unique to embryo implantation.
Limitations, reasons for caution: Only the Jeg3 choriocarcinoma cell line was used as a surrogate embryo model, which does not fully capture all stages of blastocyst implantation and invasion (e.g. syncytialisation). Future work should incorporate other cell lines and primary cells to model all elements of trophoblast adhesion, invasion and migration.
Wider implications of the findings: Modelling human embryo-endometrial interactions *in vitro* helps to widen our understanding of implantation. Such information will prove invaluable in many areas of reproductive medicine, such as increasing the success of IVF treatment and defining the causes of recurrent miscarriage.
Trial registration number: not applicable

P-359 A simple scoring system for prediction of early pregnancy loss developed by following 13,977 infertile patients after in vitro fertilization

Y. Ouyang[1], P. Cai[2], X. Li[1]

[1]*Reproductive and genetic hospital of Citic-Xlangya, Imaging Department, Changsha, China ;*
[2]*Central South University, Institute of Reproductive and Stem cell engineering, Changsha, China*

Study question: What is the performance of a simple scoring system to predict early pregnancy loss (EPL) after in vitro fertilization-embryo transfer (IVF-ET)?
Summary answer: A simple scoring system using prospectively collected routine data could be easily used in early pregnancy care and effectively guide subsequent medical plans.
What is known already: The first routine ultrasound scan is commonly arranged on day 28 after ET in most reproductive centers to determine the location and viability of the embryo. The mental pressure associated with a pregnancy of uncertain viability are significant in patients undergoing IVF-ET, thus, a rapid and accurate method to predict the possibility of early miscarriage would be helpful for determining subsequent treatment. Previous mathematical models have combined individual risk factors with reasonable performance. However, a simple scoring system that can be easily implemented in clinical practice has not been described for the prediction of EPL after IVF-ET.
Study design, size, duration: This was a prospective study in a single reproductive centre. The infertile patients included in this study underwent IVF treatment between June 2016 and December 2017.
Participants/materials, setting, methods: A cohort of 13,977 consecutive women undergoing transvaginal ultrasound scan on Day 27–29 after ET were included. Ultrasound measurements and clinical characteristics were recorded. The first trimester pregnancy outcome of these women was noted at 12 weeks of gestation. The cases of first year were used to generate a training sample (7,261) and a simple scoring system was derived from this. The cases of second year were used as a verification sample (6,716).
Main results and the role of chance: There were 12,051 cases with an ongoing pregnancy and 1,926 cases had EPL. Maternal age (MA), gestational sac diameter (GSD), crown-rump length (CRL), embryonic heart rate (HR), yolk sac diameter (YSD) and endometrium thickness (EM) on transfer day finally entered the scoring system after stepwise screening. Points associated with each category of each risk factor were computed and the risks associated with point totals were determined according to the "The Framingham Study risk score system".
The scoring system gave an area under the curve (AUC) of 0.884 (95% confidence interval 0.870-0.899) in the training set. The score totals range from point -8 to 14. When point 5 was chosen as the cutoff value, the predicting risk of EPL was 30.03%, with a sensitivity of 66.87%, specificity of 98.11%, positive predictive value (PPV) of 84.44% and negative predictive value (NPV) of 95.07% in the test set, which performed with a sensitivity of 64.69%, specificity of 98.78%, PPV of 89.87% and NPV of 93.62% in the test set. 94.01% cases of the training sample could be correctly predicted as EPL and in the verification samples, 93.91% of the cases were correctly predicted.
Limitations, reasons for caution: This scoring system was used for easy and quick prediction of EPL with false positive and false negative results and the miscarriage outcome cannot be changed by this system. Smoking variable was a potential omission in the data collection and might further improve the predictive performance if included.
Wider implications of the findings: This simple scoring system incorporates readily available data that are routinely collected in clinical practice and does not rely on complex data entry. The findings could be easily incorporated into early pregnancy care and effectively guide subsequent medical plans.
Trial registration number: not applicable

P-360 The incidence of monozygonic twins in assisted reproduction technology -a retrospective study

X. Feng[1], P. Liu[1]

[1]*Center for Reproductive Medicine, Department of Obstetrics and Gynecology-Peking University Third Hospital, Beijing, China*

Study question: does the incidence of MZT (monozygonic twin) in assisted reproduction techonology higher and what are the risk factors?
Summary answer: this retrospective research shows that blastocyst culture significantly increased the risk of monozygonic twins. However, the age, ICSI or assisted hatching have no signifcant impact.
What is known already: It is known that the incidence of monozygonic twin (MZT) in natural conception is about 0.4%. Previous report has shown that the risk of MZT has doubled after assisted reproductive technology. MZT can lead to miscarrige, increase the incidence of preterm birth and other adverse neonatal outcomes. Therefore, researchers have been take much attention to the incidence and reasons of MZT in assisted reproduction and found that maternal age, ICSI and blastocyst tranplantion may be associated with the happening of MZT.
Study design, size, duration: we conducted a retrospective study in our center based on data from 2014 to 2018. In all, 41538 patients that got pregnancy after IVF were include in this study.
Participants/materials, setting, methods: there were 20048 fresh cyclyes and 11885 frozen cycles included. We analyzed different clinical data (maternal age and stimulation strategy) and IVF strategy such as type of embryos, insemination method, embryo stage at time of ET. All pregnance were confirmed by detection of fetal heart activity . The identification of MZT is identified when more than one fetal poles was visualized in one gestational sac via trans-vaginal ultrasound.For the statistical analysis, SPSS software was used.

Main results and the role of chance: In our clinic center, there were 59 patients who were MZT from 12060 patient who transferred D3 fresh embryos(0.49%). In addition, 9 patients were MZT from 590 patients who transferred fresh blastocyst(1.52%). These two groups have significant difference. In frozen cycles, there were 32 patients who got MZT in 5042 patients who received D3 embryo transfer(0.63%)and 145 patients who got MZT in 7085 ones who received blastocyst embryo transfer(1.96%).The incidence of MZT was significantly lower in D3 ET cycles than that in blastocyst ET cycles. In addition, the incidence of MZT in patients who were more than 35 years old have no significant difference with those who wre no more than 35 years old (fresh cycles: 0.66% vs 0.47; frozen cyclyes:1.17% vs 0.86%). Moreover,we analyzed the correlation of insemination with MZT and found that there were no difference no matter whether ICSI were used or not(0.66% vs 0.57% in ICSI). At last, the manupulation of assisted hybradation have no impact on MZT incidence(1.68% vs 1.23% for AH).
Limitations, reasons for caution: . It should be noticed that more data from randomized trial were required.
Wider implications of the findings: From the data we can found that blasotcyst culture and transfer have been identifed to significantly influence the incidence of MZT. Therefore patients should be noticed of the risk of blastocyst cutlure and tranfer.
Trial registration number: no

P-361 Clinical applications of platelet-rich plasma in poor endometrium patients in IVF practice

O. Feskov[1], Y. Zhylkova[2], A. Feskova[3], O. Blazhko[4], O. Yegunkova[5]

[1]Centre of Human Reproduction Sana-Med, IVF, Kharkiv, Ukraine ;
[2]Center of Reproductive Medicine "Clinic of professor Feskov", IVF Department, Kharkiv, Ukraine ;
[3]Kharkiv National Medical University, Department of Obstetrics and Gynaecology, Kharkiv, Ukraine ;
[4]Feskov Human Reproduction Group, Surrogacy Department, Kharkiv, Ukraine ;
[5]Center of Rproductive Medicine "Clinic of Professor Feskov", Genetic laboratory, Kharkiv, Ukraine

Study question: Does the intrauterus application of platelet-rich plasma (PRP) allow to improve the condition of the endometrium and IVF outcome in repeated implantation failure patients?
Summary answer: Application of PRP in patients with refractory emdometrium resulted in satisfactory endometrial thickness. PRP was effective in IVF patients with repeated implantation failure (P< 0.05).
What is known already: The endometrium plays an important role in achieving optimal outcomes of assisted reproductive technologies. PRP is a novel method that is used in reproductive medicine to improve the IVF outcome. The mechanisms of PRP have not been completely elucidated, but laboratory studies have shown that the high concentration of growth factors in PRP can potentially speed up the healing process. Recently, the intrauterine infusion of PRP has been described as a way to promote endometrial growth and receptivity.
Study design, size, duration: The effect of the intrauterus application of PRP to improve the endometrium thickness in patients with repeated implantation failure (RIF) was studied. The implantation rates were evaluated in RIF patients in IVF programs after PRP procedure. The study's protocol was approved by the Center's IRB.
Participants/materials, setting, methods: In total, PRP group included 32 cycles of 20 patients with the mean age 34.2±3.6 y.o. The control group included 38 cycles of 23 patients with the mean age 35.7±4.2 y.o The studies period was January - December 2019. PRP was infused per intrauterine catheter on the 9th day of hormone replacement therapy cycle and progesterone administration day. All patients were transferred two good-quality blastocysts. T-test and Chi-squared test were used for data analysis.
Main results and the role of chance: After PRP infusion, the average endometrium thickness on day of progesterone administration in PRP group was 8.31±1.18mm, which was significantly thicker than control group (5.87±0.81mm) (Student t-test t=2.13, P = 0.04). The implantation rate and clinical pregnancy rate in PRP group were significantly higher than control group (28.13% vs. 15.79%, P<0.05; 25.0% vs. 10.53%, P<0.05, respectively). There was no difference in cycle cancellation rate in both groups.
Limitations, reasons for caution: The embryo transfer was done in case of the emdometrium thickness not less then 6 mm.
Wider implications of the findings: It is not clear how the intrauterine administration of PRP acts to affect endometrial thickness. Results from studies on the role of endometrial thickness on implantation and live births are contradictory. There is the urge for well-designed randomized studies to improve our knowledge on PRP in basic science.
Trial registration number: No number

P-362 New predictors of early impaired placentation preceding miscarriage before 10 weeks of gestation in IVF pregnancies: a prospective study

A. Ben-Haroush[1], H. Hamutal[2], A. Wertheimer[1], K. Tenenbaum-Gavish[3], Y. Shufaro[1], A. Idelson[3]

[1]Beilinson, IVF and Infertility Unit, Petach - Tikva, Israel ;
[2]TeleMarpe Ltd, Tel Aviv, Tel Aviv, Israel ;
[3]Rabin Medical Center, Obstetrics and Gynecology Ultrasound Unit, Petach Tikva, Israel

Study question: We prospectively evaluated early first-trimester gestational sac and fetal biometry with maternal blood PP13, to predict impaired placentation prior to miscarriage before GA 10 weeks in IVF pregnancies.
Summary answer: In IVF pregnancies with live embryo at first ultrasound scan, high UtA-PI/CRL and PP13/CRL ratios may indicate impaired placentation preceded early pregnancy loss.
What is known already: Fetal loss during the first trimester occurs in 10-20 percent of pregnancies. In a previous study we showed that small CRL in the early first trimester may predict early fetal loss in IVF pregnancies; fetal losse rate was 17.2% in pregnancies with CRL ≤10 percentile compared to 6.6% in the appropriate to GA CRL group (*P*=0.005). Placental protein 13 (PP13), is exclusively expressed in placenta from a very early stage of pregnancy and can be detected in the maternal blood from the fifth week of gestation. Some studies have indicated that damaged placenta may leak high levels of PP13.
Study design, size, duration: Cohort of 115 healthy IVF patients with a singleton viable embryo in early first trimester.
Participants/materials, setting, methods: Calculation of gestational age (GA); ultrasound evaluation of crown-rump length (CRL), mean gestational sac diameter (GSD) and volume (GSV), mean yolk sac diameter (YSD) and volume (YSV); fetal heart rate (FHR), mean uterine arteries pulsatility index (UtA-PI); and maternal blood placental protein 13 (PP13) levels. Patients were divided into three groups by GA; and early miscarriage versus ongoing pregnancy after GA 10 weeks.
Main results and the role of chance: Early fetal loss occurred in 14.8% of patients; miscarriage group had higher discrepancy between calculated and measured GA (*P*<0.001), lower GSD and GSV (*P*=0.005 and *P*=0.02, respectively), significantly different YSD and YSV, lower mean GSD and volume ratios (*P*=0.001 and *P*=0.003, respectively), and higher UtA-PI/CRL ratio with miscarriage at GA of 46-48 days and GA ≥49 days (*P*=0.034 and P=0.026, respectively). PP13/CRL ratio was higher in patients with miscarriage at GA ≥49 days (*P*<0.041).
Limitations, reasons for caution: Small cohort, only IVF pregnancies.
Wider implications of the findings: Possible very early prediction of impaired placentation prior to early pregnancy loss. A larger cohort is needed to further verify the clinical utility of these miscarriage predictions in IVF pregnancies.
Trial registration number: NA

P-363 The Association between Serum Estradiol and Progesterone on the Same Day of FET and the Pregnancy Outcome

K. Rageh[1], A. Barakat[2], N. Barakat[3]

[1]Al-Azhar university, Ob/Gyn., Cairo, Egypt ;
[2]Al-Baraka Fertility Hospital, Ivf, adliya, Bahrain ;
[3]Al- Baraka fertility hospital, lab, adliya, Bahrain

Study question: To investigate the impact of serum E2 and P levels on the same day of embryo transfer on pregnancy outcomes for FET cycles.

Summary answer: The association between serum estradiol and progesterone levels on the same day of FET and the pregnancy outcome is still not proven
What is known already: So far, most studies about FET cycles have focused on embryological factors and the thickness of endometrium, while little attention has been paid to the serum steroid hormone levels on the day of embryo transfer.

Besides endometrial thickness, E2 and P levels are also regularly monitored for endometrial receptivity. However, whether serum E2 and P levels on the day of embryo transfer can serve as an indicator for clinical pregnancy is doubtful. The effect of serum E2 and P levels on the day of embryo transfer is a matter of controversy in the literature and needs further evaluation.
Study design, size, duration: This was a retrospective cohort study (registered at ***clinical trials.gov with ID NCT04114500)***, for 402 FET cycles which conducted in Al- Baraka Fertility Hospital, Manama, Bahrain, between April 2018 and May 2019
Participants/materials, setting, methods: Endometrial preparation for 402 patients received estradiol tab. When end.thickness reached 8 mm or greater, patients were initiated on both vaginal and oral Progest. A depot GnRH agonist was administered in midluteal phase of the preceding cycle. On the same day of FET, serum levels of E2 and P were assessed, Then, transfer of PGT-euploid embryos was performed. 12 days later pregnancy test was assessed, and then ultrasound was scheduled to check the viability
Main results and the role of chance: Serum P and estradiol levels the same day of FET were measured. A multivariable analysis to assess the relationship between serum E2 & P level and pregnancy outcomes was performed, adjusted for confounding variables. Mean E2 value was 931.41 ± 438.65 pg/ml, while mean P value was 8.47 ± 9.4 ng/ml. Progesterone levels were split in terciles: T1: <15 ng/ml; T2: 15–30 ng/ml; T3: > 30 ng/ml. Out of 402 cases, 240 cases had positive pregnancy test (59.7%) while the clinical pregnancy rate was 53.9% (217 cases out of 402) with no correlation between serum (E2, P & E/P ratio) and the pregnancy rate
Limitations, reasons for caution: its retrospective design, which precludes drawing conclusions regarding how to improve pregnancy outcomes in FET patients using serum estradiol and progesterone levels as predictors; also in our study, we didn't evaluate live birth rates (LBR).
Wider implications of the findings: The implantation process is the most vital and the least understood part of reproduction.trying to understand this inigma of implantation in the future we are planning to go for a prospective study using only vaginal progesterone, with evaluation of secondary outcomes e.g. live birth rates (LBR), and spontaneous abortions/biochemical pregnancies.
Trial registration number: NCT04114500

P-364 Expression of vascular endothelial growth factor (VEGF), placental growth factor (PLGF) and insulin-growth like factor 1 (IGF-1) in serum from women undergoing frozen embryo transfer.

X. Guo[1], T.C. Li[1], X. Chen[1]

[1]The Chinese University of Hong Kong, Department of Obstetrics & Gynaecology, Hong Kong, China

Study question: Is there a difference in serum angiogenic profile on day LH+7 between pregnant and non-pregnant women undergoing frozen embryo transfer?
Summary answer: Serum PLGF level on day LH+7 in women who conceived was significantly lower than those who did not conceive.
What is known already: Angiogenesis is essential for successful pregnancy establishment. VEGF, PLGF and IGF1 are three main angiogenic factors which play significant role around the time of embryo implantation. Previous studies have shown that alternation in expression of angiogenic factors was associated with infertility and they may serve as predictive indicators for pregnancy outcome. However, the relationship between serum PLGF, VEGF and IGF1 and pregnancy outcome has not been fully illustrated.
Study design, size, duration: It is a prospective pilot study in a tertiary teaching hospital. A total of 40 infertile patients who underwent frozen embryo transfer treatment from Jan 2018 to Dec 2018 were recruited in our study.
Participants/materials, setting, methods: All the serum specimens were collected precisely on day 7 after LH surge in a natural non-conception cycle. Commercial Elisa kits were used to identify the concentrations of PLGF, VEGF, and IGF1. Demographic data and pregnancy outcomes were collected. Serum levels of PLGF, VEGF, and IGF1 were compared between patients who conceived (n=21) and who did not conceive subsequently (n=19).
Main results and the role of chance: There was no significant difference in maternal age BMI, transferred embryo numbers, endometrial thickness between the two groups. The serum concentration of PLGF in non-pregnant group (median 7.24, range 0-14.82pg/ml) was significantly (*P*=0.009) higher than it in the pregnant group (median 1.92, range 0-9.17pg/ml). IGF1 level was comparable between pregnant and non-pregnant patients (86.9±23.1 ng/ml vs. 87.2±26.5 ng/ml, *P*=0.971). There was no significant difference (*P*=0.088) in the serum VEGF level between non-pregnant group (median 233.3, range 78.89- 514.79pg/ml) and the pregnant group (median 139.0, range 50.47-379.34pg/ml).
Limitations, reasons for caution: The sample size is relatively small in this study and a large-scale study is needed to verify the results.
Wider implications of the findings: The altered expression of PLGF in serum may provide information on the prognostic value of serum angiogenic factor profile for pregnancy outcome.
Trial registration number: Nil

P-365 To compare effect of two protocol in hormone-replacement cycle for frozen-thawed embryo transfer - A single center, retrospective study

J. Gao[1], C. Ming-Hui[1], X. Yanwen[1], Z. Canquan[1]

[1]First Affilated Hospital Of Sun Yat-sen University, Reproductive Center, Guangzhou, China

Study question: What is the optimal dose for dydrogesterone combined used with progesterone vaginal gel for luteal-phase support(LPS) in hormone-replacement cycle for frozen-thawed embryo transfer.
Summary answer: 90 mg Crinone plus 20mg dydrogesterone BID has higher clinical pregnancy rate than 10mg dydrogesterone BID for LPS in hormone-replacement cycle for frozen-thawed embryo transfer.
What is known already: Vaginal progesterone gel (Crinone,8%) contains 90 mg of natural progesterone, which acts on the endometrium and myometrium and has some effect on inhibiting uterine contractions. The literature shows that the combination of Crinone and oral luteal-phase support drugs(dydrogesterone) can improve the pregnancy rate of hormone-replacement cycle for frozen-thawed embryo transfer. But what is the optimal dose for dydrogesterone is controversial problem.
Study design, size, duration: This retrospective study was conducted on 749 cycles who underwent hormone-replacement cycle for frozen-thawed embryo transfer from 1 Jan 2018 to 30 Nov 2019 at the First Affiliated Hospital of Sun Yat-sen University.
Participants/materials, setting, methods: 749 cycles underwent hormone-replacement cycle for frozen-thawed embryo transfer were enrolled. Patients used 4~9mg estradiol for 10~14 days in each treatment cycle. When the thickness of endometrium ≥8mm, progesterone was administered for 17 days. Among them, 427 cycles received 90 mg Crinone plus 10mg dydrogesterone BID(Group A), and 320 cycles received 90 mg Crinone plus 20mg dydrogesterone BID(Group B). Both of them receive single blastocyst embryo transfer at the sixth day of progesterone conversion.
Main results and the role of chance: There were no significant differences with regard to mean age, embryo transfer cycles, the thickness of endometrium on the day of progesterone conversion and embryo score between the two groups. The clinical pregnancy rate in group A was significant lower than group B (57.61% vs 66.56%, *P*=0.015).
Limitations, reasons for caution: This is a retrospective study. It suggest that 90 mg progesterone vaginal gel plus 20mg dydrogesterone BID may have better clinical pregnancy rate than 10mg dydrogesterone BID. Addition randomized prospective study are needed to confirm our finding, which is our future research direction.
Wider implications of the findings: We found that compare with 10mg dydrogesterone BID, 20mg dydrogesterone BID plus 90 mg progesterone vaginal gel would increase the clinical pregnancy rate in hormone-replacement cycle for frozen-thawed embryo transfer.
Trial registration number: no

P-366 The role of chromosomal aberrations of the embryo in the genesis of recurrent and sporadic miscarriage

E. Kudryavtseva[1], V. Kovalev[1], I. Baranov[2]

[1]Ural state medical university, Obstetrics and gynecology, Ekaterinburg, Russia C.I.S. ;
[2]National research center for obstetrics- gynecology and perinatology, organizational and methodological department, Moscow, Russia C.I.S.

Study question: Does the frequency and structure of chromosomal abnormalities in the embryo (fetus) differ with sporadic and recurrent pregnancy loss
Summary answer: Chromosomal abnormalities in the embryo are a significant cause of a miscarriage in both sporadic and recurrent
What is known already: About 50% of miscarriages are associated with the presence of chromosomal abnormalities in the embryo. It is assumed that if the patient suffers from recurrent miscarriage, that is, has a history of at least 2 consecutive cases of pregnancy loss, chromosomal abnormalities in the embryo are less common, and other reasons for the unsuccessful outcome of pregnancy should be sought. But in recent years there have been reports that, in a comparative analysis of the chromosome set in an embryo with sporadic and recurrent miscarriage, there was no significant difference in the frequency of occurrence of chromosomal pathology
Study design, size, duration: A retrospective cohort study was conducted by the method of continuous sampling, which included 1000 patients from Russia with a pregnancy demise diagnosed in the period of 6-12 weeks of gestation. The study was conducted in 2018-2019.
Participants/materials, setting, methods: The first group consisted of 681 patients whose first sporadic miscarriage was registered. The second group consisted of 319 patients who previously had a miscarriage. The products of conception (fresh samples of native biological material) obtained by vacuum aspiration were delivered to the laboratory where chromosomal microarray analysis was performed.
Main results and the role of chance: In group 1, various CAs in the embryo / fetus were detected in 378 samples (55.5%), in group 2 - in 203 samples (63.5%). The frequency of occurrence of chromosomal abnormalities in patients who already have a history of miscarriage was higher than with sporadic miscarriage - the differences are statistically significant (p = 0.015). There were no significant differences in the structure of chromosomal abnormalities. Autosome trisomy and numerical abnormalities of sex chromosomes were most often detected. So chromosomal abnormalities in the embryo are a significant cause of a miscarriage in both sporadic and recurrent. Structural rearrangements were detected in 52 samples (5.2%), and 30 (57.7%) of them were submicroscopic, and would not have been detected using standard cytogenetic studies. Genetic analysis of abortive material is an important component of the examination for the selection of further management tactics for patients. CMA is an effective research method when conducting genetic analysis of conception products.
Limitations, reasons for caution: In different ethnic groups, the frequency and structure of chromosomal abnormalities may vary
Wider implications of the findings: In many cases, a genetic study of abortive material makes it possible to clearly establish the cause of miscarriage, reduce the number of tests and diagnostic procedures assigned to patients, and optimize the algorithm of examination and preconception preparation.
Trial registration number: not applicable

P-367 Dydrogesterone addition to vaginal progesterone and transfer postponement improve outcome in patients with low P levels following hormonally substituted cycles for frozen-thawed embryo transfer

I. Cedrin - Durnerin[1], C. Vinolas[1], F. Krief[1], B. Dagher-Hayeck[1], M. Peigne[1], C. Sifer[2], S. Sarandi[2], B. Bennani Smires[2], M. Grynberg[1]

[1]Hôpital Jean Verdier, Service de médecine de la reproduction et préservation de la fertilité, Bondy, France ;
[2]Hôpital Jean Verdier, Laboratoire de biologie de la reproduction, Bondy, France

Study question: Does dydrogesterone addition to vaginal progesterone (P) and postponement of frozen thawed embryo transfer (FET) improve outcome in patients with low P levels following hormonal replacement therapy?
Summary answer: Dydrogesterone addition to vaginal P and 1-day FET postponement provide similar outcome in patients with low P levels compared to normal P "in phase" transfers.

What is known already: In artificial cycles for FET, low serum P levels on the day of transfer have been associated to decreased pregnancy and live birth rates. In our hands, measurement of serum P levels prior to transfer and if required, adjustment of vaginal P doses associated to 1-day FET postponement significantly improved outcomes. Despite this therapeutic strategy, more than 10% of cycles were cancelled for persistent inadequate serum P levels. Therefore, we modified our protocol by adding dydrogesterone to vaginal P in patients with low P levels prior to FET and similarly postponed embryo transfer by one day.
Study design, size, duration: This is a retrospective analysis of 249 prospectively collected FET cycles from November 2018 to October 2019. Endometrial preparation was achieved by sequential administration of vaginal estradiol until endometrial thickness >7 mm, followed by transdermal estradiol combined with 800 mg/day vaginal micronized P (400 mg twice a day). Our previous ROC analysis of serum P levels on FET day showed that optimal P level was 11 ng/mL to maximize sensitivity and specificity for live birth.
Participants/materials, setting, methods: This study was conducted in a university hospital. Serum P was measured on D1 following exogenous vaginal P introduction in the evening (referred as D0). When P levels were >11 ng/mL, embryo transfer was performed "in phase" on D2, D3 or D5 depending on embryo stage at cryopreservation. When P levels were <11 ng/mL, dydrogesterone (10 mg three times a day orally) was added to vaginal P and FET was postponed by one day.
Main results and the role of chance: Mean serum P level on D1 was 10.2 + 3.8 ng/mL, range (2.6-25.3 ng/mL). Serum P <11 ng/mL were observed in 63% of cycles (mean P level: 7.8 + 1.9 ng/mL vs. 14.1 + 2.9 ng/mL in patients with P >11 ng/mL, p<0.0001). On D1, serum estradiol levels were also significantly lower in patients with P <11 ng/mL (271 + 202 vs. 354 + 320 pg/mL, p<0.01). Therefore, 158 FET were performed with dydrogesterone addition from D1 onwards and postponed by one day while 91 FET were performed "in phase" following introduction of vaginal P. Characteristics of patients in both groups were similar for age (34 + 5 vs. 34 + 6 years), endometrial thickness prior to P introduction (9.6 + 2.0 vs. 9.7 + 2.2 mm), number of transferred embryos (1.4 + 0.5 vs. 1.5 + 0.5), embryo transfer stage (D2/D3/blastocyst: 7/32/61% vs. 5/38/57%). This strategy led to similar positive pregnancy test (37.3% vs. 40.6%, NS), heartbeat activity at 8 weeks (29.1% vs. 31.8%, NS) and ongoing pregnancy rates at 12 weeks (27.2% vs. 31.8 %, NS) between "dydrogesterone addition and 1-day postponement of FET" and embryo transfers performed "in phase".
Limitations, reasons for caution: The number of cycles has to be extended to confirm these preliminary data.
Wider implications of the findings: These results suggest that serum P measurement prior to ET followed by further addition of dydrogesterone to vaginal P and postponement of transfer might optimise the outcome of patients with low P levels in hormonally substituted FET cycles and avoid cancellation of a large number of cycles.
Trial registration number: not applicable

P-368 Endometrial thickness on the day of ovulation trigger is an effective predictor of pregnancy outcomes after frozen blastocyst transfer in spontaneous natural cycles

S. Onogi[1], K. Ezoe[2], S. Nishihara[1], J. Fukuda[1], T. Kobayashi[1], K. Kato[1]

[1]Kato Ladies Clinic, Gynaecology, Tokyo, Japan ;
[2]Kato Ladies Clinic, R&D division, Tokyo, Japan

Study question: Can the endometrial thickness (EMT) on the day of ovulation trigger predict the pregnancy outcomes after single vitrified-warmed blastocyst transfers (SVBTs) in spontaneous natural cycles?
Summary answer: The increased EMT on the day of the trigger was associated with improved ongoing pregnancy rate and decreased miscarriage rate in the first trimester.
What is known already: The relationship between the EMT on the day of embryo transfer (ET) and pregnancy outcomes has been controversial for

decades. Numerous studies reported that the decreased EMT on the day of ET was associated with a reduced likelihood of pregnancy; therefore, the EMT has been used as a predictor of pregnancy outcomes. However, recent studies demonstrated that the EMT on the day of ET is a poor predictor and has only a small independent prognostic value. The correlation of the EMT on the day of ovulation trigger with pregnancy outcomes after SVBT in spontaneous natural cycles is currently undetermined.

Study design, size, duration: A total of 901 SVBTs in spontaneous natural cycles, from November 2018 to October 2019, were analysed. Associations of EMT on the days of the trigger (EMT-Trigger) and SVBT (EMT-SVBT) with clinical and ongoing pregnancy rates were statistically evaluated. The factors possibly associated with EMT on the day of the trigger, such as patient and cycle characteristics, were also investigated.

Participants/materials, setting, methods: After monitoring follicular development and serum hormone levels, ovulation trigger was performed using a nasal spray containing buserelin, a gonadotropin-releasing hormone agonist. After ovulation was confirmed, SVBTs were performed on day 5. The EMT-Trigger and EMT-SVBT were evaluated using ultrasound on the day of the trigger and immediately before the SVBT procedure.

Main results and the role of chance: The patients were allocated according to the quartiles of EMT-Trigger as follows: EMT <8.1 mm, 8.1 mm ≤ EMT < 9.1 mm, 9.1 mm ≤ EMT < 10.6 mm, and EMT ≥10.6 mm. The increase in EMT-Trigger was significantly associated with the improvement of clinical and ongoing pregnancy rates ($P = 0.0003$ and $P < 0.0001$, respectively) and decreased miscarriage rates in the first trimester ($P = 0.0487$). The patients were also allocated according to the quartiles of EMT-SVBT: EMT <9.1 mm, 9.1 mm ≤ EMT < 10.1 mm, 10.1 mm ≤ EMT < 12.1 mm, and EMT ≥ 12.1 mm. EMT-SVBT was associated with clinical and ongoing pregnancy rates ($P = 0.0053$ and $P = 0.0010$, respectively), but not with the miscarriage rate ($P = 0.0848$). Additionally, multivariate logistic regression analysis demonstrated a significant correlation between the EMT-Trigger and ongoing pregnancy (adjusted odds ratio [AOR], 1.154; 95% confidential interval [CI], 1.046-1.274; $P = 0.0042$). However, no correlation was observed between EMT-SVBT and ongoing pregnancy (AOR, 1.043; 95% CI, 0.958-1.136; $P = 0.3251$). The decreased EMT-Trigger was significantly associated with an increase in female age ($P < 0.0001$) and shortened follicular/proliferation period ($P < 0.0001$).

Limitations, reasons for caution: The data used in this study were obtained from a single-centre cohort; therefore, multi-site studies will be required to ascertain whether these findings can be generalised to other clinics with different protocols and/or patient demographics.

Wider implications of the findings: This is the first report demonstrating a correlation between the EMT on the day of the trigger and pregnancy outcomes after frozen blastocyst transfer in spontaneous natural cycles. Our results suggest that EMT on the day of the trigger could be an effective predictor of pregnancy outcomes.

Trial registration number: not applicable

P-369 Impact of Preimplantation Genetic Testing for Aneuploidies (PGT-A) on first trimester biochemical markers - PAPP-A (placenta associated plasma protein) and free β-hCG (human chorionic gonadotropin)

D. Markova[1], K.O. Kagan[2], M. Hoopmann[2], H. Abele[2], E. Abecia[1], H. Fatemi[3], B. Lawrenz[3]

[1]IVI RMA Middle East Fertility Clinic, Fetal medicine, Abu Dhabi, United Arab Emirates ;

[2]Women's University Hospital- Tuebingen- Germany, Feto-Maternal Medicine, Tuibingen, Germany ;

[3]IVI RMA Middle East Fertility Clinic, Reproductive medicine, Abu Dhabi, United Arab Emirates

Study question: Is there a difference in concentrations of first trimester biochemical markers amongst patients with IVF/PGT-A, IVF/noPGT-A (fresh / frozen embryo transfer) and spontaneous conception?

Summary answer: There is a statistically significant difference in the concentrations of PAPP-A, but not in the levels of free β-hCG amongst the analysed groups.

What is known already: PAPP-A and free β-hCG are the two serum biomarkers used in calculation of the first trimester risk for chromosomal abnormalities and preeclampsia. It is a well-known fact that several factors like cigarette smoking, ethnicity and type of conception affect the levels of these two markers. The levels of PAPP-A are reduced and the levels of free β-hCG are increased in women who conceived through ART when compared with naturally conceived pregnancies. Moreover IVF/ICSI procedure, type of embryo transfer as well as freezing and thawing of embryos, might have an impact on the levels of first trimester biochemical markers.

Study design, size, duration: A cross-sectional, observational, collaborative, retrospective study was conducted between June 2009 and December 2019 in women with singleton pregnancies after either spontaneous conception, or IVF with PGT-A and frozen embryo transfer (FET) or after IVF without PGT-A and fresh transfer (ET) or FET and who had first trimester combined screening test between 10 and 14 weeks of gestation.

Participants/materials, setting, methods: In IVF/PGT-A-cycles, trophectoderm biopsy was performed. Serum PAPP-A and free β-hCG were measured at 10 to 14 weeks of gestation and analysed by Cobas E and Kryptor, certified by Fetal Medicine Foundation(FMF). Levels for both parameters were converted into Multiples of the Median (MoM) for corresponding gestational age by software of FMF. Both parameters were compared between the following groups: IVF/PGT-A/FET versus IVF/noPGT-A/FET; IVF/noPGT-A/ET versus IVF/noPGT-A/FET, spontaneous pregnancy versus IVF/PGT-A/FET or IVF/noPGT-A/ET and IVF/noPGT-A/FET.

Main results and the role of chance: The Kolmogorov-Smirnov test was used to analyse the normality of the distribution of variables. Difference of median of PAPP-A and free β-hCG were analysed by the Wilcoxon rank-sum test with nonparametric ANOVA. SAS studio™ software was used for statistical analysis.

A total number of 728 patients were included. Patients were divided into four groups; (i) IVF/PGT-A/FET (n=143); (iia) IVF/noPGT-A/ET (n=346) and (iib) IVF/noPGT-A/FET (n=100); (ii) naturally conceived pregnancies (n=139).

The median levels of PAPP-A were 0.97MoM; 1.12MoM; 1.20MoM and 1.03MoM respectively.

The median PAPP-A was the lowest in the group with IVF/PGT-A/FET and the highest in the group with IVF/noPGT-A/FET.

A statistically significant difference was observed in the median PAPP-A between IVF/PGT-A/FET group versus IVF/noPGT-A/FET group (p=0.01), spontaneous pregnancies versus IVF/noPGT-A/FET (p=0.01), and spontaneous pregnancies versus IVF/noPGT-A/ET (p=0.06).

No difference was observed when the group with naturally conceived pregnancies was compared with IVF/PGT-A/FET group (p=0.5) and in the group with IVF/noPGT-A/FET versus IVF/no PGT-A/ET (p=0.3).

The median levels of free b-HCG are 1.12MoM; 1.00MoM; 1.01MoM and 0.98MoM respectively.

Median free b-HCG was the lowest in the group with natural conception.

No statistically significant difference was observed in the concentrations of median level of free b-HCG amongst the compared groups (p>0.05).

Limitations, reasons for caution: The limitations of the study are the retrospective design and the ethnic diversity in the groups due to the multicentric study design.

Wider implications of the findings: PGT-A and ET-type have an implication on PAPP-A levels. The impact and pathophysiology of IVF related procedures (freezing and thawing of the embryo, trophoectoderm biopsy) on levels PAPP-A require further evaluation in order to assess the need for adjustments on the first trimester biochemical markers for pregnancies after IVF/PGT-A.

Trial registration number: Not applicable

P-370 Blastocyst morphology is not associated with maternal first trimester serum markers after fresh single embryo transfer (SET)

A. Pérennec[1], A. Reignier[1], T. Goronflot[2], P. Barrière[1], T. Fréour[1], T. Lefebvre[1]

[1]Department of Biology and Reproductive Medicine, Nantes University Hospital, Nantes, France ;

[2]Data Clinic- INSERM, Nantes University Hospital, Nantes, France

Study question: Is there an association between blastocyst morphology and maternal first trimester serum markers in In Vitro Fertilization pregnancies obtained after fresh single embryo transfer ?

Summary answer: Blastocyst morphology is not associated with serum levels of PAPP-A and b-hCG in first trimester screening after fresh single embryo transfer.

What is known already: Blastocele expansion, inner cell mass (ICM) and trophectoderm (TE) morphology are used to evaluate blastocyst implantation potential. Serum levels PAPP-A and b-hCG are used for first trimester combined screening, as they are associated with the risk of fetal aneuploidy and placental disorders. Several studies analyzed first trimester serum markers in IVF (In Vitro Fertilization) pregnancies and found lower PAPP-A level than in spontaneous pregnancies, while the results remained unclear regarding b-hCG levels. Several hypotheses have been raised to explain this apparent decrease, but the pathophysiology remains unclear, as well as the potential association between embryo morphology and early placentation.

Study design, size, duration: This bi-centric retrospective study was conducted between January 2012 and August 2018. We included 122 women aged from 18 to 43 years-old, whose pregnancy progressed at least beyond 13 weeks after a single blastocyst transfer and who participated in the first trimester combined screening test: 43 in a public IVF Center and 79 in a private IVF center.

Participants/materials, setting, methods: Day 5 and day 6 blastocysts were evaluated according to Gardner and Schoolcraft classification. Blastocysts were divided into three groups : excellent (≥ 3AA), good (3-6AB, 3-6BA, B2), medium to poor (3-6BB, 3-6AC, 3-6CA, B1, 3-6CB, 3-6BC). First trimester serum markers were measured in maternal blood between 11 and 13 weeks of amenorrhea + 6 days with Roche method and were expressed in MoM (multiple of median). Univariate and multivariate analyses were performed.

Main results and the role of chance: Body mass Index, smoking status, type of infertility, geographical origin, anti-mullerian hormone (AMH) level, ovarian stimulation characteristics, pregnancy outcomes and obstetrical complications were comparable between the three groups. Female age was statistically lower in the « medium to poor » group than in other groups. There were no significant differences in mean first trimester serum markers between the three groups (PAPP-A : p = 0,20 ;b-hCG : p = 0,12). No significant difference was found either between mean first trimester serum markers and ICM morphology (PAPP-A : p = 0,67 ; b-hCG : p = 0,60), TE morphology (PAPP-A : p = 0,66 ; b-HCG : p = 0,25), or blastocele expansion (PAPP-A : p = 0,22 ; b-hCG : p = 0,48). After adjustement on potential confounding factors (female age, type of gonadotropin, parity, number of oocytes retrieved and occurrence of ovarian hyperstimulation syndrom), the multivariate analyses did not report any significant association between PAPP-A or bHCG levels and blastocyst morphology.

Limitations, reasons for caution: "Poor" (≥B3CB and ≥B3BC) and "medium" (≥B3BB, ≥B3AC, ≥B3CA and B1) quality blastocysts were grouped together and represented only 27 blastocysts.

Wider implications of the findings: Our study concluded that first trimester serum markers were not statistically different according to blastocyst morphological characteristics. Although this needs further confirmation, this suggests that blastocyst morphology could have an impact on implantation, but not on placentation. Therefore, these findings are reassuring for couples undergoing IVF and blastocyst transfer.

Trial registration number: Not applicable

P-371 Endometrial fluid derived extracellular vesicles as low-invasive diagnostic biomarkers of implantative endometrium

J. Ibañez Perez[1], M. Diaz-Nuñez[2], L. Lainz[2], M. Diez-Zapirain[2], M. Iglesias[2], A. Expósito[2], M. Gonzalez[3], J.J. Lozano[4], A.M. Aranzay[3], E. Gonzalez[5], F. Royo[6], N. Subiran[7], R. Matorras[2], J.M. Falcon-Perez[8]

[7]Department of Physiology- Faculty of Medicine and Dentistry- University of the Basque Country UPV/EHU, Biocruces, Leioa, Spain ;
[8]Ikerbasque- CIC bioGUNE, Exosomes Laboratory, Derio, Spain

Study question: Is it possible to define a simple, sensitive and reproducible low-invasive extracellular vesicles (EVs) -based method to allow the quick identification of an implantative endometrium?

Summary answer: It is possible to obtain and analyze EVs and EVs-associated miRNAs from a small volume of endometrial fluid samples.

What is known already: Increasing embryo implantation rates has become one of the greatest challenges in ARTs. Usually an endometrial-biopsy is done to identify a receptive endometrium, which prevents embryo transfer in the same cycle, as it is detrimental for the implantation. Implantation is a complex process, which requires a synchrony between the development of the embryo and the endometrium, but also, an adequate embryo-endometrial cross-talk. The presence of EVs as mediators of this communication has been describe in the endometrial fluid (EF). The molecular analysis of the content of the EVs from EF could be a non-invasive method to improve the implantation rates.

Study design, size, duration: The population under study consisted of a group of 45 women who assisted at the Human Reproduction Unit from January 2018 to June 2019.

The study was approved by our Institutional Ethical and Investigation Board (CEIC 09/54 and CEIC 11/45).

Participants/materials, setting, methods: The main inclusion criteria were; cycle duration between 27 and 29 days, normal uterine and ovarian ultrasound, no previous gynecological pathologies and age between 18 and 37 years.
A pool of EF was used for the establishment of a robust methodology for analyzing EVs from endometrial fluid in clinical settings, where the sample is limited and no sophisticated equipment is available. For that, five different methodologies were compared in triplicate.

Main results and the role of chance: From the five methods compared, two of them consisted in the direct extraction of RNA while in the other three; an enrichment of EVs was done before the RNA extraction. SmallRNAseq was performed to determinate the most efficient method and showed that the protocols with a previous enrichment step of EVs obtained a higher miRNA expression.

Once the best method was selected, it was applied in a set of real samples with different implantation outcome. The content of miRNAs (mainly associated with EVs) of endometrial fluid samples from women in whom the implantation was successful (n=15) and unsuccessful (n=15) were analyzed. The results obtained from the differential analysis of the set of samples with different implantation outcome are being analyzed and it is expected that the results will be available by the time this communication is presented.

Limitations, reasons for caution: The main problem when working with biological replicates is the impossibility to quantify the sample of origin before starting with the analysis. Therefore, finding an adequate way to normalize the samples is crucial for analyzing the results.

Wider implications of the findings: This work demonstrate that it is possible to obtain and analyze EVs and EVs-associated miRNAs from a small volume of endometrial fluid samples, which allows the use of EV-miRNAs as a non-invasive biomarkers for the detection of an implantative endometrium.

Trial registration number: not applicable

P-372 An increased % of CD56+CD16+ NK cells in the endometrial biopsy is not related with recurrent miscarriage when maternal Killer cell Immunoglobulin-like Receptors are considered

D. Alecsandru[1], A. Pacheco[2], N. Garrido[3], A. Barrio[4], P. Aparicio[5], A. Pellicer[6], J.A. Garcia -Velasco[4]

[6]IVI RMA- Roma- Italy, Department of Reproductive Endocrinology and Infertility- IVI RMA- Roma- Italy, Roma, Italy

Study question: Could the increased % of CD56+CD16+ NK cells in the endometrial biopsy in oocyte donation recipients be considered as a risk factor for recurrent miscarriage?
Summary answer: An increased % of CD56+CD16+ NK cells in the endometrial biopsy is not related with recurrent miscarriage when maternal KIR genotype is considered
What is known already: There is still a current controversy regarding the relationship between an increased % of uNK cells in mid-secretory endometrium and its association with recurrent miscarriage. Increased risk of recurrent miscarriage (RM) has described in KIR AA mothers when the fetus has more HLA-C2 genes than the mother, and this HLA-C2 are paternally or egg donor inherited. In ART oocyte donor cycles, oocyte HLA-C behaves as the paternal HLA-C and KIR-HLA-C combination is not currently taken into consideration on donors' selection. KIRAA women have lower live birth rates (LBR) after double embryo transfer (DET).
Study design, size, duration: Between January 2017 and June 2019 we performed a prospective study of 139 women undergoing one cycle of oocyte donation-ART. They had recurrent miscarriage (RM) of unknown etiology. Thirty nine out of 139 patients underwent an endometrial biopsy under sterile conditions with a Pipelle catheter in the month prior of the embryo transfer (ET). Twenty-one healthy oocyte donors were included as a control group and they had an endometrial biopsies too.
Participants/materials, setting, methods: All the patients were selected from IVI RMA Clinics. KIR and HLA-C typing was performed for patients and HLA-C for partners and oocyte donors. They had a normal thrombophilia tests. The miscarriage and LBR has analyzed. The immune cell populations on biopsy were analyzed by 3 techniques: flow cytometry, immunohistochemistry and gene expression. A HLA-C tetramer has used to investigate the mother KIR biding to the embryo HLA-C.
Main results and the role of chance: The median age of our patients was 40 years, and 25 years for oocyte donors. In our cohort the pregnancy rate was 71.2%, the miscarriage rate was 31.6% (20.8% were clinical miscarriages), and the live birth rate was 39.5%. A higher miscarriage rate after DET in KIR AA (47.8%) compared to KIR AB (10.5%) and KIR BB (6.7%) ($p < 0.003$) was observed. A significantly decreased LBR has observed after DET in KIR AA (4.3%) compared to AB (26.3%) or BB (46.7%) ($p=0.009$). We analyzed the % and gene expression of CD56bright, CD56+CD16+, TregCD25+CD4+FoxP3+ cells. No differences were observed on CD56bright or Tregs when compared to controls. A higher CD56+CD16+ % was observed in patients (median 10.2), when compared to controls (6.3) $p<0.01$, but no differences were observed by KIR genotype among patients.

A lower gene expression (1/FC) of IL-10 was observed in the patients group compared with the control group ($p<0.02$), but no differences were observed by KIR genotype among patients. No differences have observed on TNFalpha gene expression between patients and control nor either by KIR genotype among patients.

There weren´t any differences on HLA-C tetramer binding to the uNK cells between groups or by maternal KIRs.
Limitations, reasons for caution: Our sample was small and this is the first report analyzing the reproductive outcome in oocyte donation by the endometrial % of CD56+CD16+ NK cells and maternal KIR. However, apart from statistical significance, the association strength was noticeably high, which confers our findings more confidence.
Wider implications of the findings: A higher miscarriage rate was observed in KIR AA patients but there weren´t differences in the % of endometrial CD56+CD16+ NK cells between KIR AA, AB or BB. Their increased % observed in the patients when compared to control group cannot be related with an increased risk of miscarriage.
Trial registration number: Not applicable

P-373 Efficacy of Endometrial Scratching on Pregnancy rate in women with Unexplained and Mild Male Factor Infertility after Failed Intrauterine Insemination Cycles A Randomised Controlled Cycle

C. Thyagaraju[1], M.S. Madhuri[1], P. Dasari[1]

[1]*JIPMER, Obstetrics and Gynecology, Pondicherry, India*

Study question: Does Endometrial Scratching(ES) in proliferative phase increase the probability of pregnancy in women undergoing Ovulation Induction and Intrauterine Insemination(IUI) after previous failed IUI cycles?
Summary answer: Endometrial Scratching in stimulated IUI cycle is a cost-effective and easy technique which may improve clinical pregnancy rate in women with previous failed IUI cycles
What is known already: Endometrial Scratching(ES) has been suggested as an intervention to increase the probability of pregnancy in women undergoing IVF. Majority of studies reported that ES improves outcome in IVF, IUI and natural conceptions: however, the size and quality of studies are poor which really questions the presence of any beneficial effect. Endometrial injury is often performed by pipelle biopsy that has an established safety profile. However, it is also known to be associated with a moderate degree of discomfort/pain and bleeding and requires an additional pelvic examination. Neither of these studies reported the pain/discomfort and bleeding secondary to the procedure.
Study design, size, duration: A prospective randomized controlled trial. One hundred sixty-two women (81 in each group) with primary/secondary infertility were randomized into intervention and control group. Sample size was estimated using the statistical formula for comparing two proportions. The minimum expected difference in the pregnancy rate between the group is considered as 20% and the sample size is estimated at 5% level of confidence and 80% power. The study was conducted from June 2017 to June 2019
Participants/materials, setting, methods: Couples aged between 25 to 35years attending the Infertility outpatient clinic in OBG department, JIPMER, Pondicherry, India. Unexplained or mild male factor infertility with previous up to 3 failed IUIs were randomised according to random blocks. Three cycles of ovulation induction with Clomiphene citrate and Gonadotrophins followed by IUI was done. ES was done using pipelle on day8/ 9 of the stimulated cycle in the intervention group. Pain and bleeding were noted after the procedure.
Main results and the role of chance: The mean age of women was 29.1 ± 3.4 years. There was a significant difference in the mean duration of infertility between two groups with a P-value of 0.041. There was no statistical difference in the distribution of type of infertility or unexplained and mild male factor infertility ($p=0.17$, $p=0.807$ respectively). There was no statistically significant difference with respect to the number of prior failed IUI ($p=0.279$). The clinical pregnancy rate in the ES group was 22.2% in comparison 9.8% in the control group. In the intent to treat analysis, with a P-value of 0.03 calculated from Chi-square test($p<0.05$) there was statistically significant difference in the pregnancy rate between Intervention and Control group. There is less than a 3% chance that the differences are not real. Efficacy of intervention was found to be Fourteen Percent (14%). Two patients in ES group had abortions and either of the group had no multiple pregnancies. There was an increased pregnancy rate (38.8%) in the third IUI cycle in the Intervention group compared to the Control group (12.5%)($p=0.43$). Fifty-one women (63%) had marked a VAS pain score of 4-5 with Mean VAS score of 3.42 ± 1.35. Twelve women (12.2%) experienced mild spotting post-procedure.
Limitations, reasons for caution: Small Sample size. Older age group might have led to a low pregnancy rate. Many unknown factors besides poor endometrial receptivity might have led to repeated failure cycles and reduced CPR. ES was done using the gentle movement of Pipelle which might have led to less inflammatory response for implantation.
Wider implications of the findings: Endometrial Scratching in IUI will be an inexpensive alternative to IVF for couples after IUI failures especially in developing countries, with an acceptable pregnancy rate and does not demand any special qualification. Larger and adequately powered studies are needed to elucidate the beneficial effects of endometrial scratching on Implantation.

Study question: Are criteria that determine when an early pregnancy is nonviable conservative enough to enroll women in a clinical trial regarding treatment?
Summary answer: Conservative criteria adopted to diagnose a nonviable pregnancy of unknown location as part of a RCT did not eliminate enrollment of a viable gestation.
What is known already: Current clinical criteria to consider a pregnancy non-viable vary in clinical guidelines. When an early gestation is not visualized with ultrasound, serial hCG values are used to determine viability prior to potential intervention. NICE 2019 defines a change of 63% or greater over 48 hours as potentially viable. ACOG 2018 defines a minimal rate consistent with a viable gestation to be 49% or greater over 48 hours (for initial values under 1500 mIU/mL). A viable intrauterine gestation has been noted with a rate of as low as 35% over 48 hours (Seeber et al. Fert and Sert,2006;86:454-459.).
Study design, size, duration: ACT or NOT is an RCT that evaluated the treatment of women with a persistent pregnancy of unknown location. Inclusion criteria included no definitive ultrasound evidence of intrauterine or extrauterine gestation and a plateau in hCG, defined as a < 30% in 2 days, < 50% in 3 days, < 75% at 4 days, < 100% at 5 days, < 130% at 6 days or >166% at 7 days. Two clinicians confirmed eligibility.
Participants/materials, setting, methods: After determination of eligibility subjects were randomized 1:1:1 to expectant management and to two different active treatment arms.
Main results and the role of chance: A participant was enrolled, randomized to expectant management, and was later noted to have a viable gestation. A 33-year-old, G2 P1001, who conceived with use of clomiphene citrate and IUI was enrolled at 4 5/7 weeks gestation. She presented with abnormal serial hCG values of 7% in 2 days and 24% over 4 days: 86 at GA 4 0/7, 92 at 4 2/7 and 107 at 4 5/7. Ultrasound at GA of 4 5/7 demonstrated no evidence of an intrauterine or extrauterine gestation. Subsequently hCG values rose normally: 348 at 5 0/7, 803 at 5 2/7, and 2477 at 6 0/7. A viable IUP was diagnosed at 6 5/7 with a CRL 7.7mm and cardiac activity. She elected to proceed with prenatal care and delivered at term without complication. This event was reported to the DSMB and IRB and judged to be unanticipated based on current clinical standards. However, a memo was circulated to all participating centers to use caution against declaring non-viability when; a) using early hCG values prior to 6 wks gestation when the date of conception is known, b) the hCG is continuously rising, and c) in those who may be at greater risk for multiple pregnancy.
Limitations, reasons for caution: While this case represents a single event from a larger RCT, it highlights the limitations of clinical guidelines based solely on laboratory tests. Criteria to classify an early gestation as non-viable, based on only hCG values, may not be 100% predictive and should include all aspects of the clinical setting.
Wider implications of the findings: Despite conservative criteria, a viable gestation was unintentionally enrolled in trial designed to manage a non-viable gestation. If this participant was actively treated her pregnancy may have been interrupted. Current clinical standards may need to be amended to ensure a pregnancy of unknown location is nonviable prior to treatment.
Trial registration number: NCT01800162

P-375 Predictive value of serum HCG concentrations in pregnancies achieved after thawing embryo transfer

S.J. Chon[1]

[1]Gil Hospital, Obstetrics and Gynecology, Incheon-si, Korea- South

Study question: What would be cut off values of serum HCG level in maternal blood measured on seventh day of thawing blastocyst transfer to confirm stable clinical pregnancy and live birth rates?
Summary answer: The cut off values predicting a clinical pregnancy was 22.8 IU/L and for ongoing pregnancy was 26.45 IU/L.
What is known already: Threshold values for predicting a clinical pregnancy for a fresh blastocyst were 111IU/l and for a vitrified-warmed blastocyst 137IU/l.
Study design, size, duration: A cryopreserved thawing embryo transfer (T-ET) cycles were retrospectively analyzed a database of clinical and laboratory information between 1 January 2015 and 30 February 2018 at a single fertility center.
Participants/materials, setting, methods: In the present study, a total of 166 patients with T-ET were included and only serum HCG levels drawn 7 days after the T-ET were included. The percentage for the area under the curve and the 95% confidence interval were generated for each ROC curve. The AUC measures the diagnostic accuracy of HCG on pregnancy outcome; an AUC closer to 1.0 denotes a perfect test.
Main results and the role of chance: Among 166 patients who underwent T-ET, 89 resulted in a positive maternal serum HCG; 31 resulted in a biochemical pregnancy, and 14 in clinical abortion, and 44 patients achieved an ongoing pregnancy and 43 of them finally achieved live births. Of the 44 ongoing pregnancies, 43 live births were successful in the T-ET cycle of which difference were very small, however they were shown separately because of the significant meaning of live births. The cut off values predicting a clinical pregnancy was 22.8 IU/L with sensitivity of 91.4% and a specificity of 91.7%. The cut off values predicting an ongoing pregnancy for a T-ET was 26.45 IU/L, with a sensitivity of 93.2%, a specificity of 84.4%, and live birth was 27.95 IU/L, with a sensitivity of 90.7 %, a specificity of 84.6 %.
Limitations, reasons for caution: This is a retrospective study with small sample size and it is a single centered study.
Wider implications of the findings: Clinicians could inform patients who have undergone thawing single embryo(blastocyst) transfer whether their positive serum hCG would present better outcomes or not based on these cut off values.
Trial registration number: GBIRB2019-310

P-376 4D ultrasonographic evaluation of uterine peristalsis correlates with progesterone levels in patients with repetitive implantation failure.

B. Moliner, M.D.[1], **J. Llacer**[1], **A. Bernabeu**[1], **J.C. Castillo**[1], **A. Fuentes**[1], **F. Sellers**[1], **R. Bernabeu**[1]

[1]Instituto Bernabeu, Reproductive Medicine Department, Alicante, Spain

Study question: Does 4D ultrasonographic evaluation of uterine peristalsis on the day of embryo transfer correlate with progesterone levels in patients with repetitive implantation failure (RIF)?
Summary answer: Uterine peristalsis evaluated by 4D ultrasound shows correlation with progesterone levels when assessed on the day of embryo transfer in patients with RIF.
What is known already: The role of progesterone in the inhibition of uterine peristalsis is widely known. Uterine peristalsis and progesterone levels on the day of embryo transfer are described as potential factors influencing pregnancy outcomes in IVF cycles. However, reliable methods demonstrating a correlation between these two entities specifically in patients with RIF are still under research.
Study design, size, duration: Our retrospective cohort study (November 2017-January 2020) included all consecutive IVF cycles of RIF patients (n=153) who underwent uterine contractility/progesterone levels assessment on the day of embryo transfer. RIF was defined as an unsuccessful implantation of a total number of ≥3 blastocysts originating from oocyte donation or autologous PGT-A cycles. Participants underwent frozen embryo transfer cycles (FET) and were evaluated for uterine contractions and serum progesterone levels 30 minutes before their embryo transfer procedure.
Participants/materials, setting, methods: Uterine contractions (UC) were assessed by recording a 6-minute-long video using 2D vs 4D mode (Voluson E10) by a single operator (BM). Contractions were counted visually on a 15x accelerated recording. In order to define low progesterone levels, we separated progesterone levels in quartiles, counting last quartile as Low progesterone level group (LP=< 9,2 ng/ml; N=38), considering the rest as Normal Progesterone level (NP>9,2 ng/ml; N=115).
Main results and the role of chance: Overall, patients mean age was 41 years, with an average of 4.1 embryo transfers performed previously and with

an average of 5.1 embryos transferred. The average of contractions measured in 2D was 0.62 contractions per minute (cpm) while the average of contractions measured in 4D was 0.99 cpm. There were no differences between the groups of uterine factor (adenomyosis, myomas, adhesions or polyp) or endometriosis, as well as of the variables previously mentioned such as age, the number of embryo transfers made previously or the number of embryos transferred previously. Differences were observed in uterine contractility measured by 4D ultrasound, observing 1.3 cpm in LP group while in HP group an average of 0.9 cpm was observed. This difference was statistically significant (p = 0.012) giving a RR of 1.6 (95% CI 0.6 to 4). However, uterine contractility assessment using 2D didn't show statistically significant differences (p = 0.315), observing a mean of 0.8 cpm in the LP group and a mean of 0.6 cpm in the NP group.

Limitations, reasons for caution: The inherent risk of bias associated to retrospective studies. Additionally, the small sample size -especially for the subgroup analysis (normal vs low progesterone levels)- precludes robust conclusions. Caution is warranted in extrapolating these results to patients without previous implantation failure.

Wider implications of the findings: Our findings suggest that low progesterone levels constitute a significant factor for increased uterine contractility. Furthermore, 4D ultrasound appears to be a reliable method for assessment of uterine peristalsis, thus should be considered for routine evaluation in RIF patients undergoing cryotransfer in artificial cycles.

Trial registration number: None

P-377 Anti-Müllerian hormone receptor type II causing repeated implantation failures through the endometrium apoptosis of the luteal phase

F. Yunxing[1], H. Rong[2]

[1]18309609178, Ningxia Medical University Shuang Yi Campus, Yinchuan, China ; [2]Ningxia Medical University / Ningxia Medical University General Hospital, Reproductive Medicine Center of Ningxia Medical University General Hospital, Yinchuan, China

Study question: To detect the expression of AMH and anti-Müllerian hormone receptor (AMHR)II at the maternal–fetal interface and explore whether AMH and AMHRII participated in the occurrence of repeated implantation failure (RIF).

Summary answer: AMHRII had an effect on RIF via the AMH/AMHRII signaling pathway. It participated in the occurrence of RIF by interfering with endometrial decidualization and apoptosis.

What is known already: The abnormal expression of key proteins and hormones at the maternal–fetal interface affected the maternal–fetal communication and led to adverse pregnancy outcomes. The expression of AMHRII in endometrial tissues was closely related to the reproductive ability of mice.

Study design, size, duration: From January 2015 to May 2016. The 154 endometrial tissues in the early follicular, follicular, and luteal phases were collected from 41 women with infertility due to tubal or male factors alone; 41 samples were also collected from patients with RIF. The 20 placental tissues were collected in early, mid and late pregnancy respectively. 12 blastocysts were cultured from nontransplanted fourth-order embryos with poor quality on the third day.All patients age were less than 35.

Participants/materials, setting, methods: 1. Relative expression of AMH and AMHRII in Endometrium and placenta were analyzed using immunohistochemistry,WB and qRT-PCR. 2. Expressions of AMH and AMHRII mRNA in blastocysts detected using a single-cell real-time polymerase chain reaction. 3. Apoptosis in the endometrium during the luteal phase detected by TUNEL and WB. 4. The expression of estrogen receptor (ER), IGFBP1, and PRL were tested via immunohistochemistry. 5. The relationship between AMHRII and ER, IGFBP1, and PRL.

Main results and the role of chance: AMH and AMHRII were less expressed in the normal endometrium during the menstrual cycle. AMHRII was slightly highly expressed in the endometrium during the menstrual cycle, especially in the luteal phase. AMHRII was highly expressed in the placental tissues during early pregnancy and in the second and third trimesters. In addition, the expression of AMHRII mRNA was detected in the blastocysts, but no expression of AMH mRNA was observed. Positive expression of AMHRII in patients with RIF was 29.3%, which was higher than that in patients of normal childbearing age, especially during the luteal phase. TUNNEL and WB results indicated the proportion of patients with RIF and high expression of AMHRII was significantly higher than the proportion of patients with RIF and low expression of AMHRII and the proportion of normal individuals.The ER, IGFBP1, and PRL expression in the endometrium of patients with RIF and high expression of AMHRII was significantly lower than that in patients with RIF and normal expression of AMHRII. A negative correlation was found between the expression of AMHRII and ER, IGFBP1 and PRL in the endometrium during the luteal phase in patients.

Limitations, reasons for caution: Clinical samples are more difficult to obtain.Further studies with more samples are required to tested. Interfering gene expression at the cellular level to elucidate the exact underlying molecular mechanisms about AMHRII in RIF.

Wider implications of the findings: This study was novel in reporting the expression of AMH and AMHRII at the normal maternal–fetal interface. The abnormally increased expression of AMHRII might participate in the occurrence of RIF via a mechanism associated with the interference of endometrial decidualization and apoptosis, ultimately resulting in impaired endometrial receptivity.

Trial registration number: not applicable

P-378 Human endometrial glandular organoids: a powerful 3D-cell model to mimic morphological and molecular changes of the receptive endometrium at the implantation window

A. Luddi[1], V. Pavone[1], G. Morgante[1], L. Governini[1], B. Semplici[1], L. Benincasa[1], V. De Leo[1], P. Piomboni[1]

[1]University of Siena, Molecular and Developmental Medicine, Siena, Italy

Study question: Does a 3D-culture model of human endometrial glandular organoids mimic the morphology and the gene expression profile of a receptive endometrium at the implantation window?

Summary answer: Endometrial organoids are surrogate as regard morphology, creation efficiency, expandability, gene expression profile; pinopodes, reliable marker of endometrial receptivity, are detectable after *in vitro* decidualization.

What is known already: Many evidences support the existence in the human of a narrow window of uterine receptivity, which opens during the mid-luteal phase, during which endometrium becomes receptive toward the embryo. At this time, formation of pinopodes on the apical membranes of the endometrial epithelial cells occurs, a phenomenon that is considered as a reliable morphologic marker of endometrial receptivity. Due to ethical concerns to study human implantation *in vivo,* this *in vitro* three-dimensional culture system offers the opportunity to evaluate the endometrial microenvironment and to investigate the molecular mechanisms underlying the implantation process.

Study design, size, duration: Endometrial biopsies have been collected from healthy women, who underwent ovarian surgery from January to October 2019. The epithelial cells were isolated and 3D culture was applied to obtain organoids. Morphology, ultrastructure as well as gene expression profile of key genes known to be involved in the implantation process have been evaluated, before and after in vitro hormonal treatments to induce morphological and molecular modifications mimicking the proliferative and secretive phase of the uterine cycle.

Participants/materials, setting, methods: Endometrial specimens have been collected from women of proven fertility (n=5; 22-39 years old). Organoids of epithelial cells have been obtained, and then exposed for 4 days to estrogen alone or in combination with progesterone and cAMP, mimicking the proliferative and the secretory phase, respectively. Then, organoids were fixed and processed for TEM and SEM analysis or processed for RNA extraction and gene expression analysis by digital droplet PCR (ddPCR).

Main results and the role of chance: Our data highlight that organoids obtained from human endometrium represent a good model to study the physiological function of the endometrial epithelium. TEM analysis showed that organoids preserve glandular organization as well as ultrastructural characteristics. Moreover, a scanning electron microscopic (SEM) survey of endometrial organoids, definitively demonstrates the dramatic changes occurring in the luminal surface according to hormonal treatment. In organoids treated with E2, mimicking the proliferative phase, the luminal surface is relatively smooth or exhibit irregular micro-extensions; indeed, it appears overlaid with a rich net of microvilli and cilia clusters of different length. The organoids mimicking the secretory phase are characterized by the presence of large cytoplasmic apical protrusions traditionally called "pinopodes", that bulge out of the entire luminal cell surface. These protrusions have regular contours and are characterized by a

significant loss of free surface micro-extensions. These data are also confirmed by ddPCR analysis, that revealed significant modulation of genes involved in the endometrial receptivity depending on hormone treatment: when 3D-cultured organoids were supplemented with E2, the expression of *PGR*, *MMP26* and *PAEP* significantly increased if compared to control. More interestingly, E2+MPA+cAMP treatment increased the expression of HOXA 10, *IGF1*, *VEGF*, *MMP26* and *PAEP*, while *ESR1* significantly decreased.

Limitations, reasons for caution: Larger study needs in order to confirm these data, above all for supporting conclusions from gene expression profiles. Moreover, further development of this approach based on the incorporation of other endometrial cell types is looked-for a better understanding of mechanisms underlining the embryo implantation establishment.

Wider implications of the findings: 3D-culture model of glandular endometrium not only represents a valuable research tool to study molecular mechanisms underlying human implantation *in vitro*, but also will provide a valuable model to carry out comparative studies on specific mechanisms that may drive endometrial dysfunction, paving the way to the setup of personalized treatments.

Trial registration number: Not applicable

P-379 management and outcome of interstitial pregnancy after in vitro fertilization/embryo transfer: a retrospective consecutive series of 185 cases

C. Wang[1], S. Yang[1], R. Li[1], J. Qiao[1]

[1]Peking University Third Hospital, Obstetrics and Gynecology, Beijing, China

Study question: Surgical management of interstitial pregnancy (IP) with or without intrauterine pregnancy (IUP): cornual resection or cornuostomy?

Summary answer: Compared with cornual resection, cornuostomy by laparoscopy showed no difference in the removal of ectopic pregnancy and the preservation of intrauterine pregnancy.

What is known already: IP is a rare type of ectopic pregnancy, but its incidence rises among patients undergoing in Vitro Fertilization/Embryo Transfer (IVF/ET) treatment. Most patients show no specific clinical manifestations, but once the interstitial portion ruptured, patients may face serious life threats.

Study design, size, duration: A total of 185 cases who were diagnosed with IP followed IVF/ET and treated in our hospital between Jan 2010 and Oct 2019 were included, of which 66 (35.68%) were interstitial heterotopic pregnancy (IHP). The data of each patient, including age, history of gynecologic surgeries, details of IVT/ET process, therapeutic interventions and reproductive outcome, were collected through electronic medical record database and analyzed retrospectively.

Participants/materials, setting, methods: Measurement data were presented as mean±SD or median (minimum-maximum), and statistical significance of differences among the groups was analyzed by Student's t-test or Mann–Whitney U test. Categorical variables were reported as n%, and statistical significance of differences among the groups was analyzed by chi-square test or Fisher's exact test. A two-sided p value< 0.05 was considered statistically significant. All statistical analyses were performed with the use of SPSS statistics for Windows version 22.0 software.

Main results and the role of chance: The average number of embryos transferred was 2.08±0.416. 171 patients received Day 3 embryos and 14 patients received Day 5 blastocysts. 118 patients underwent fresh ET and 67 patients underwent frozen ET. There were no differences between IP without IUP patients and IHP patients on number of embryos transferred (2.034±0.43 vs 2.136±0.35, p=0.098) or type of ET (fresh ET 68.91% vs 54.55%, p=0.052), but IP without IUP patients received more Day 3 embryos transferred (94.96% vs 86.36%, p=0.040), and showed earlier gestational age (days) at diagnosis (43.84±6.08 vs 50.68±10.16, p<0.001). Patients are treated mainly by surgery, including 9 laparotomies, 113 laparoscopic cornuostomies (LC), 30 laparoscopic cornual resections (LCR) and 7 laparoscopic loop ligatures. LC and LCR shared the similar duration of surgery (minutes) [51 (9-189) vs 61(23-155), p=0.317] and intraoperative blood loss [5 (1-300) vs 10 (2-200), p=0.317]. There were no significant differences between LC and LCR on live birth rate (91.4% vs 77.8%, p=0.574) among IHP patients and persistent ectopic pregnancy rate (6.3% vs 0.0%, p=0.560) among IP without IUP patients. No surgical complications (including infection, uncontrolled bleeding, uterine rupture during subsequent pregnancy or delivery) were observed in our cohort.

Limitations, reasons for caution: This is a retrospective case-control study, which theoretically has selection bias, information bias and confounding bias. Although it has been controlled in the design and implementation, relevant bias interference cannot be completely excluded. In addition, the sample size is relatively small, although literature with larger samples never have been published.

Wider implications of the findings: Surgical management is a safe and effective approach for IP and even for IHP. Compared with cornual resection, cornuostomy by laparoscopy showed no difference in the removal of ectopic pregnancy and the preservation of intrauterine pregnancy, but the risk of persistent ectopic pregnancy was worthy of attention.

Trial registration number: Not applicable

P-380 Female lifestyle factors and risk of recurrent pregnancy loss: systematic review and meta-analysis

K.Y.B. Ng[1,2], G. Cherian[1], A. Kermack[1,2], S. Bailey[1,2], N. Macklon[3,4], S. Sunkara[5], Y. Cheong[1,2]

[1]Princess Anne Hospital, Obstetrics and Gynaecology, Southampton, United Kingdom ;
[2]University of Southampton, School of Human Development and Health, Southampton, United Kingdom ;
[3]University of Copenhagen, Zealand University Hospital, Copenhagen, Denmark ;
[4]London Women's Clinic, London Women's Clinic, London, United Kingdom ;
[5]Kings College London, Department of Women and Children's Health, London, United Kingdom

Study question: Do female lifestyle factors influence the risk of recurrent pregnancy loss (RPL)?

Summary answer: Overweight and obese women had a significantly higher risk of RPL; the impact of smoking, alcohol consumption and caffeine intake on RPL remains uncertain.

What is known already: Recurrent pregnancy loss, defined as the occurrence of two or more consecutive miscarriages occurs in 1-2% of couples, and is a diagnosis that remains unexplained in a large proportion of cases. Whilst the specific mechanisms leading to RPL are still relatively unknown, poor lifestyle is associated with a hostile reproductive environment, which may compromise optimal embryo implantation and securement of a pregnancy. Although associations between certain lifestyle factors and the risk of sporadic miscarriage have been reported, whether lifestyle factors impact the risk RPL is less well known. It is important to understand any probable associations to improve patient management.

Study design, size, duration: This is a systematic review and meta-analysis addressing the impact of female lifestyle factors on the risk of RPL. Electronic databases including Medline, Embase, Cochrane Library, CINHL and Pubmed were searched until August 2019. The lifestyle search terms included 'diet', 'smoking', 'alcohol', 'caffeine', 'exercise' and 'BMI'. The search term for miscarriage history included 'miscarriage', 'recurrent pregnancy loss', 'recurrent miscarriage' and 'spontaneous abortion'.

Participants/materials, setting, methods: Full text manuscripts were reviewed for relevancy by two independent authors. Studies were included if they explored women of reproductive age, who had been exposed to an aspect of female lifestyle, such as obesity, being overweight, underweight, smoking and alcohol intake. The outcome assessed was the risk of having RPL in this population. Where possible, individual study estimates were pooled using either fixed or random effects meta-analysis.

Main results and the role of chance: A total of 24,705 records were identified from the electronic search and an additional 192 records identified through hand searching of references. Fifteen studies were included in the systematic review and meta-analysis; 8 case control studies, 4 cohort studies, 2 survey based studies and 1 observational study. Meta-analyses of 4 studies showed that the odds of RPL in the obese compared to women with normal BMI is 1.79 (95% CI 1.34, 2.41). The odds of RPL in women with BMI>25 compared to women with normal BMI is also significantly increased (OR 1.33, 95% CI 1.13, 1.56). Meta-analysis of 5 studies showed that being underweight does not increase the risk of RPL (OR 1.00, 95% CI 0.59, 1.70). Meta-analysis of 3 studies shows no increase in risk of RPL in women who smoked cigarettes compared to non smokers (OR 1.62, 95% CI 0.90, 2.93), and no increased risk of RPL in women who consumed alcohol compared to those who do not (OR 1.12, 95% CI 0.88, 1.44). Meta-analyses of 2 studies showed no increased risk

of RPL in women who have higher caffeine intake (>99mg/day) than women who have lower caffeine intake (≤99mg/day) OR 1.35 (95% CI 0.97, 1.89).
Limitations, reasons for caution: This review is limited by heterogeneity in the definition of RPL and methods of quantifying smoking, alcohol and caffeine intake between studies. Some studies did not restrict on whether the miscarriages were consecutive. This review was limited to studies in English and we did not assess impact of male lifestyle.
Wider implications of the findings: Being overweight and obese contributed significantly to increased risk of RPL by over 1.3- and 1.8-fold respectively. Whether lifestyle interventions including weight loss programmes are beneficial require further investigation. Smoking, alcohol and high caffeine intake did not increase the risk of RPL, but evidence is limited given very few studies.
Trial registration number: not applicable

P-381 Regulation of the immune tolerance-inducing Human Leukocyte Antigen-G (HLA-G) for induction of peripheral and placental maternal tolerance of pregnancy.

G. Persson[1], C.S. Stæhr[1], F.S. Klok[1], J.B.S. Bork[1], C. Isgaard[1], M. Lebech[2], T.V.F. Hviid[1]

[1]Zealand University Hospital, Department of Clinical Biochemistry, Roskilde, Denmark ;
[2]Zealand University Hospital, Department of Gynaecology and Obstetrics, Roskilde, Denmark

Study question: How is the expression and the isoform profile of HLA-G regulated at the feto-maternal interface and systemically in the mother in uncomplicated pregnancy versus pre-eclampsia?
Summary answer: Levels of peripheral and placental soluble HLA-G (sHLA-G) are not correlated and may represent different compartments. HLA-G expression profile can be regulated directly by cytokines.
What is known already: The expression of paternally derived antigens by the fetal cells during establishment of pregnancy must involve induction of maternal tolerance. HLA-G expression by the endometrium and placental trophoblast cells is an important factor that allows generation of tolerance. HLA-G expression may be modulated by local factors such as hormones and cytokines (e.g. progesterone and IFN-γ). Implantation failure, recurrent abortion and pregnancy complications such as pre-eclampsia (PE) are often characterized by an altered HLA-G, cytokine and hormone profile. However, these measurements are often based on systemic serum levels. No clear picture of the local HLA-G regulation has yet been established.
Study design, size, duration: The direct effect of cytokines on HLA-G expression was studied *in vitro* by stimulating the chorioncarcinoma cell line JEG-3 with regulatory, anti- and pro-inflammatory cytokines. From October 2017 until present 30 women with uncomplicated pregnancies and 20 cases of PE diagnosed according to the Danish guidelines have been recruited at Zealand University Hospital, Denmark. Peripheral blood was collected pre-partum. Cord blood, placental biopsies and blood were collected within 30 minutes from birth.
Participants/materials, setting, methods: JEG-3 cells were stimulated for 24 or 72 hours with IL-2, IL-4, IL-6, IL-10, IL-12, IL-15, IL-17A, TGF-β_1, TNFα and IFN-γ1b. RNA was isolated from the placental biopsies, and serum and EDTA plasma were obtained from placental and maternal blood samples. Cord blood was used for HLA-G genotyping. HLA-G expression level was analyzed by flow cytometry, ELISA and digital droplet PCR. The mRNA isoform profile was analyzed using reverse transcription PCR and fragment analysis.
Main results and the role of chance: Peripheral and placental sHLA-G levels were not correlated. Cases with PE showed lower levels of peripheral sHLA-G, while no difference between groups was observed in placental sHLA-G levels. The expression pattern of the HLA-G mRNA isoforms were G1>G3=G2/4>G5=G6 for both the JEG-3 cell line and the placental biopsies. *In vitro* analysis showed that IL-2, IL-6 and TNF-α decreased expression of HLA-G, while IFN-γ upregulated its expression in JEG-3 cells. Interestingly, stimulation of JEG-3 with IL-10 changed the isoform profile, leading to an almost two-fold increase of the level of HLA-G1 over HLA-G2/4 and -G3 transcripts compared to the control. No differences in the isoform profile were observed between placental biopsies from uncomplicated pregnancies and PE placental biopsies, although cases of PE did have lower levels of HLA-G1. In ongoing analyses we are comparing the cytokine and hormone profile in the two patient groups and will correlate it to the level of HLA-G. Cell assays analyzing the effect of cytokine and hormone cocktails will be studied to evaluate the direct effect on HLA-G regulation.
Limitations, reasons for caution: As the JEG-3 cell line only represents an *in vitro* model for human trophoblast cells, it might not reflect *in vivo* settings. Also, cytokines co-exist within the local milieu and could have synergistic, antagonistic or indirect effects mediated through regulation of other immune factors on HLA-G expression *in vivo*.
Wider implications of the findings: This study provides a possible link between the increased levels of anti-inflammatory cytokines and reduced levels of sHLA-G. This could prove to be important for both early establishment of pregnancy and pregnancy complications such as PE. Also, systemic rather than placental inflammation might be involved in the manifestation of PE.
Trial registration number: not applicable

P-382 Evaluation of endometrial expression of cell adhesion genes in recurrent implantation failure (RIF) patients

A. Pathare[1], I. Hinduja[2]

[1]P. D. Hinduja Hospital and Medical Research centre, Department of IVF and Research, Mumbai, India ;
[2]P. D. Hinduja Hospital and Medical Research centre, Department of IVF, Mumbai, India

Study question: Does the endometrium of recurrent implantation failure (RIF) patients reveal differential expression of cell adhesion genes than fertile women in controlled ovarian stimulation (COS) cycle.
Summary answer: Out of seven cell adhesion genes evaluated in the study, five showed significant differential expression in endometrium of RIF patients than fertile women under COS.
What is known already: The cell adhesion molecules expressed by endometrium during window of implantation are proven to be important for endometrial receptivity. Based on our previously published whole genome microarray study, genes like CD300A, Cadherin-3 (CDH3), Cartilage Oligomeric Matrix Protein (COMP), Hyaluronan Binding Protein 2 (HABP2), Collagen Type XXII Alpha 1 Chain (COL22A1), Thrombospondin 1 (THBS1), Microfibril Associated Protein 4 (MFAP4) were associated with cell adhesion as one of the most significant biological functions among RIF patients during COS. Thus, it is worthwhile to study their expression in larger cohort of RIF patients under COS.
Study design, size, duration: Case-control study included RIF patients (n=25, cases) and healthy fertile oocyte donors (n=25, controls), both undergoing COS. The endometrial tissues were collected in the period of 2016-2019.
Participants/materials, setting, methods: Endometrial tissue was collected from cases and controls on Human chorionic gonadotropin (HCG)+7th day during COS. RNA extracted from tissue was converted to cDNA which was further subjected to real time PCR to study 'gene expression' by SYBR green chemistry. The differential expression of genes 'CD300A, CDH3, COMP, HABP2, COL22A1, THBS1, MFAP4' in cases were calculated by delta-delta-CT method, using fold change (FC) as parameter. Level of significance was determined using Mann-Whitney T test.
Main results and the role of chance: CDH3 (P=<0.0001, FC:-2.81), COMP (P=<0.0001, FC:-6.46), HABP2 (P=0.026, FC:-2.00), THBS1 (P=0.0238, FC:-1.70), MFP4 (P=0.0350, FC:-1.88) genes majorly involved in functions of cell adhesion like extracellular matrix organization, adhesion junctions in endometrium epithelium were observed to be significantly down-regulated with fold change > 2 in 'cases' compared to 'controls'
Limitations, reasons for caution: The study was performed in COS cycle, to rule out the hormonal bias. Therefore, the data cannot be generalized to overall cohort of RIF patients. Also, due to modest sample size of the study, it is necessary to be substantiated in larger population of RIF patients.
Wider implications of the findings: Down-regulation of cell adhesion panels in RIF patients indicate the impairment in endometrial receptivity which possibly contributes to repeated failure of implantation. On validating these markers in larger cohort of RIF patients, the panel can be implemented for assessment of endometrial receptivity to evaluate cell adhesion function in endometrium.
Trial registration number: Not applicable

P-383 Circulating miRNome during the implantation window as a non-invasive diagnostic tool to predict successful IVF/ICSI cycle

C. Baron[1], D. Haouzi[1], F. Entezami[2], S. Brouillet[3], S. Hamamah[3]

[1]Inserm U1203, IRMB- Hôpital St-Eloi- CHU Montpellier, Montpellier, France ; [2]American Hospital of Paris, IVF department, Neuilly-Sur-Seine, France ; [3]Arnaud de Villeneuve Hospital- CHU Montpellier, ART/PGD Department, Montpellier, France

Study question: Do circulating miRNAs profile during the implantation window under the same HRT treatment for frozen embryo replacement cycle, predict successful pregnancy ?

Summary answer: We identified a miRNA signature in serum during the implantation window that can predict successful pregnancy.

What is known already: The development of non-invasive tests predicting the pregnancy outcomes remains a challenge in assisted reproductive technology (ART). However, to date, very few studies analyzed the miRNome in bloodstream during the implantation window to identify potential circulating biomarkers related to the pregnancy outcomes.

Study design, size, duration: Serum (n=14) were collected during the implantation window from RIF patients (mean ± SD, age: 38.6 ± 5.0 years) under hormone replacement therapy (HRT) treatment for subsequent frozen embryo transfer. RNAs were extracted to perform the miRNA expression profile. Then, miRNA expression was analyzed according to the following pregnancy outcome: successful implantation (n=7) or implantation failure (n=7). Successful implantation was defined as both positive b-hCG and clinical pregnancy and implantation failure as negative b-hCG.

Participants/materials, setting, methods: Serum were obtained during a mock HRT treatment cycle from 14 repeated implantation failure (RIF) patients. Then, miRNA expression profile between groups, successful *vs*. implantation failure after frozen embryo replacement was evaluated by NGS using the HTG EdgeSeq miRNA Whole Transcriptome Assay (Illumina, Firalis). miRNA sequencing data were normalized using the method recommended by HTG molecular diagnostic. Then, statistical analysis and receiver operating characteristic (ROC) analysis were applied to miRNA sequencing data.

Main results and the role of chance: We identified 44 miRNAs differentially expressed between groups with a fold change > 2 and a P-value < 0.05. All miRNAs were overexpressed in serum from patients with successful implantation. *Supervised hierarchical clustering of these 44 miRNAs showed a good segregation of serum samples from patients with and without a successful implantation. related to these 44 miRNAs, we note four of them which are members of the let-7 family [*miR-1 (x2.4, p = 0.017, AUC = 0.88), miR-2 (x2.2, p = 0.004, AUC = 0.94), miR-3 (x2.1, p = 0.001, AUC = 0.90), miR-4 (x2.1, p = 0.001, AUC = 0.98)]. The microRNA target filter function from Ingenuity software predicted that 1375 mRNAs were targeted by the let-7 family that are involved in cell invasion, proliferation, growth and survival via integrin subunit beta 3 (*ITGB3*), vimentin (*VIM*), B-cell CLL/lymphoma 2 like 1 (*BCL2L1*) that play a central role in endometrial receptivity acquisition and implantation process. These results might have potential clinical applications to develop a non-invasive diagnostic tool to predict successful implantation, to avoid endometrium biopsy and consequently, to increase IVF/ICSI success.

Limitations, reasons for caution: Further investigations with a larger number of patients are in progress to validate theses results.

Wider implications of the findings: Circulating miRNAs profile of the implantation windows during a cycle preceding frozen embryo transfer cycle can predict the successful implantation. This information is crucial and can lead to the development a prognostic tool of the attempt, opening new perspectives in the patient care management.

Trial registration number: ID: NCT04192396

P-384 Four-fold increase in live birth rate: proof of the benefits of window of implantation testing in RIF patients by a prospective multicenter trial

F. Entezami[1,2], D. Haouzi[2,3], A. Ferrières-Hoa[2,3], C. Vincens[3], S. Bringer-Deutsch[3], E. Vintejoux[3], S. Hamamah[2,3]

[1]American Hospital of Paris, IVF, Neuilly sur Seine, France ; [2]Université Montpellier- CHU Montpellier- Hôpital Saint Eloi, Inserm U1203-, Montpellier, France ; [3]Arnaud de Villeneuve Hospital- CHU Montpellier, ART-PGD department, Montpellier, France

Study question: What outcome benefits are expected in RIF patients after customized embryo transfer based upon identification of endometrial receptivity window by transcriptomic approach.

Summary answer: Customized embryo transfer according to window of implantation testing improves pregnancy and birth outcomes for RIF patients.

What is known already: A receptive endometrium is mandatory for successful implantation of a competent embryo. For years, endometrial receptivity assessment was established by indirect methods and several non-invasive approaches have been reported with controversial results and poor predictive value. Transcriptomic and proteomic approaches have also been used to define molecular signatures and identify specific biomarkers of human endometrial receptivity. We previously identified a set of genes as biomarkers of endometrial receptivity and developed an innovative test based on quantification by RT-qPCR of these biomarkers in endometrium biopsies and tested its relevance in fertile patient.

Study design, size, duration: Endometrial biopsies were performed during the implantation window 7-9 days after the LH surgein natural cycle or 5-9 days after progesterone administration under HRTrespectively. According to transcriptomic testing result in the subsequent frozen embryo transfer cycle (FRET), blastocysts were transferred at the specific day where endometrium was identified as receptive and cleavage stageD2/D3 embryos were transferred72/48 hours before the specific cycle day where endometrium was identified as receptive.

Participants/materials, setting, methods: During 2015-2018 a total of 217 RIF patients (4.4±1.9 failed fresh/frozen transfers of 6.4±3.6 embryos) were enrolled. Genomic testing of endometrial biopsies was performed under natural/HRTcycles and mRNA expression of genes predictive of receptivity were established by RT-qPCR. Customized embryo transfer (n=157 patients) was performed in a subsequent FRET cycle based upon these results. Clinical pregnancy and live birth rates (LBR) were compared to control RIF patients with standard FRET in natural/HRT cycles (n=60 patients).

Main results and the role of chance: Customized embryo transfer using the genomic testing strategy yielded spectacular increase in outcome for 157 RIF patients (age 37.2±4.3 years). Comparison of the results between the study group and the control group showed significantly higher rates for implantation (22.7% vs 7.2%, p=0.0001), clinical pregnancy (38.8% vs 15.0%, p=0.0006), ongoing pregnancy (36.3% vs 8.3%, p=0.00002) and live birth rates (31.8% vs 8.3%, p=0.0002). Analyses of endometrial receptivity status revealed mostly a delay both in natural and HRT cycles between 1 to 3 days. Most patients achieved pregnancy after the first customized FRET (70%). Better clinical pregnancy and live birth rates were obtained with blastocyst transfer compared to cleavage stage transfers (respectively 36.3% vs 22.5% and 29.5% vs 14.0%). Whatever the day of transfer, results were significantly higher in the study group compared to the control group, with ongoing pregnancy rate for transfer of cleavage-stage embryos of 21.1% compared to 4.5% in the control group (p=0.03). In blastocyst transfer group ongoing pregnancy rate of 33.9% was significantly greater than 8.6% in the control group (p=0.003).

Limitations, reasons for caution: The benefit of this innovative strategy should be analysed with respect to the genetic status of the transferred embryos after PGT for aneuploidy.

Wider implications of the findings: In RIF patients customized embryo transfer according to endometrial transcriptomic testing improves dramatically the clinical outcome by increasing almost four-fold the LBR. In our study, the majority of RIF patients displayed a delay in their receptivity window of 1- 3 days, revealing a potential cause for their previous implantation failures.

Trial registration number: NCT04192396

P-385 Hysteroscopic endometrial peeling: a different approach to endometrial scratching

T. Alkon[1], M. Luna-Rojas[1], C. Hernandez-Nieto[1], D. Cassis-Bendeck[1], B. Sandler[1]

[1]Reproductive Medicine Associates of New York, Reproductive endocrinology and Infertility, Mexico City, Mexico

Study question: Does hysteroscopic endometrial peeling improve reproductive outcomes in women with implantation failure?
Summary answer: Women with implantation failure may benefit from intraoperative endometrial peeling prior to a frozen embryo transfer (FET).
What is known already: Trials on endometrial scratching with pipelle and diagnostic hysteroscopies in women with implantation failure have demonstrated methodological limitations and high risk of bias, making it unclear whether these procedures improve reproductive outcomes. To date, no study has described the effects of intentional endometrial lesion through hysteroscopy.
Study design, size, duration: A retrospective, cohort study included infertile patients who failed transfers of at least two good quality blastocysts. Thereafter, underwent an endometrial peeling through hysteroscopy and subsequently a blastocyst FET from January 2018 to December 2019. A sample size of 70 patients per group was calculated to be necessary to detect a 15% difference in clinical pregnancy rates with 80% power. Alpha=0.05.
Participants/materials, setting, methods: Women <40 years, with implantation failure, normal saline sonogram and, no previous uterine surgeries were segregated into two groups: A) 70 patients underwent hysteroscopic endometrial peeling, which consists on removing the superficial endometrial layer of the whole uterine cavity with hysteroscopic biopsy forceps and B) 85 controls who did not undergo surgical endometrial peeling. All patients underwent a subsequent blastocyst FET. Trophectoderm biopsy cases were excluded from the analysis.
Main results and the role of chance: In total, 155 women were included in the cohort. No differences were found in age, body mass index, baseline FSH, AMH, baseline antral follicle count, previous number of stimulation/IVF cycles, number of embryos transferred and, embryonic quality among cohorts. Evaluating the endometrium, no differences were observed in the endometrial pattern, however, a significant difference in the endometrial thickness (8.5±1.4mm vs 9.0±1.6mm, p=0.03) was noted among groups. When analyzing the subsequent FET cycle, statistical significance was observed in implantation rates (38.8% vs 16.6%, p= 0.01) and clinical pregnancy rates (65.7% vs 30.3%, p=0.0009). No difference was found in clinical loss rates (10.4% vs 17.1%, p=0.08) among Group A vs Group B respectively.

Of the patients who underwent surgical endometrial peeling, 15.7% (11/70) had the following incidental intraoperative findings: mild intrauterine and/or cervical adhesions (4/70, 0.05%), endometrial polyps (8/70, 11.4%), polypoid endometrium (6/70, 0.8%). 63.6% of the patients with incidental findings became pregnant.
Limitations, reasons for caution: This study is limited by its retrospective nature. Additionally, in patients with noted uterine pathology, appropriate surgical management was administered in the same setting, this could have biased the results. Future randomized controlled trials are needed with euploid frozen embryo transfers.
Wider implications of the findings: This study describes for the first time the clinical utility of mechanically peeling the superficial endometrial layer through hysteroscopy in women with implantation failure. Our findings suggest that surgically removing superficial endometrial tissue, promotes the generation of new receptive tissue, favoring embryo implantation.
Trial registration number: Not applicable

P-386 HCG improves pregnancy chances in embryo transfers using euploid embryos and Gestational Carriers after one implantation failure

J. Mashiach[1], A. Roumia[1], M. Dviri[2], N. Weizman[1], S. Baram[1], C. Librach[3]

[1]CreATe Fertility Center, CreATe Fertility Center, toronto, Canada ;
[2]CreATe Fertility Center, CrATe Fertility center, Toronto, Canada ;
[3]CreATe Fertiity Center- Unviversity of Toronto, Obstetrics and Gynecology, Toronto, Canada

Study question: Does intrauterine hCG improve pregnancy rate in frozen single embryo transfer of euploid embryos in Gestational Carriers (GC)?
Summary answer: After a first failed euploid single embryo transfer into a GC, intrauterine administration of hCG appears to improve the chances of subsequent implantation and pregnancy.
What is known already: Implantation is considered the "black box" in ART. Implantation is a highly regulated process that requires: receptive endometrium, functional blastocyst, and interaction between them. Human chorionic gonadotropin (hCG) is a hormone synthesized and released by the syncytiotrophoblast. It stimulates the ovarian production of progesterone during the first trimester of pregnancy. Several studies suggest that intrauterine hCG increases the pregnancy rate. The hCG may promote peritrophoblastic immune tolerance, which facilitates trophoblast invasion by inducing an increase in endometrial T-cell apoptosis. It may also support trophoblast apposition and adhesion by regulating proteins involved in implantation as well as altering endometrial secretory parameters.
Study design, size, duration: We retrospectively reviewed all single euploid frozen embryo transfers (FET) of euploid embryos into GCs at the CReATe Fertility Center between Jan 2017 and Mar 2019. Mosaic embryos were excluded. We compared the cycles in which 50 µL of hCG was introduced into the uterine cavity 10-15 min prior to embryo transfer vs. cycles where no hCG was administered. We then compared the first transfer and all transfers after a failed transfer in both groups.
Participants/materials, setting, methods: We analyzed FET cycles of Euploid embryos in GCs. The GC's underwent a pelvic US and sonohysterogram before ET. The patients received HRT for uterine preparation. hCG insertion was used in the transfer cycle at the discretion of the fertility physician.
Main results and the role of chance: First transfer

	With hCG n(%)	Without hCG n(%)	P Value
Age	26.44±4.78	27.62±4.47	.289
Endometrial thickness	10.8±2.02	10.43±2.02	.52
Morphology			.350
1	6/18 (33.3%)	29/196 (14.8%)	
2	9/18 (50%)	128/196 (65.3%)	
3	2/18 (11.1%)	28/196 (14.3%)	
Egg donation	15/18 (83.3%)	152/196 (77.6%)	.57
Adjunct therapy	18/18 (100%)	153/196 (78.1%)	<.001
Pregnancy	13/18 (72%)	132/195 (67%)	.69
Clinical Pregnancy	13/18 (72%)	119/195(61%)	.87

After at least 1 failed transfer

	With hCG n(%)	Without hCG n(%)	P Value
Age	26±3.67	27.9±4.61	.035
Endometrial thickness	10.81±2.27	9.92±2.27	.52
Morphology			.51
1	4/34 (11.7%)	16/111 (14.4%)	
2	23/34 (67.6%)	57/111 (51.3%)	
3	4/34 (11.7%)	25/111 (22.5%)	
Egg donation	30/34 (88.2%)	82/111 (73.8%)	.21
Adjunct therapy	31/34 (91.1%)	60/111 (54%)	<.0001
Pregnancy	21/34(61.7%)	59/111 (53%)	.02
Clinical pregnancy	20/34(58.8%)	44/111(40%)	.04

Using a logistic regression model, accounting for age at OPU, adjunct therapy and intrauterine hCG administration, in those with 1 or more previous failed

transfers, we observed that intrauterine hCG administration was significantly associated with the chance of achieving pregnancy (CI 1.048-6.57 p=0.039).
Limitations, reasons for caution: The retrospective nature of the study and the relatively small study size are the main limitations of this study.
Wider implications of the findings: In our model of euploid embryos in "proven" uteri of GCs, we can investigate implantation in the most optimal clinical setting possible. When implantation of a euploid embryo fails (i.e failed first transfer), intrauterine administration of hCG appears to increase the chance for pregnancy.
Trial registration number: n/a

P-387 Endometrial receptivity - Is it possible to make the "old" research methods more informative?

I. Gyulmamedova[1], T. Zadorozhna[2], T. Tatarchuk[3], O. Girina[4], N. Vladykina[4], M. Sokolova[5], O. Gyulmamedova[6], V. Sosnina[7], O. Nosenko[8]

[7]Medical Center IPF, -ivf-, Kyiv-, Ukraine ;
[8]Odessa National Medical University, Department of Obstetrics and Gynecology, Odessa, Ukraine

Study question: Is the proposed examining technology of endometrium receptivity informative in women with Recurrent Implantation Failure (RIF)?
Summary answer: The complex application of the morphological, immunohistochemical methods, scanning electron microscopy is informative and effective for the diagnosis of endometrial receptivity in women with RIF.
What is known already: Single competent blastocyst transfer in maximum endometrium receptivity is the key goal for reproductive medicine. Knowledge of the implantation window (IW, is especially important in patients with recurrent implantation failure (RIF). Significant efforts are focused on the search and implementation of non-invasive endometrial receptivity biomarkers - proteomics and lipidomics in intrauterine fluid in the cycle of embryo transfer (ET). Gene-array methods are used to analyze the global gene profile of endometrial cells. However, in the daily work, morphological research and endometrium dating, as well as scanning electron microscopy (SEM), continue to be of clinical interest due to their availability.
Study design, size, duration: During 2010-2019 In 77 patients with RIF on the 7-10th day of the menstrual cycle, an endometrial biopsy / hysteroscopy was performed. A morphological , immunohistochemical (CD-138) study was performed; After correction of the revealed disorders, in the following cycles, the endometrial biopsy was obtained at P+6; P+8 or P + 7; P + 9 day of exposure to progesterone. A morphological study (MS) and SEM were carried out. Descriptive statistics methods used.
Participants/materials, setting, methods: The age of the patients - 34.8± 0.59,, the duration of infertility 8.48 ± 0.64 , the number of IVF attempts 3,11 ± 0.19. According to the results of MS, patients were divided: **Gr1** - 13 (16,88%) - the endometrium without morphological abnormalities.**Gr2** - Chronic endometritis with micro- macropolyposis, confirmed by CD 138 – 19 (24, 68 %); **Gr3** - Stromal fibrosis, endometrial hypoplasia - 29 (37,66%).**Gr4**- dyschronosis of glands and stroma - 16 (20,78%)
Main results and the role of chance: Not informative results (NIR), repeated biopsy (RB) at a later date after additional treatment : Gr 2 - 6 (31,58 %) , Gr3 - 3 (10,34%); Gr 4 - 2 (11.1%)**The reason NIR**: Dense film, an abundance of red blood cells, absence pinopodia - P + 6; P + 8; Gr1 - no indication for a RB (P1-2<0.02). In all 11 patients with RB, temporary trends in the formation of pinopodia persisted **Few pinopodia:** Cr1 - 1 (7,69%) , Gr 2 - 12 (63,16%); Gr 3- 16 (59%), Gr 4 – 6 (37,5%) patients (P <0.04;1-2,1-3,1-4) **Dyschronosis of the development of pinopodia**: 1 (7,69 %), 2 (10,53%), 3 (11,11%), 14 (87,5 %) respectively (P 1-4 <0.001) **The lag of the formation of pinopodia** for 2 or more days: 8 (61,54%) , 13 (68,42%) , 19 (65,52%), 5 (31,25%) respectively (P> 0.05; 1-2,1-3.1-4). ***Lack of regression, polymorphism of microvilli;*** *Gr 1 -0; Gr 2* - 2 (10,53%) ; Gr 3 - 7 (25,00%) , Gr 4 – 9 (56,25%) *(* P 1-3 <0.03; P 1-4 <0.001).After correction of the revealed disorders in women with RIF– ET according to the implantation window was performed pregnancy rate - 48 (62,34 %)
Limitations, reasons for caution: Gr1 the main reason of RIF is the peculiarity of IW, expected to have a high clinical effect using genetic methods. Gr 2, Gr3 clinical efficacy depends not only on IW, but also deviations in the structure of the endometrium. Gr1 -dyschronosis is the most complex and needs further research.
Wider implications of the findings: The proposed examining technology of endometrium receptivity helps to obtain pregnancy in complex category of patients with RIF. The proposed examining technology remains an informative, reproducible, accessible method. The technology help determine the indications for molecular genetic studies of the endometrium and interpret the results
Trial registration number: not applicable

P-388 Significance of invasion of decidualized endometrial stromal cells by human embryonic stem cells derived trophoblastic spheroids (BAP-EB) in pregnancy outcomes of in vitro fertilization (IVF)

Y.L. Lee[1,2], S.W. Fong[1], K.C. Lee[1], A.C.H. Chen[1,2], K.F. Lee[1,2], W.S.B. Yeung[1,2], E.H.Y. Ng[1,2]

[1]The University of Hong Kong, Obstetrics and Gynaecology, Hong Kong, Hong Kong ;
[2]The University of Hong Kong Shenzhen Hospital, Shenzhen Key Laboratory of Fertility Regulation, Shenzhen, China

Study question: Does invasion of decidualized endometrial stromal cells (hEnSC) towards trophoblast-like BAP-EB relate to IVF pregnancy outcome?
Summary answer: The invasion of decidualized hEnSC from patients with a live birth towards BAP-EB was significantly higher than those with negative pregnancy outcome.
What is known already: The success rate of IVF remains low even after the transfer of good quality embryos. Implantation-competent blastocysts can induce migration of decidualizing hEnSC. The encapsulation of the invading blastocyst by the decidua supports subsequent trophoblast invasion. The study of the dynamic fetal–maternal interaction between the decidua and the implanting blastocyst requires a proper implantation model. We have derived trophoblastic spheroids (BAP-EB) from human embryonic stem cells that resemble human trophectoderm and trophoblast during early implantation process. They attach specifically onto receptive endometrial epithelial cells. BAP-EB can be used as human embryo surrogate for studying the early implantation process.
Study design, size, duration: hEnSC were isolated from endometrial biopsies obtained from IVF patients in their natural cycle 7 days after luteinizing hormone surge (LH+7). Human embryonic stem cells were differentiated into early trophectoderm-like BAP-EB-48h or trophoblast-like BAP-EB-96h. An invasion assay using Matrigel Invasion Chamber was established with decidualized hEnSC and BAP-EB-48h or -96h. hEnSC isolated from patients with live births (n=5) and negative pregnancy outcomes (n=5) in their subsequent stimulated IVF cycle were compared.
Participants/materials, setting, methods: Human endometrial stromal cell line (T-HESC) was induced to decidualize in vitro. Purity of primary hEnSC was confirmed by immunohistochemical staining of stromal (Vimentin) and epithelial (cytokeratin) markers. The 24h-invasion of decidualized hEnSC through Matrigel towards trophectoderm-like BAP-EB-48h or trophoblast-like BAP-EB-96h was compared to medium alone control. The expression levels of decidualization markers (PRL, IGFBP1) and the invasion ability towards BAP-EB were compared between hEnSC isolated from patients with live births and negative pregnancy outcomes.
Main results and the role of chance: After treatment with cAMP for 3, 6 and 9 days, the decidualization markers PRL and IGFBP1 were significantly induced from day 6 onwards. The isolated primary hEnSC were of high purity as demonstrated by positive vimentin staining (>95%) but not cytokeratin staining. The invasion of hEnSC through Matrigel towards medium alone without BAP-EB, BAP-EB-48h or BAP-EB-96h was quantified by the absorbance of crystal violet stained cells. It was found that significantly more hEnSC invaded towards BAP-EB-96h than BAP-EB-48h when compared to medium alone control, suggesting the specific invasion of hEnSC towards the trophoblast-like but not the trophectoderm-like BAP-EB. The decidualization and invasion abilities of hEnSC

isolated from patients with live births and negative pregnancy outcomes were compared. The expression levels of PRL and IGFBP1 were similar in the two groups of patients 6 days after in vitro induction of decidualization (p>0.05). The invasion of hEnSC through Matrigel in the presence or absence of BAP-EB-96h was measured. Interestingly, the percentage of BAP-EB-96h-induced invasion was significantly higher in hEnSC from patients with live births (54.3% ±11.1%) than those with negative pregnancy outcomes (20.8%±9.1%, p<0.05). The data indicated a correlation of responsiveness of hEnSC towards BAP-EB with pregnancy outcome.

Limitations, reasons for caution: BAP-EB and the isolated endometrial stromal cells may not fully represent the in vivo developed human blastocysts and endometrial cells, respectively. The in vitro nature of the hEnSC experiments and the limited sample size in this study may also limit the interpretation of the data.

Wider implications of the findings: The study of early implantation failure is limited by the number and the ethical concerns of human embryos donated for research. The current data demonstrated the potential use of BAP-EB as human embryo surrogate for assessing the responsiveness of hEnSC towards implanting embryos and as predictive tool for pregnancy outcome.

Trial registration number: nil

P-389 Maternal germline factors associated with aneuploid pregnancy loss: a systematic review.

U. Blyth[1], L. Craciunas[2], M. Choudhary[3]

[1]Newcastle upon Tyne Hospitals NHS Foundation Trust, Academic Foundation Programme, Newcastle upon Tyne, United Kingdom ;

[2]Newcastle upon Tyne Hospitals NHS Foundation Trust, Obstetrics and Gynaecology, Newcastle upon Tyne, United Kingdom ;

[3]Fertility Centre at Life- Newcastle upon Tyne Hospitals NHS Trust- Biomedicine West Wing- Newcastle upon Tyne- NE1 4EP- UK, Reproductive Medicine, Newcastule upon Tyne, United Kingdom

Study question: Which maternal germline factors have been associated with pregnancy loss secondary to numerical chromosome abnormalities of the embryo?

Summary answer: A range of maternal germline factors such as insertions, deletions, translocations, copy number variants or single gene mutations have been associated with aneuploid pregnancy loss.

What is known already: Miscarriage describes the spontaneous loss of pregnancy before the threshold of viability; the vast majority occur before 12 weeks of gestation. Miscarriage affects 1 in 4 couples and is the most common complication of pregnancy. Chromosomal abnormalities of the embryo are identified in approximately 50% of first trimester miscarriages; aneuploidy accounts for 86% of these cases.

The majority of trisomic miscarriages are of maternal origin with errors during meiotic division of the oocytes. Chromosome segregation errors in oocytes may be sporadic events secondary to advancing maternal age; however, there is increasing evidence to suggest possible maternal germline contributions to this.

Study design, size, duration: A systematic review of the literature was conducted to identify maternal germline factors associated with pregnancy loss secondary to numerical chromosome abnormalities of the embryo. The literature search was run in September 2019 using the electronic databases: OVID MEDLINE, EMBASE and the Cochrane Library. No time or language restrictions were applied to the searches, only primary research was included. The review protocol was registered with PROSPERO (CRD42019153653) following PRISMA guidelines.

Participants/materials, setting, methods: Participants were women who had suffered pregnancy loss secondary to numerical abnormalities of the embryo. Study identification and subsequent data extraction was performed by two authors independently and in duplicate. The Newcastle-Ottawa Scale was used to judge included studies on three broad perspectives: the selection of study groups; the comparability of the groups; and the ascertainment of either the exposure or outcome of interest for case-control or cohort studies respectively. The results were synthesised narratively.

Main results and the role of chance: The literature search identified 2639 titles, out of which 54 were eligible for inclusion in this systematic review. They reported on maternal germline factors having variable degrees of association with pregnancy loss of aneuploid origin. The AmiGO gene ontology database was used as a reference to establish the functional role currently attributed to the genes reported.

Structural factors inherited from mothers directly by embryos were the majority of the cases reported and included: Robertsonian translocations, deletions and insertions. Cases of maternal mosaicism leading to aneuploidy in the embryo included: trisomy 9 and duplication of chromosome 4p. Several of these cases were identified using FISH in addition to traditional karyotyping techniques.

Germline factors with a plausible role in aneuploid pregnancy loss of maternal origin included: skewed X-inactivation and FMR1 repeats.

Studies that reported the association of single gene mutations with aneuploid pregnancy loss were conflicting. Single gene mutations with an uncertain role in aneuploid pregnancy loss included: SYCP3 and MTHFR. Both genes have an established role in cell division in animal models however the research in humans is inconclusive.

One study reported an association of a single gene mutation of NLRP7 in women with recurrent molar pregnancies.

Limitations, reasons for caution: Whilst this review was based on a broad systematic search of the literature most studies identified were case reports: only a fraction were cohort studies of moderate quality. The role of paternal germline factors in aneuploid pregnancy loss was not addressed in this systematic review and warrants future research.

Wider implications of the findings: Identifying maternal genetic factors associated with an increased risk of aneuploidy will expand our understanding of cell division, nondisjunction and miscarriage secondary to embryo aneuploidy.

The candidate germline factors identified may be incorporated in a screening panel for women suffering miscarriage of aneuploidy aetiology to facilitate counselling for subsequent pregnancies.

Trial registration number: PROSPERO registration number CRD42019153653

P-390 Pattern of early beta human chorionic gonadotropin (β-hCG) in intracytoplasmic sperm injection (ICSI) for pregestational testing for monogenic disorders (ICSI/ PGT-M) versus ICSI only cycles

N. Samara[1], E. Haikin-Herzberger[1], A. Dick[1], H. Amir[1], A. Reches[1], M. Malcov[1], D. Ben Yosef[1], F. Azem[1]

[1]lis maternirty hospital- Sourasky medical center.affiliated with the Sackler Fac, Wolf PGD Stem Cell Lab- Racine IVF Unit, Tel Aviv, Israel

Study question: Is there a difference in β-hCG pattern in pregnancies achieved following ICSI/PGT-M versus ICSI?

Summary answer: A comparable pattern of early β-hCG rise were observed in ICSI/PGT-M cycles compared with ICSI only.

What is known already: Initial serum β-hCG level is used to confirm pregnancy following IVF, scheduled follow-up testing is accepted to reassure normal progression and prediction of outcome. β-hCG levels and pattern of increase are well correlated with pregnancy outcome. In our unit, fertilization in PGT-M cycles is routinely achieved by ICSI, to avoid sperm contamination of analysis result. On day 3 or 5, embryonic biopsy is performed for genetic analysis, which might affect syncytiotrophoblast secretion of β-hCG. Our aim was to assess early β-hCG rise in ICSI/PGT-M compared to ICSI cycles in order to evaluate possible effect of biopsy on early β-hCG rise

Study design, size, duration: This retrospective cohort study was performed at a tertiary university-affiliated medical center. It included patients with single embryo transfer, from ICS/PGT-M and ICSI only cycles, performed in our IVF unit between June 2017 and September 2018. Both fresh and frozen embryo transfer (FET) cycles were included. A total of 163 cycles with a positive β-hCG result were available for analysis, of which 85 of ICSI/PGT-M and 78 of ICSI

Participants/materials, setting, methods: In ICSI/PGT-M cycles embryo biopsy took place on day 3 or 5 according to genetic analysis method, control group included patients undergoing ICSI during same period. First β-hCG was timed on day 10-12 according to transfer day and second test was usually taken two days later. In order to adjust for different period of time between the two tests and for the none-linear elevation of Beta-HCG we used a calculated parameter - ln (Delta-Beta-HCG/period).

Main results and the role of chance: The two groups were comparable with respect to age, BMI and parity. Gravidity was significantly higher in the ICSI/PGT-M than in ICSI group (2.0±1.8 vs.0.8±1.1, p<0.01). In the majority of PGT-M cycles embryos were transferred on day 5 and none were transferred on day 3, compared to ICSI cycles in which the majority of embryos were transferred on day 3, in ICSI/PGT-M cycles some embryo were transferred on day 4 shortly after receiving genetic analysis results (61.9% vs 33.8% for day 5-6, 38.1% vs 1.3% for day 4 and 0% vs. 64/9% for day 2-3, p<0.01). Once β-hCG was positive, the clinical pregnancy rates were 98.2% in the ICSI/PGT-M group compared to 92.2% in the ICSI group. Similarly, live birth rates (65.8% in the PGT-M vs. 72%% in ICSI) were not significantly different. Differences between serum β-hCG levels were not statistically significant between two groups in both first and second tests, neither when comparing the ln(delta-β-hCG/period). After adjustments for age, number of previous pregnancies, fresh vs. frozen and embryo day of transfer, ln(delta-Beta-hCG/period) was still comparable between ICSI/ PGT-M group and ICSI group.

Limitations, reasons for caution: Our study is a retrospective one, with potential biases inherent to its design. In some cases, lag time between first and second β-hCG levels was not constant due to scheduling constraints.

Wider implications of the findings: Our study shows no difference in the early pattern of serum β-hCG levels between ICSI/PGT-M cycles and ICSI cycles. It reassures that embryo biopsy for ICSI/PGT-M, taken at day 3 or 5 in both fresh and frozen cycles, does not affect early β-hCG rise, correlated with pregnancy outcome.

Trial registration number: not applicable

P-391 Pregnancy viability in relation to demographic and repeated sonographic and serum biomarkers

J.F. Petersen[1], L. Friis-Hansen[2], T. Bryndorf[3], A.K. Jensen[4], A. Nyboe Andersen[5], E. Løkkegaard[1]

[1]North Zealand Hospital, Obstetrics and gynecology, HIllerød, Denmark ; [2]North Zealand Hospital, Clinical Biochemistry, Hillerød, Denmark ; [3]Private Practice, Gynecological clinic, Copenhagen, Denmark ; [4]Institute of Public Health- University of Copenhagen, Section of Biostatistics, Copenhagen, Denmark ; [5]Rigshospitalet, The Fertility Clinic, Copenhagen, Denmark

Study question: Which individual and combined variables of demography, transvaginal sonography and serum markers are the best dynamic predictors of viability in the first trimester?

Summary answer: Combined maternal age, hCG, crown-rumP-length and bleeding data was the best model to dynamically predict miscarriage, closely followed by maternal age, hCG, estradiol and bleeding

What is known already: Early pregnancy losses are common and about 25% of recognized pregnancies end in a miscarriage. More precise prediction of miscarriage could potentially alleviate the anxiety of couples experiencing symptoms but remains challenging. The diagnosis often depends on the development of ultrasonic or biochemical evidence. Maternal age is the principal risk factor and the current tendency towards delayed childbearing leads to an increased incidence of clinical visits for viability reassurance. Early pregnancy diagnostics is usually based on retrospective demographic, ultrasonic or biochemical data. Potentially, all three sources prospectively combined carries an increased accuracy compared with any one-parameter diagnostics

Study design, size, duration: A prospective cohort of pregnant women with asymptomatic and assumed healthy pregnancies of no more than 55 days' gestation was recruited and followed from June 2016 to March 2017 at two University Hospitals in Copenhagen, Denmark. Participants had repeated visits every second week from 4–14 weeks' gestation until either miscarriage or confirmed viability at the end of the first trimester. The study population included 203 women with 715 visits

Participants/materials, setting, methods: Before inclusion, participants and male partners completed a validated questionnaire for baseline demographic data. At each visit, a panel of 29 commonly used blood-samples, transvaginal sonography and symptoms of miscarriage was recorded. Based on updated values, unadjusted hazard ratios (HR) identified the eight most influential biomarkers on the risk of miscarriage. Testing these in adjusted groups of three, 56 different combinations were evaluated for their ability to individually and dynamically predict viability at each visit

Main results and the role of chance: From adjusted odds ratios (aOR) of demographic factors, older (aOR 1.2, 95%CI [1.1; 1.3], p < 0.01) or obese (>35kg/m^2) women (aOR 3.4, 95%CI [1.1; 10], p = 0.03) had increased risks of miscarriage. Risk was reduced after having previously delivered >2 babies (aOR 0.1, 95% CI [0.01; 0.6], p = 0.02). Regarding the serially collected data, maternal age remained a risk factor for miscarriage especially in women aged ≥35 years (HR 2.6, 95%CI [1.2–5.6]). Ultrasonical alterations in crown-rumP-length, mean gestational sac diameter or presence of bleeding were also important (HR 0.76, 95%CI [0.69–0.82], HR 0.72, 95%CI [0.64–0.79] and HR 1.13, 95%CI [1.03–1.27], respectively). Biochemically, serum hCG, progesterone and estradiol, respectively showed the most distinct effect with hazard ratios of 0.36, 95%CI [0.26–0.48], 0.76, 95%CI [0.75–0.77]and 0.80, 95%CI [0.75–0.84], respectively. From the tested 56 different combinations, a model including maternal age (>35 years or not), bleeding (yes/no), CRL (mm) and hCG (U/L) data was the best to predict miscarriage (WAIC score 3118, differences were evaluated by the statistical Watanabe-Akaike information criterion (WAIC)). The best combination without sonographic data (WAIC 3424) was the combination of maternal age, bleeding, hCG and estradiol

Limitations, reasons for caution: Fetal karyotype was unavailable due to logistics and heart rate frequency was not measured due to risk of doppler heat-induced damage. Because of the demands of serial data collection, the sample size was too small for other estimates than the WAIC for the quality of prediction in each model

Wider implications of the findings: Reassuring, the widely applied approach of combining hCG, CRL and bleeding data for early pregnancy outcome turned out to be the best. However, without sonography the best model had nearly the same ability. Future trials might explore this combination in women with pregnancies <7 weeks' gestation or unknown location

Trial registration number: NCT02761772

P-392 Extracellular vesicles: an important biomarker in recurrent pregnancy loss?

N. Rajaratnam[1], N.E. Ditlevsen[2], M.M. Jørgensen[3], O.B. Christiansen[4]

[1]Aalborg University Hospital, Emergency- and Trauma Center, Aalborg, Denmark ; [2]Region Hospital North, Emergency Department, Hjoerring, Denmark ; [3]Aalborg University Hospital- The Faculty of Medicine, Clinical Immunology and Clinical Diagnostics, Aalborg, Denmark ; [4]Aalborg University Hospital- The Faculty of Medicine, Obstetrics and Gynaecology, Aalborg, Denmark

Study question: Can different types of extracellular vesicles (EVs) markers be used as predictive markers of pregnancy outcome in recurrent pregnancy loss (RPL) patients?

Summary answer: Although tendencies were found, there were no significant differences in the progression of EV levels throughout pregnancy between RPL patients with live birth or miscarriage.

What is known already: RPL defined as ≥ 3 miscarriages has an estimated incidence of 1-3% in all couples. The etiology of RPL is considered to be multifactorial. EVs are small particles secreted into plasma that take part in numerous physiological processes and their contents provide information about the originating cell and pathophysiological states in different diseases. In pregnancy disorders, changes can be seen in the composition, bioactivity and concentration of placental and non-placental EVs. So far no laboratory test has a good diagnostic value in predicting new pregnancy loss in RPL patients.

Study design, size, duration: Prospective cohort study performed at a tertiary university-affiliated centre for RPL from the period July 2018-June 2019. The study includes 26 pregnant RPL patients, n=20 with live birth (LB) and n=6 with a new miscarriage (MI). Within these groups 4 patients in the MI group received intravenous immunoglobulin (IVIG) as treatment, and 8 in the LB group. The decision to provide IVIG was mainly made on the basis of a high number of previous miscarriages.

Participants/materials, setting, methods: Up to 5 blood samples were obtained from each patient: 1 baseline before pregnancy and 1-4 during pregnancy in gestational week 6, 8, 10 and 16. The samples were analyzed for EV type and concentration with EV Array, a method able to capture EVs by using an antibody panel targeting membrane proteins. 32 different markers were

analyzed specific for immunology/inflammation, coagulation, hypoxia, placenta and hormones.
Main results and the role of chance: The analysis showed that within the LB group (n=20, IVIG n=8, no IVIG n=12) there was a statistically significant (from $p < 0.01$ to $p < 0.0001$) increase in 47 % of the EV subtypes in the group receiving IVIG, between the sample taken before pregnancy and IVIG treatment and the sample taken at gestational week 6 after initiation of IVIG. Regarding pregnancy outcome, several graphs were made with median values for the LB group compared with graphs for each of the 6 miscarried pregnancies, These showed clear tendencies towards different progressions of the EVs positive for markers CD9, CD81, Annexin V (general EV markers), CAXII (hypoxia marker), FSHR, LHR (hormone receptors), TRAIL (immunological marker) and PLAP (placental marker). One patient with miscarriage of a normal but severely growth-restricted fetus in gestational week 21 already exhibited a marked decline of almost all EV subtypes from week 12.
Limitations, reasons for caution: A limitation is the small study size. It is unclear which changes in EV levels are induced by the growing, and in some cases probably ischemic placenta and which are exclusively due to the IVIG administration.
Wider implications of the findings: This is the first study of EVs in pregnancies of RPL patients.In a larger study it will be possible to investigate whether the clear tendencies for different progressions of EV subtypes during pregnancies with successful and unsuccessful outcomes still applies and whether it can be used as a prognostic biomarker.
Trial registration number: Ethics committee approval number: N-20180025

P-393 Relationship between the percentage of endometrial senescent cells and uterine natural killers (uNK) cells during the mid-luteal phase in women with recurrent pregnancy failure

D. Parvanov[1], R. Ganeva[1], N. Vidolova[1], G. Stamenov[2]

[1]Nadezhda Women's Health Hospital, Research, Sofia, Bulgaria ;
[2]Nadezhda Women's Health Hospital, Obstetrics and Gynecology, Sofia, Bulgaria

Study question: Is there an association between the presence of $p16^{INK4a}$-positive cells in different endometrial compartments and CD56+ uNK cells during the mid-luteal phase in RIF patients?
Summary answer: The percentage of endometrial stromal $p16^{INK4a}$-positive cells positively correlates with the abundance of CD56+ uNK cells in RIF women during the mid-luteal phase.
What is known already: $P16^{INK4a}$ is commonly measured in order to assess the level of senescence in the human endometrial tissue. Recent studies have shown that p16-positive senescent cells are involved in endometrial receptivity and in the acute cellular remodelling during the embryo implantation period. Recognition and elimination of these senescent cells by immune cells, especially CD56+ uNK cells, play an essential role in tissue repair and homeostasis. However, data about the association between the abundance of senescent cells and uNK cells in human endometrium is still scarce.
Study design, size, duration: This is an observational study of 92 women with recurrent implantation failure (RIF) who had an endometrial biopsy during the mid-lutheal phase. We used immunohistochemical (IHC) markers, p16 and CD56, in order to analyze the association between senescent cells and uNK in human endometrium.
Participants/materials, setting, methods: Our study was performed at Nadezhda Women's Health Hospital, Bulgaria. Patient biopsies with known pregnancy outcome were retrieved from our tissue bank. Tissue sections were stained immunohistochemically for CD56 (a uNK-specific cell surface antigen) using CD56 antibody (E-AB-62136, Elabscience, USA), or p16 senescent biomarker using $p16^{ink4a}$ antibody (Master Diagnostica, Granada, Spain). The percentage of positively stained cells was calculated after enumeration by two independent investigators in multiple endometrial sections.
Main results and the role of chance: The percentage of p16-positive cells in the endometrial stroma during the mid-luteal phase in the studied group of patients ranged between 0.03% and 6.73%, while it varied between 0.06% and 42.79% in the glands, and between 1.05% and 88.90% in the luminal epithelium. CD56-positive uNK cells were found only in the stroma and their abundance ranged between 0.01% and 34.17%.

No correlation was found between the frequencies of occurrence of senescent p16+ glandular and luminal epithelial cells and CD56+ cells ($p>0.05$). In contrast, the abundance of p16+ stromal cells showed low, but a significant correlation with the percentage of CD56+ stromal cells ($R=0.28$; $p<0.01$).
Limitations, reasons for caution: The study was limited in sample size.
Wider implications of the findings: Increased cell senescence in endometrial stroma during the mid-luteal phase is associated with rise in uNK cells in women with recurrent pregnancy failure. These results confirm the role of uNK cells in the selective clearance of senescent cells in the endometrium during the period of embryo implantation.
Trial registration number: NA

P-394 Aspirin and low-molecular-weight heparin combination therapy provides favorable immunomcompetent milieu to protect pregnancy in hyperhomocysteinemic women with recurrent pregnancy loss

P. Chakraborty[1], S. Chatterjee[2], D. Patra[2], S. Parvin[1], S. Kalapahar[1], R. Chattopadhyay[1], S. Ghosh[1], M. Chakraborty[1], S.N. Kabir[1], B. Chakravarty[1]

[1]Institute of Reproductive Medicine- Kolkata., Department of Assisted Reproduction, Kolkata, India ;
[2]Vidyasagar University, Tissue culture and molecular biology, Kolkata, India

Study question: Does aspirin and low-molecular-weight heparin (LMWH) combination therapy offer a favorable immunological milieu to salvage pregnancy in hyperhomocysteinemic women with recurrent pregnancy loss (RPL)?
Summary answer: Aspirin-LMWH combination therapy attenuates Th17 cell response and stimulates Th2-associated cytokine and chemokine production to confer immunocompetency and protect pregnancy in hyperhomocysteinemic women with RPL.
What is known already: The fetal immune tolerance is effected by a balance between T-helper (Th)-1, Th2, Th17, and regulatory responses involving both innate and adaptive immune cells orchestrated by signaling molecules (chemokines and cytokines). Women with RPL and/or recurrent implantation failure are reported with an elevated Th1/Th2 cell ratio and increased immune inflammatory responses at maternal-fetal interface. We have previously demonstrated that combined aspirin-LMWH anticoagulant therapy improves rate of pregnancy salvage in hyperhomocysteinemic women with RPL *(PLOS One 2013)*. We hypothesized that LMWH might persuade an immune-modulatory milieu, which could balance the pro-inflammatory response implicated in pathogenesis of RPL.
Study design, size, duration: This prospective cohort study in 53 hyperhomocysteinemic (homocysteine>12mmol/L) women with RPL is conducted between August 2017 and December 2019 at Institute of Reproductive Medicine, Kolkata. Patients (n=24) were supplemented with aspirin (5mg/day) alone or in combination with LMWH (2500IU/day) (n=29) for 12 weeks. They are analyzed for cytokines related to Th1 (interferon (IFN)-g, tumor-necrosis-factor (TNF)-a), Th2 (interleukin (IL)-10, IL-13) and Th-17 (IL-6, IL-23, transforming-growth-factor (TGF)-b) with their respective chemokines (CXCL10, CXCL11), (CCL17, CCL22) and (CCL20,CXCL1,CXCL8).
Participants/materials, setting, methods: Plasma samples obtained at gestational weeks (g.w.) 6 and 12 are analyzed by multiplex fluorochrome and Luminex performance assay for levels of Th1, Th17, and Th2-related cytokines and chemokines respectively. Percentage of Th17 and T-regulatory (Treg) cells in peripheral-blood-mononuclear-cells (PBMC) is detected by flow-cytometry. Differences in chemokine levels in between the groups were assessed by linear mixed models. Statistical significance was set at $p < 0.05$ as evaluated by student's T-test.
Main results and the role of chance: No differences are observed in cytokine and/or chemokine level/s at g.w. 6 between the groups. The percentage of Th17 cells (IL-17+/CD4+) significantly decreased ($2.98 \pm 0.68\%$ vs. $1.74 \pm 0.29\%$; $p<0.01$) with a simultaneous increase ($4.94 \pm 1.38\%$ vs. $3.03 \pm 0.91\%$; $p<0.02$) in percentage of Tregs (CD4+CD25brightFoxp3+ T cells) in aspirin-LMWH-treated cohort. The combination group, although documented a decreased concentration/s (pg/ml) of Th17-type cytokines (IL-6 (1.88 ± 0.65 vs. 0.91 ± 0.43; $p<0.04$ and IL-23(17.94 ± 9.76 vs. 7.78 ± 3.43; $p<0.01$)), at g.w. 12, concentration of TGF-β was significantly higher (3909.05 ± 1248.35 vs. 2469.83 ± 1058.71; $p<0.01$) which cue to probable maintenance of balance of inflammatory response in first trimester. Improvement in IL-10 concentration (6.32 ± 2.46 vs. 8.87 ± 4.32; $p<0.02$) was documented

after combination treatment. No differences were observed in Th1-type cytokine level/s (IFN-γ (1.97 ± 0.69 vs. 1.76 ± 0.34) and TNF-α (1.03 ± 0.37 vs. 0.98)) providing a favorable shift in the combination cohort indicating a Th2 bias. Mixed linear model test showed an increase in CCL22 ($p<0.05$); and a decrease ($p < 0.04$) in CCL20 during g.w.12 while CXCL10, CXCL11, CXCL1, CXCL8, CCL17, CCL22 do not differ during the treatment.

Limitations, reasons for caution: Future studies with higher sample size should corroborate the current findings. Moreover, this is an observational study not supported by appropriate/untreated controls because of stringent regulation/s from local ethics board. LMWH treatment was not continued beyond 12 weeks of gestation for absence of systematic network monitoring in our set-up.

Wider implications of the findings: Aspirin-LMWH supplementation augments the number of Treg cells and increases IL-10 that perhaps provide a favorable immunocompetent milieu to protect pregnancy in hyperhomocysteinemic women with RPL. Further ongoing studies will look into the duration of LMWH regimen for better immunosupression.

Trial registration number: NA

P-395 Evaluating the clinical utility of endometrial receptivity analysis test in women with recurrent pregnancy loss

M. Luna[1], T. Alkon[1], C. Hernandez-Nieto[1], D. Cassis-Bendeck[1], B. Sandler[1]

[1]Reproductive Medicine Associates of New York, Reproductive Endocrinology and Infertility, New York- NY, U.S.A.

Study question: Does endometrial receptivity analysis (ERA) test offer clinical utility in patients with recurrent pregnancy loss (RPL)?

Summary answer: Women with RPL may benefit from a personalized adjustment in timing of frozen embryo transfer.

What is known already: Successful embryo implantation requires an appropriate embryonic development, coincident with a receptive endometrium. Defects in endometrial receptivity contributing to implantation failure, remain not only the major rate-limiting step in vitro fertilization (IVF) success, but also a major culprit in unexplained infertility and spontaneous abortions. Because of this, the ERA test was developed. ERA test enables the determination of a personalized window of implantation (WOI). However, clinical evidence is still scarce regarding the value of performing an endometrial receptivity test in women with RPL.

Study design, size, duration: Monocentric prospective study from June 2018 to April 2019. 10 women with at least 2 consecutive miscarriages under 10 weeks of gestation of unexplained origin after IVF conceptions, underwent an ERA test. Subsequently, a single frozen euploid embryo transfer (SET) with appropriate adjustment in timing according to the ERA test was performed.

Participants/materials, setting, methods: Women with RPL of unexplained origin, <40 years, history of a full-term pregnancy after a euploid embryo transfer, normal karyotypes, uterine cavity assessed by hysteroscopy and no identified thrombophilia's were included. Participants were administrated oral/transdermal estradiol on cycle day two for endometrial preparation. When the endometrial thickness was ≥ 7 mm/ triple line pattern, luteal support was begun using vaginal and intramuscular progesterone. Endometrial biopsy was performed upon completion of 5 days of progesterone.

Main results and the role of chance: 100% of the patients were found to have a non-receptive endometrium. Five were pre-receptive (24 hours), three early receptive (12 hours), and two late receptive (12 hours). After a personalized SET was performed, 70% (7/10) became pregnant. Of the 70% of the women that achieved a pregnancy, 1 patient had a miscarriage at week 10 and the remaining had a live birth.

Limitations, reasons for caution: This a pilot study performed to test the utility of ERA test in women with RPL. Due to the size of the study, the effects of more subtle covariates would not have been detected. Future randomized controlled trials are needed.

Wider implications of the findings: A displaced implantation window was found in all the patients analyzed with RPL. These findings suggest for the first time, that the WOI may change after a full-term pregnancy or surgical uterine manipulation. These results enable appropriate study design of future studies.

Trial registration number: Not Applicable

P-396 Multidisciplinary approach in repeated implantation failure patients' evaluation

S. Bordoli[1], M. Scarrone[1], F. Pasi[2], V. Canti[3], L. Quaranta[3], R. De Lorenzo[1], S. Cella[1], V.S. Vanni[4], E. Papaleo[3], P. Giardina[3], P. Rovere Querini[1]

[1]Vita-Salute San Raffaele University, Internal and Specialistic Medicine, Milan, Italy ; [2]IRCCS San Raffaele Hospital, Obstetrics and Gynecology, Milan, Italy ; [3]IRCCS San Raffaele Hospital, IVF unit, Milan, Italy ; [4]Vita-Salute San Raffaele University, IVF Unit, Milan, Italy

Study question: Do repeated implantation failure (RIF) patients benefit from medical multidisciplinary evaluation?

Summary answer: An internist evaluation from an immunological, endocrinological and hematologic point of view, associated with the gynaecological one in RIF patients can improve their reproductive prognosis.

What is known already: No consensus regarding the definition of RIF has been reached. A widely accepted definition is the failure of implantation of at least three good quality embryos, in at least three fresh or frozen cycles transferred in women aged <40 years. These women are usually evaluated only in the context of IVF units. Pathogenesis is still unclear and multifactorial (embryo factors, maternal/endometrial factors, gamete factors and ART techniques associated factors). Recurrent pregnancy loss (RPL) is instead well known to benefit from thorough medical investigations since many causes other than gynaecological ones have been proved to be associated to RPL.

Study design, size, duration: We performed a prospective observational study of patients referred to recurrent pregnancy loss and implantation failure outpatient clinic at San Raffaele Hospital (Milan, Italy) between March 2019 and March 2020 (still ongoing). The patients reproductive complaints were RIF (n=43) or RPL (n=110).

Participants/materials, setting, methods: We studied patients according to demographic data, past medical history (genetic diseases, hypertension, abnormal thyroid function, congenital or acquired thrombophilia, history of DVT or pulmonary embolism, autoimmune diseases), past gynecological and obstetric history. Laboratory test have been prescribed to investigate autoantibodies, inflammatory indexes or dysmetabolic conditions. In order to assess the relevance of the evaluation and management, we have longitudinally followed patients during fertility procedures after the first visit and collected pregnancy rates and outcomes.

Main results and the role of chance: When we compared the prevalence of abnormal findings in RIF and RPL we found no statistically significant ($p>0.5$) difference in the distribution, suggesting that the factors contributing to the poor reproductive outcomes in these two dramatically different groups of patients may be similar. In a significant proportion of RIF patients we detected positive antinuclear antibodies (32.5%) antithyroid antibodies (18.6%), prothrombin mutation (11.5%), hyperhomocysteinemia and positive antiphospholipid antibodies (6.9%). Moreover, after appropriate treatment and proper support, 15 patients underwent a further IVF cycle and n=8 (implantation rate 0.53) had a positive pregnancy test, compared to an implantation rate of 0.15 normally reported in RIF patients undergoing a subsequent embryo transfer.

Limitations, reasons for caution: The small number of patients assessed so far in our multidisciplinary clinic is the main limitation of this work. An increment of data collection and pregnancy rate and outcomes will be of interest.

Wider implications of the findings: The establishment of a multidisciplinary team comprising an infertility specialist flanked by an internist could improve assisted reproductive technology (ART) outcomes by detecting immunological/endocrinological problems that may play a role in both implantation failure pathogenesis and physiological pregnancy development.

Trial registration number: non applicable

P-397 Low iron stores are associated with Recurrent Pregnancy Loss but does not predict subsequent loss or ability to conceive

M. Georgsen[1], M.C. Krog[2], A.S. Korsholm[3], H.W. Hvidman[3], A.M. Kolte[1], A.S. Rigas[4], H. Ullum[4], S. Ziebe[3], A.N. Andersen[3], H.S. Nielsen[5], M.B. Hansen[6]

[1]Copenhagen University Hospital- Rigshospitalet, The Recurrent Pregnancy Loss Unit- The Fertility Clinic, Copenhagen, Denmark ;

[2]Copenhagen University Hospital- Rigshospitalet, The Recurrent Pregnancy Loss Unit- The Fertility Clinic and Department of Clinical Immunology, Copenhagen, Denmark ;
[3]Copenhagen University Hospital- Rigshospitalet, The Fertility Clinic, Copenhagen, Denmark ;
[4]Copenhagen University Hospital- Rigshospitalet, Department of Clinical Immunology, Copenhagen, Denmark ;
[5]University of Copenhagen- Rigshospitalet- and Amager-Hvidovre Hospital, The Recurrent Pregnancy Loss Unit and Department of Gynaecology-and-obstetrics, Copenhagen, Denmark ;
[6]Copenhagen University Hospital- Rigshospitalet, Department of Clinical Immunology, Copenhagen, Denmark

Study question: Is low iron stores associated with Recurrent Pregnancy Loss (RPL) and does low iron stores impair the ability to conceive?
Summary answer: S-ferritin levels were inversely related to number of previous losses in women with RPL. Low iron stores did not affect the ability to conceive.
What is known already: Iron requirements are increasing during pregnancy and iron deficiency is common among women of reproductive age. Iron is essential for hemoglobin production, cellular metabolism and the immune system. Iron deficiency has been suggested to affect fertility due to the iron requirements of the developing oocytes. Low maternal iron stores result in lower birth weight and increase the risk of preterm birth. Studies of iron stores and sporadic pregnancy loss are sparse and contradictory. Furthermore, an association between iron deficiency and RPL has not previously been studied.
Study design, size, duration: A cohort study comparing s-ferritin levels in women with RPL (n=84) referred between 2013-2016 with a control group of women of reproductive age with no known fertility problem (n=153). The study investigated whether s-ferritin correlated to the ability to conceive and time to conception during the first two years after sampling and whether s-ferritin were associated with outcome of the first pregnancy after referral for RPL women.
Participants/materials, setting, methods: The study included women with RPL (≥3 pregnancy losses) referred to the Danish RPL unit and women who consulted the Fertility Assessment and Counselling Clinic both located at Copenhagen University Hospital, Denmark. Pregnancy history were recorded and serum samples were collected at first consultation and stored at -20°C until analysed. Follow-up on verified pregnancies was done after two years for both groups. Women who did not try to conceive or underwent fertility treatment were excluded.
Main results and the role of chance: Women with RPL had lower s-ferritin compared with the control group, 39.9 µg/L versus 62.2 µg/L (p=0.001) and had a higher prevalence of low iron stores (s-ferritin <30 µg/L), 35.7 % versus 13.7 % (p<0.001). There was an inverse relationship between s-ferritin levels and number of pregnancy losses before referral for the RPL women. When divided into groups of 1) 2-3 losses, 2) 4 losses, and 3) ≥5 losses, median s-ferritin levels differed significantly between the groups (p=0.010). There was no association between s-ferritin levels and the ability to conceive or time to pregnancy in neither the RPL nor the control group. S-ferritin did not predict the risk of losing the first pregnancy after referral in the RPL group.
Limitations, reasons for caution: This study is limited by the relatively small sample size and the low prevalence of iron deficiency in the studied population which may explain why we did not find a correlation between iron deficiency and subsequent pregnancy loss or ability to conceive.
Wider implications of the findings: The findings indicate that low s-ferritin could be a relevant risk factor in women with RPL. It should be investigated whether iron status should be assessed routinely before pregnancy in both healthy women and women with RPL and whether iron supplementation may increase the chance of live birth.
Trial registration number: Not applicable

P-398 Does pregnancy implantation site and trophoblastic ring thickness at early gestational scan predict outcomes of an intrauterine pregnancy? An observational study

L. Nancarrow[1], S. Vinayagam[1], M. Swanson[1], K. Ford[1], D. Hapangama[2], R. Hombury[3], R. Russell[1]

[1]Liverpool Womens Hospital, Hewitt fertility centre, Liverpool, United Kingdom ;
[2]University of Liverpool, Institute of translational medicine, Liverpool, United Kingdom ;
[3]Homerton University Hospital, Homerton fertility centre, London, United Kingdom

Study question: Does the pregnancy implantation site and trophoblastic ring thickness in an early scan predict outcomes and complication rates of intrauterine pregnancies?
Summary answer: Pregnancies located in the lower half of the uterine cavity with a thinner trophoblastic ring were more likely to miscarry.
What is known already: Women routinely have early gestation scans to assess the location and to confirm viability of pregnancy. This reassures most women who continue to have an uneventful pregnancy, although unfortunately some will later have a miscarriage or later pregnancy complications. Trophoblastic ring may be related to placentation and no previous studies have examined the predictive role of trophoblastic ring thickness at time of early gestation scanning in pregnancy outcomes and late pregnancy complications. Implantation sites after an embryo transfer had not been associated with pregnancy outcomes.
Study design, size, duration: This was a prospective observational study in a tertiary referral publically funded IVF unit in UK. 300 patients who attended for early pregnancy scan following single embryo transfer over a 14-month period were included after obtaining Informed consent.
Participants/materials, setting, methods: Patient typically underwent their early pregnancy scan between 6-8 weeks gestation. Inclusion criteria included any live ongoing singleton pregnancy following single embryo transfer and a 3D image was obtained of the uterus. Exclusion criteria were Women with uterine cavity abnormalities, multiple pregnancies or double embryo transfers were excluded. Patients were followed up to until the end of pregnancy, either miscarriage, term or preterm birth. Any adverse pregnancy outcomes (pre-eclampsia, IUGR etc) were also recorded.
Main results and the role of chance: Of the 300 patients recruited, at this interval review 286 pregnancies were ongoing with the remaining 14 ending up as miscarriages. Women who miscarried were older than those with ongoing pregnancies (mean ages 36.3 vs 33.5 years; p=0.002) but there were no other demographic differences were identified (e.g. BMI). Mean trophoblastic ring was thicker in the ongoing pregnancy group when compared with women who miscarried (7.14mm vs. 5.4mm; p=0.008).

Of the 14 miscarriages, 4 were located in the lower half of the uterine cavity. 18 pregnancies were located in the lower half of the cavity in the remaining ongoing pregnancies. This indicated a significant increase in miscarriage rate when implantation occurred in the lower half of the cavity (p=0.01).
Limitations, reasons for caution: This is an observational study without intervention. The observed difference may be attributable to the differences in patient age, but the slight difference of <3 years is unlikely to be the sole reason.
Wider implications of the findings: Investigation of trophoblastic ring thickness as a marker of pregnancy outcome/complications is warranted. Identifying non-invasive biomarkers facilitating studies of trophoblast invasion could lead to development of therapeutic strategies targeting complications of pregnancy. Avoiding embryo deposition in the lower cavity and correlating implantation site following embryo transfer also requires further investigation.
Trial registration number: not applicable

P-399 Proteomic signatures in Assisted Reproduction Technology (ART) cycles

V. Kanaka[1], A. Papadopoulou[2], S. Proikakis[2], P. Drakakis[1], T.G. Tsangaris[1], D. Loutradis[1]

[1]Department of Obstetrics and Gynecology, Alexandra Hospital, School of Medicine ;
[2]Proteomics Research Unit, Biomedical Research Foundation of the Academy of Athens, Athens, Greece

Study question: The identification of biomarkers for successful embryo implantation and pregnancy onset in In Vitro Fertilization (IVF) by proteomic analysis
Summary answer: Twenty four proteins were differentially expressed among women achieving and not achieving pregnancy after IVF and embryo implantation
What is known already: More than 400,000 babies from 1,6 million Assisted Reproduction Technology (ART) cycles are born around the world every year. The efficacy of in vitro fertilization cycles (IVF) has improved significantly over the past 40 years. However better understanding of the reproductive process may help increase birth rate. Proteomic analysis of the embryo secretome that

has already been done has shown a positive correlation between high levels of leptin and human leukocyte antigen (HLA) with the implantation potential of the embryo. Moreover previous studies have shown that protein AMBP and Leucine-rich alpha-2-glycoprotein play an important role in the implantation process.

Study design, size, duration: Proteomic analysis was performed for the analysis of peripheral blood serum of women undergoing IVF treatment age 30-43. Blood was collected prior to the IVF program, at the day of embryo transfer as well as 6 and 12 days post embryo transfer. In order to compare successful and unsuccessful cycles, twenty women is the size of the study by which ten has successful implantation and ten unsuccessful in a three years duration of the study.

Participants/materials, setting, methods: After serum was obtained, two dimensional gel electrophoresis (2DE) followed by MALDI-TOF–MS/MS Mass Spectrometry were performed to analyze the differential expression of proteins in the serum samples among women having successful and unsuccessful IVF cycles.

Main results and the role of chance: Twenty four proteins were differentially expressed among women achieving and not achieving pregnancy. Specifically, protein AMBP, Apolipoprotein A-IV, Growth/differentiation factor 2, Glucosamine-6-phosphate isomerase 2, G patch domain and ankyrin repeat-containing protein 1, Hemoglobin subunit beta, Kelch-like protein 23, Zinc-alpha-2-glycoprotein, Leucine-rich alpha-2-glycoprotein, Vitronectin, protein NATD1 and Plasminogen were expressed only in successful cycles. Proteins that were present only in unsuccessful resulting cycles are proteins that belong mainly to the immune system and include Complement C1r subcomponent, Complement C1s subcomponent, Complement C1q subcomponent subunit B, Ig mu heavy chain disease protein, Ig mu chain C region as well as Hemopexin, Serum paraoxonase/arylesterase 1, Alpha-2-macroglobulin, Tyrosine-protein kinase STYK1, Angiotensinogen, Keratin, type I cytoskeletal 9 and Keratin, type II cytoskeletal 1

Limitations, reasons for caution:

–No Donor cycles

–Age limited to 30-43 years old

–The results must be evaluated in a larger cohort and longer duration of time.

Wider implications of the findings: Predicting pregnancy and improving drugs for IVF treatment. Improve IVF pregnancy rates and success.

Trial registration number: non applicable

P-400 Ovarian hyperstimulation and high levels of progesterone are detrimental for ectopic pregnancy in ART

I. Oprova[1], N. Magunska[2], T. Milachich[3], A. Shterev[2], P. Andreeva[1]

[1]Shterev Hospital, Assisted Reproduction Department, Sofia, Bulgaria ;
[2]Shterev Hospital, Department of Obstetrics and Gynecology, Sofia, Bulgaria ;
[3]Shterev Hospital, IVF and Andrology Laboratory, Sofia, Bulgaria

Study question: Could ovarian hyperstimulation and high levels of Progesterone be a risk factor for an ectopic pregnancy in ART?

Summary answer: Endometrium thickness over 12 mm and progesterone level under 1 ng/ml and FrET could be a preventive measure for EP development.

What is known already: The ectopic pregnancy (EP) rate has been reported higher after assisted reproductive technology (ART) than after a spontaneous conception. The factors associated with abnormal implantation are widely discussed and not completely clear.

Study design, size, duration: The present study was an observational retrospective trial, performed in a private IVF clinic. It encompassed 366 women who have undergone in vitro fertilization treatment: stimulated cycles with fresh embryo transfers (STIM ET) and hormone replacement therapy with frozen embryo transfers (Fr ET).

Participants/materials, setting, methods: Four features were evaluated: endometrial thickness at the day of ET, stage of the embryos transferred – cleavage stage (day 3) or blastocyst stage (day 5), the progesterone level on the day of hCG in stimulated cycles, ovarian hyperstimulation (OHS). The primary outcome measure was a development of EP. Logistic regression was performed to utilize the significance of the numbers.

Main results and the role of chance: At total of 366 Fresh ET or Fr ET cycles were compared, 41 with EP and 325 with an intrauterine pregnancy. We detected that thin endometrium could be risky for developing EP, but only in stimulated cycles (endometrium in STIM ET and EP = 10.7 mm versus STIM ET and no EP = 11.8 mm; p = 0.029). In contrast, with Fr ET cycles, the size of the lining was not important for the occurrence of EP (Fr ET and EP = 10.6 mm versus Fr ET and No EP = 11.14 mm; p = 0.2). This comparison emphasizes the observation that EP is more often detected in stimulated than in frozen cycles (61.98 % versus 39.02%; p = 0.04). Something more, most of the EP are resulted after a transfer of blastocyst stage embryos but only in stimulated cycles (EP rate 52% versus 21%, p = 0.0009). Also, we have established that high level of Progesterone on the day of hCG trigger could contribute for an ectopic embryo implantation (progesterone in STIM ET and EP = 1.05 ng/ml versus STIM ET and no EP = 0.59 ng/ml; p = 0.0014).

Limitations, reasons for caution: The study was a retrospective cohort study at a single center, larger trials with an increased number of patients needed to confirm our finings.

Wider implications of the findings: This study shows an increased risk of an ectopic pregnancy in stimulated ET cycles than in FrET. These findings suggest elevated progesterone and hormonal milieu of ovarian stimulation was detrimental for ectopic pregnancy. Freeze all strategy followed by Fr ET would decrease chance of ectopic pregnancies in ART.

Trial registration number: Not applicable

P-401 Characterization of bHCG trends in Euploid Frozen-Thawed Embryo Transfer Cycles by Initial Value

J. Chervenak[1], R. Setton[2], A. Petrini[2], K. Hancock[2], P. Chung[2], Z. Rosenwaks[2]

[1]New York Presbyterian/Weill Cornell, Obstetrics and Gynecology, New York, U.S.A. ;
[2]Center for Reproductive Medicine, Obstetrics and Gynecology, New York, U.S.A.

Study question: What is the predictive value of initial bHCG change stratified by initial bHCG value in frozen-thawed embryo transfer (FET) cycles with preimplantation genetic testing (PGT)?

Summary answer: This study affirms that the initial bHCG level and its initial rate of change are strong independent predictors of live birth in euploid FET.

What is known already: Existing studies have established initial bHCG level and subsequent rate of rise after IVF as one of the earliest means of predicting pregnancy outcome. Over the past decade, the proportion of FET and PGT have increased. There is limited data to inform prognostic counseling in this population. Further, the effect of the initial value of bHCG on the expected rate of rise of bHCG has not been well characterized.

Study design, size, duration: This is a retrospective cohort study in which all FET cycles that had a transfer of a single PGT-euploid embryo performed in an academic medical center from 2013 to 2019 were screened for inclusion. Only cycles that resulted in a positive initial serum bHCG on CD 28 or 29, followed by a rise in the serum bHCG value 48 hours later, and a subsequent maximum of one gestational sac were included in the study.

Participants/materials, setting, methods: There were 596 FETs during the study time period that met the inclusion criteria. Groups were stratified by initial bHCG level (group 1: <50 mIU/mL; group 2: ≥50 mIU/mL and ≤100; and group 3: >100 mIU/mL) and compared across the rate of change of this value over two days (≤50%, 51-99%, and ≥100%). Statistical analysis was performed using Chi-square and Fisher's exact t-test.

Main results and the role of chance: Baseline age and BMI were similar for all groups. For group 1, the live birth rate (LBR) was the lowest of the cohorts (LBR 19.57%) and there was no significant difference in the chance of live birth regardless of whether bHCG rose <50% (LBR 10%), between 51-99% (LBR 10%), or ≥100% (LBR 26.9%, p=0.16). For group 2, the LBR significantly increased across the three categories of rate of bHCG rise (LBR 25% for ≤50% rise, vs. 54.5% for 51-99% rise, vs. 70.5% for ≥100% rise, p<0.05). Similarly for group 3, the LBR significantly increased across the three categories (LBR 10% for ≤50% rise, vs. 84.1% for 51-99% rise, vs. 90.1% for ≥100% rise, p<0.05 for all). For groups 2 and 3, an increase of bHCG of more than 50% is strongly associated with an increased LBR (p=0.02 and p=<0.0001, respectively). In the absence of a bHCG rise of >50% over 2 days, there was no significant difference noted between the 3 groups and prognosis was poor (LBR 14.29%).

Limitations, reasons for caution: This study examines bHCG values taken during a narrow interval of days after FET. The results of this study may not be generalizable to values taken outside of this timeframe.

Wider implications of the findings: The findings of this study elucidate the relative impact of initial serum bHCG values in FET with PGT cycles for predicting live birth and offer a counseling tool for the clinician.
Trial registration number: not applicable

P-402 The impact of chronic endometritis on pregnancy outcomes in women with recurrent implantation failure

Y. Liu[1], X. Chen[1], W.C. Cheung[1], Y. Zhao[1], R. Qi[1], J.P.W. Chung[1], C.C. Wang[1], T.C. Li[1]

[1]The Chinese University of Hong Kong, Department of Obstetrics and Gynaecology, Shatin- Hong Kong, China

Study question: Does the presence of chronic endometritis (CE) affect pregnancy outcomes in women with recurrent implantation failure (RIF)?
Summary answer: Chronic endometritis was associated with a lower successful implantation rate in women with RIF.
What is known already: Chronic endometritis is a state of persistent inflammation in the endometrial lining, which has been reported to be associated with reproductive failure, including RIF. Plasma cell density in the entire endometrial biopsied tissue has been put forward as a more reliable and accurate method of plasma cell assessment for the diagnosis of CE, and that the prevalence of CE in women with reproductive failure was only 10%. However, the proof of this measurement requires clinical studies to confirm that it is of useful prognostic value and leads to effective treatment on CE.
Study design, size, duration: This is a case-control observational study on pregnancy outcomes in 64 reproductive-age women with RIF undergoing endometrial scratch in a natural cycle preceding frozen-thawed embryo transfer with the use of nondonor oocytes. All the women are classified with CE status using a stringent plasma cell density threshold, > 5.15 CD138+ plasma cells/10 mm^2, which was the 95th percentile of a fertile control population and served to establish a normal reference range.
Participants/materials, setting, methods: Women failing to achieve a clinical pregnancy after transfer of at least four good-quality embryos in three or more transfer cycles and seeking treatment in our unit were included. Endometrial specimens were collected precisely 7 days after LH surge (LH+7) and plasma cell density was determined based on Syndecan-1 (CD138) positive cells in the entire biopsy section. The clinical information (e.g. successful implantation rate and clinical pregnancy rate) for these patients was reviewed and analyzed.
Main results and the role of chance: Among 64 patients recruited, 24 of them were excluded because of the loss of follow-up and high uterine killer cells count. Thus, a total of 40 patients were studied. 10% (4/40) of them were found to have CE, and the other 90% (36/40) did not have CE. There was no difference in maternal age, body mass index, history of pregnancy or duration of infertility between the CE and non-CE groups.

We observed a lower successful implantation rate in the CE group when compared with the non-CE group [50.0% (2/4) *vs.* 52.8% (19/36), respectively], while the unsuccessful implantation rate is higher in the CE group [47.2% (17/36)] than the non-CE group [50.0% (2/4)], but without a significant statistical difference (p =1.000).

However, the clinical pregnancy rate is higher in CE group than non-CE group [50% (2/4) *vs.* 36.1% (13/36), respectively]. Further, the non-pregnancy rate is lower in CE group [50.0% (2/4) *vs.* 63.9% (23/36), respectively, p =0.622].
Limitations, reasons for caution: The limitation of this study is that it only involved four women with CE due to its prevalence of 10% in our unit using the novel diagnostic method, which precludes the analysis of the relationship between CE and pregnancy outcomes in women with RIF.
Wider implications of the findings: We reported the presence of CE may affect the successful implantation rate in women with RIF. We reason that CE may provide a role in predicting the prognostic value in other subgroups of reproductive failure, such as recurrent miscarriage and infertility.
Trial registration number: ChiCTR-IOC-16007882

P-403 Shortened time to live birth in subfertile women undergoing endometrial diagnostic biopsy

V. Mitter[1], S. Meier[2], T.T. Rau[3], M. Von Wolff[1], M. Zwahlen[4], A.S. Kohl Schwartz[3]

[1]University Women's Hospital and University of Bern, Gynaecological Endocrinology and Reproductive Medicine, Bern, Switzerland ;
[2]University Women's Hospital, Gynaecological Endocrinology and Reproductive Medicine, Bern, Switzerland ;
[3]Bern University Hospital and University of Bern, Institute of Pathology, Bern, Switzerland ;
[4]University of Bern, Institute of Social and Preventive Medicine, Bern, Switzerland

Study question: What is the impact of diagnostic endometrial biopsy and treatment of chronic endometritis (CE) on the time-to-pregnancy and live birth in women with recurrent pregnancy loss or recurrent implantation failure?
Summary answer: Diagnostic endometrial biopsy and treatment of chronic endometritis reduces time-to-pregnancy an time to live birth in women with recurrent pregnancy loss or recurrent implantation failure.
What is known already: Up to 57% of women with recurrent pregnancy loss (RPL) and up to 66% of women with recurrent implantation failure (RIF) suffer from CE. Recently, a meta-analysis showed higher pregnancy and live birth rates after antibiotic treatment for CE in women with RIF. This was also found in a meta-analysis of trials on endometrial scratch injury in women who had two or more implantation failures. However, there remains a need to investigate the effect of diagnosis and treatment of CE and endometrial scratch injury specifically in women with RPL and RIF.
Study design, size, duration: This is a retrospective analysis of a cohort of women at the University Women's Hospital of Bern, Switzerland diagnosed for recurrent pregnancy loss or recurrent implantation failure between January 2014 and April 2019 (n=127). 108 fulfilled inclusion criteria, 61 with RPL and 47 with RIF. 41 served as historical controls as we only performed hysteroscopic assessment without biopsy and detection of plasma cells until 2016.
Participants/materials, setting, methods: We defined RPL as ≥ three consecutive miscarriages and RIF as ≥ six toP-quality cleavage-stage embryos unsuccessfully transferred. We performed diagnostic hysteroscopy and endometrial biopsy. The pathologist stained endometrial tissue with hemalaun-eosin and immunohistochemically for CD138. In cases of chronic endometritis, defined as presence of ≥ one plasma cell, we treated with antibiotics. We used Cox regression to adjust for confounding factors such as age of mother and parity and stratified by RPL and RIF.
Main results and the role of chance: Of 108 women, forty-one (38%) had standard hysteroscopic assessment and served as control (control group). The remaining 67 (62%) women had a diagnostic endometrial biopsy and histopathological assessment. In 25 (37%) women, no plasma cells were detected (CEneg). Forty-two (63%) women were positive for chronic endometritis and subsequently treated with doxycycline 100mg twice a day orally for two weeks (CEpos). The women in CEpos group (hazard ratio = 2.86; 95% CI 1.45 – 5.63; p= 0.002) had a higher, and women in CEneg group (HR =2.11; 95% CI 0.87 – 5.08; p=0.095) a possibly higher chance for a clinical pregnancy than women did in the control group. We observed similar results for the probability of a live birth: for women of CEpos group, the hazard ratio is 4.00 (95% CI 1.65 – 9.71; p=0.002) and for women of CEneg the hazard ratio is 2.02 (95% CI 0.71 – 5.70; p=0.184), both compared to the control group. In all women with biopsy (groups CEng and CEpos), the hazard ratio was 2.62 (CI 95% 1.39 – 4.94; p=0.003) for a clinical pregnancy and 3.00 (CI 95% 1.38 – 6.52; p= 0.005) for a live birth compared to the control group.
Limitations, reasons for caution: This is a retrospective analysis of data from our center. We did not perform test-of-cure after Treatment unless a woman had a subsequent miscarriage. However, our interest lied in the general impact on the time-to-pregnancy of an endometrial diagnostic biopsy and subsequent Treatment of CE.
Wider implications of the findings: In women suffering from RPL or RIF, we suggest performing endometrial biopsy, diagnosis and treatment of CE to shorten the time-to-pregnancy and live birth. Endometrial biopsy itself might have an effect on time-to-pregnancy and live birth. Possible rehabilitative healing processes may need some time.
Trial registration number: not applicable

POSTER VIEWING SESSION
MALE AND FEMALE FERTILITY PRESERVATION

P-404 The impact of the BRCA gene mutations on the reproductive potential in patients with active breast cancer undergoing fertility preservation

S. Arab[1], A. Badeghiesh[2], W. Buckett[3]

[1]McGill University, Department of Obstetrics and Gynecology-Reproductive Endocrinology and Infertility Centre, Montreal, Canada ; [2]McGill University, Department of Obstetrics and Gynecology, Montreal, Canada ; [3]McGill University, Department of Obstetrics and Gynecology-Reproductive Endocrinology and Infertility Center, Montreal, Canada

Study question: Do breast cancer patients with the BRCA gene mutations have lower ovarian reserve and poorer ovarian response than non-BRCA breast cancer patients?
Summary answer: Breast cancer patients with the BRCA gene mutations have similar ovarian reserve and ovarian stimulation respond compared to non-BRCA breast cancer patients.
What is known already: Controversy exists about fertility and ovarian reserve in BRCA mutation carriers. Some studies suggest that these patients may have low ovarian reserve and poor ovarian stimulation response. However, most data exists in carriers without breast cancer, rather than women with breast cancer undergoing fertility preservation prior to gonadotoxic treatment. What data does exist in breast cancer patients is from very small studies with conflicting results. Concerns about poorer response to stimulation in BRCA carriers may lead to women electing not to pursue fertility preservation or to being overstimulated.
Study design, size, duration: A retrospective cohort study of 131 breast cancer patients with known BRCA status who had had undergone fertility preservation at a university teaching hospital ART center from 2005-2019
Participants/materials, setting, methods: Breast cancer patients < 40 years old who had undergone fertility preservation with either IVF or IVM before starting gonadotoxic therapy; known BRCA status; both ovaries were present and no ovarian disease or surgery. Before starting the treatment, antral follicle count (AFC) was determined. Total of oocytes retrieved, number of MII oocytes , oocyte fertilization rate (where appropriate) and the number of oocytes and/or embryos cryopreserved were compared according to BRCA status.
Main results and the role of chance: Of 244 breast cancer patients <40 years who underwent fertility preservation between 2005 and 2019, 131 had known BRCA status and 125 fulfilled the above criteria. A total of 94 (75%) patients were BRCA negative, of whom 52 (55%) underwent fertility preservation with stimulation (IVF) and 42 (45%) without stimulation (IVM), and 31 (25%) patients were BRCA positive, of whom 16 (52%) underwent IVF and 14 (45%) underwent IVM .The patient mean ages (30+/-4.1 vs 32+/-4.2)(P=0.98), AFC (17+/-10 vs 17+/-9) (P=0.83) and, where appropriate, total gonadotrophin dose (2468 IU vs 1961 IU)(P=0.46) and days of stimulation (8.7+/-62 days vs 7.2+/-5.4 days)(P=0.26) were similar in BRCA positive compared to BRCA negative patients. In terms of reproductive response, there were no significant different between BRCA positive and BRCA negative patients in the total number of eggs retrieved overall (12.1+/-9 vs 11.0+/-8)(P=0.65), the total number eggs retrieved following IVF (14.1+/-7.2 vs 12.7+/-6.1)(P=0.47) or IVM (11.9+/-10.6 vs 10.4+/-9.2)(P=0.60), the number of MII oocytes collected (5.5+/-6.5 vs 5.2+/-5.1) (P=0.76), the number of fertilized oocytes (where appropriate) (4.9+/-6.0 vs 3.2+/-4.9)(P=0.18), the number of cryopreserved oocytes (3.1+/- 3.6 vs 2.0+/-2.9)(P=0.16)and the number of cryopreserved embryos (4.2+/-7.1 vs 4.8+/-6.5)(P=0.37). There was no difference between BRCA1 and BRCA2
Limitations, reasons for caution: The main limitations are the retrospective cohort study design which could introduce unidentified biases (although the BRCA status was not known beforehand in most cases) and the relatively small sample size which would miss small but real differences.
Wider implications of the findings: Comparable ovarian reserve and reproductive performance when undergoing fertility preservation should be reassuring for BRCA mutation carriers with breast cancer that outcomes are similar to non-BRCA carriers. BRCA carriers with breast cancer should be offered fertility preservation and protocols should not be changed solely on the basis of BRCA status.
Trial registration number: MUHC (ARSU6002/2020-6219)

P-405 Low in vitro maturation rates of oocytes recovered during ovarian tissue cryopreservation of very young girls compared to post-menarche patients undergoing fertility preservation before oncotherapy

Y. Fouks[1], E. Hamilton[2], Y. Cohen[1], Y. Hasson[1], Y. Kalma[1], F. Azem[1]

[1]Tel-Aviv Medical Center affiliated to the Sackler Faculty of Medicine- Tel-Aviv University, Lis Maternity Hospital- Department of Obstetrics and Gynecology-Fertility Division-, Tel Aviv, Israel ; [2]Tel Aviv University, Sackler Faculty of Medicine, Tel Aviv, Israel

Study question: What are the outcomes of IVM of oocytes in very young patients scheduled for onco-therapy?
Summary answer: Oocytes recovered from girls younger than 5 years of age who undergo fertility preservation have a lower maturation rate in IVM compared to older females.
What is known already: In vitro maturation (IVM) of oocytes recovered during ovarian tissue cryopreservation is often practiced although it is still considered experimental. To date, only a few studies have examined the success of this maturation process in pre-menarchal girls.
Study design, size, duration: A total of 93 patients aged 0–25 years who underwent ovarian tissue cryopreservation as part of onco-fertility preservation between 2007 and 2019 were included in the study.
Participants/materials, setting, methods: Oocytes were recovered from the medium following ovarian tissue cryopreservation protocol and matured over 48 hours. Their development and maturation rate were recorded and compared between the different age groups.
Main results and the role of chance: The patient's age was positively and inversely correlated with the total number of mature oocytes. The absolute maturation rate in post-menarche and pre-menarche patients differed significantly (32.7% vs 11.3%, $P > 0.001$, respectively), while the degeneration rate of the oocytes did not (38.9% vs 33.4%, $P = 0.167$). The pre-menarche group had significantly lower rates of total mature oocytes compared to the post-menarche group (99 vs 9, $P = 0.004$). A subanalysis of the oocytes recovered from patients aged 1-5 years demonstrated that very few mature oocytes completed the IVM protocol.
Limitations, reasons for caution: This study was limited by its small sample size and retrospective nature.
Wider implications of the findings: Oocytes recovered from girls younger than 5 years of age who undergo fertility preservation have a lower maturation rate in IVM compared to older females. This may indicate a need for alternative methods for preserving the oocytes of very young patients.
Trial registration number: N/A

P-406 Pregnancy outcomes and affecting factors in the patients undergoing fertility treatments after high-dose medroxyprogesterone acetate therapy for endometrial cancer

A. Kawasaki[1], Y. Mori[1], H. Itagaki[1], H. Ijiri[1], T. Sato[1]

[1]University of Tsukuba, Department of Obstetrics and Gycecology, Tsukuba, Japan

Study question: Are fertility treatments beneficial for the patients after conservative management of endometrial cancer? What are affecting factors for the success of fertility treatments?
Summary answer: Fertility treatments bring good pregnancy outcomes for the patients after high-dose medroxyprogesterone acetate (MPA) therapy for endometrial cancer. Several factors may reduce pregnancy outcomes.
What is known already: MPA therapy is an option for young patients in an early stage of endometrial cancer who wish to preserve their fertility. While fertility treatments can lead to early pregnancy and bring relatively good pregnancy outcome for patients after MPA therapy, we must pay attention to disease recurrence. Some affecting factors for pregnancy outcomes such as endometrium damage, tumor characters etc. are indicated but enough evidence has not been shown.
Study design, size, duration: In this study, 40 patients of endometrial cancer after MPA therapy are recruited from the database of our institute from 1998 to 2018. In those patients, 22 patients underwent fertility treatments just after getting remission of endometrial cancer (FT group). Age-matched control groups were made of 213 general infertility patients who underwent reproductive treatments (C group) and 127 patients who underwent IVF-ET in our institute(C-IVF group).

Participants/materials, setting, methods: Clinical pregnancy rate and live birth rate were compared between FT group and C group or C-IVF group. We also calculated recurrence rate and compared between FT group and a group of patients who underwent no fertility treatments after MPA therapy (non-FT group). Next, we investigated the affecting factors on pregnancy outcomes of patients in FT group. The data were analyzed using t-test and chi-square test. The level of significance was set at $P<0.05$.
Main results and the role of chance: The pregnancy rate in FT group was 59.1% while 56.8% in C group. The pregnancy rate was 44.9% in C-IVF group and 35.7% in patients who underwent IVF-ET in FT group. No statistically significant difference was observed in the pregnancy rate between FT group and control groups. The disease recurrence rate was 31.6% in FT group and 21.4% in non-FT group. Regarding patients who failed to get pregnancy in FT group, thin endometrium, low ovarian reserve, changing institute for fertility treatments and disease recurrence were common factors related to the failure.
Limitations, reasons for caution: To confirm the results of this study, the sampling numbers are too small. A multi-center study is desirable to collecting more data. The large scale analysis is necessary to rule out cofounding factors and prove true variables affecting pregnancy outcomes.
Wider implications of the findings: Patients undergoing infertility treatments after MPA therapy should pay attention to the possibility of increasing risk of disease recurrence. The adverse factors are considered in performing fertility treatments. A close relationship between specialists of oncology and reproduction is important not to miss disease recurrence.
Trial registration number: not applicable

P-407 Fifteen year single center experience in sperm banking for cancer patients: use and reproductive outcomes in survivors

S. Stigliani[1], C. De Leo[2], E. Maccarini[1], P. Scaruffi[1], I. Casciano[1], P. Anserini[1]

[1]IRCCS Ospedale Policlinico San Martino, UOS Physiopathology of Human Reproduction, Genoa, Italy ;
[2]University of Genoa, DINOGMi, Genoa, Italy

Study question: Which are usage rates of frozen semen and results of in vitro fertilization (IVF) cycles in cancer patients that cryopreserved their semen before gonadotoxic treatments?
Summary answer: The percentage of patients who used their frozen semen was 6% and the outcomes of the IVF cycles confirmed the validity of the procedure.
What is known already: Some cancer diagnoses and treatments can place patients at risk for infertility, since gonadotoxic treatments may damage spermatogenesis. Sperm cryopreservation is an established and safe technique recommended by international guidelines for cancer-related fertility issues, to preserve fertility of cancer patients who are treated during their reproductive years. Literature data report not uniform rates - ranging from 5% to 29% - of cancer survivors' use of their cryopreserved semen. Collection of follow-up data about reproductive outcomes of cancer survivors who use their frozen semen in IVF cycles is necessary to evaluate the clinical impact of this procedure.
Study design, size, duration: This was a retrospective study which reported data of 683 cancer patients who referred to our center from 2004 to 2019 for fertility counseling and preservation before gonadotoxic therapies.
Participants/materials, setting, methods: A total of 632 oncological patients cryopreserved their own semen following international guidelines. Semen was evaluated according to the World Health Organization 2010 manual and it was cryopreserved using standard slow freezing method with nitrogen steam. The ICSI cycles were performed according to conventional procedures and outcomes were collected.
Main results and the role of chance: Among the 683 cancer patients who referred to our laboratory, the most frequent pathologies were leukemia and lymphoma (44%), followed by testicular cancer (35%). Patients' median age was 32 years (range 13-65). A total of 632 patients cryopreserved their semen. Over the years, 46% of patients continued to renew maintenance of their cryopreserved samples; 32% of patients were lost at follow-up; 10% were discarded according to patient's will; 6% of banked samples were discarded because patients died; 2% of patients moved their sperm samples to another fertility center for IVF treatments; 4% used their frozen semen for IVF at our center. Men who used their frozen semen for IVF cycles were survivors of leukemia and lymphomas (52%), and testicular cancer (20%) and others (28%). At the time of cryopreservation patients were in childbearing age (median age: 35 years, range 21-53) and at the time of IVF treatments the median age was 38 years (range: 26-54). As regard as outcomes, 33 ICSI cycles were performed with the frozen sperms, fertilization rate was 68%, implantation rate was 25%, cumulative birth rate was 30%, with a total of 15 healthy babies born from 2009 to 2019.
Limitations, reasons for caution: This was a single-center study reporting data from a limited number of patients. Since our center is the regional referent semen bank, we will continue on banking semen of oncological patients and on collecting follow-up data. Thus, clinical value and limitations will be deepened in a larger cohort.
Wider implications of the findings: Sperm cryostorage is simple and feasible for male adults and adolescents and it should be part of fertility management for patients candidate for receiving gonadotoxic therapies. The usage rate may increase during the years and a regular follow-up may prevent storage of unnecessary samples.
Trial registration number: not applicable

P-408 Clinical evidence of follicle activation and loss in human ovaries post chemotherapy

D. Shai[1], H. Roness[1], I. Spector[1], H. Raanani[1], S. Aviel-Ronen[2], M. Shapira[1], M. Baum[1], I. Gat[1], D. Meirow[1]

[1]Sheba Medical Center, Morris Kahn Fertility Preservation Center, TEL AVIV, Israel ;
[2]Sheba Medical Center, Department of Pathology and Talpiot Medical Leadership Program, Tel aviv, Israel

Study question: What are the immediate pathophysiological findings related to follicle survival, dynamics and stromal injury in ovaries of patients treated with alkylating and non-alkylating agent chemotherapy.
Summary answer: Follicle activation and not primordial follicle apoptosis or stromal fibrosis may be an underlying mechanism of chemotherapy-induced follicle loss in patients treated with alkylating agents.
What is known already: Alkylating agents are the most ovotoxic of the chemotherapy agents, causing significant loss of ovarian follicle reserve, however very little data exists to explain the mechanisms underlying this loss in the ovaries of patients exposed to chemotherapy treatments Some mechanisms have been suggested, such as apoptosis of primordial follicles, stromal and blood supply changes and accelerated activation of primordial follicles. Examining the acute changes in human ovaries recently exposed *in vivo* to alkylating and non-alkylating chemotherapy will increase our understanding of the mechanisms of chemotherapy--induced follicle loss and enable development of targeted Fertility Preservation strategies.
Study design, size, duration: Histological analysis of ovarian cortical tissue removed from 96 women aged 15-39 with cancer diagnoses who were undergoing ovarian tissue cryopreservation for fertility preservation. Forty-eight had received chemotherapy treatment within six months of tissue retrieval; 24 with alkylating agents and 24 with non-alkylating agent chemotherapy. Ovarian cortical tissue from 48 age-matched patients who had not received chemotherapy were used as controls.
Participants/materials, setting, methods: Fresh ovarian tissue samples were paraffin embedded, serially sectioned and histologically evaluated for follicle numbers by three independent researchers. Immunohistochemical staining was conducted for apoptosis (cleaved Caspase-3), FOXO3a, collagen (Sirius red) and neovascularization (CD34).
Main results and the role of chance: Ovaries of women treated with alkylating chemotherapy contained significantly more growing follicles compared with age-matched controls (mean of 4.2 ± 0.6 growing follicles per section compared to 2.2 ± 0.3, $p=0.004$). The number of growing follicles was significantly inversely correlated with time from treatment ($r = -0.52$, $p=0.009$), such that the highest number of growing follicles was seen in ovaries removed within a few days of chemotherapy exposure. Despite a significant drop in primordial follicle population in ovaries treated with alkylating chemotherapy, no increased expression of apoptosis marker cleaved Caspase-3 was seen in primordial follicles even within a week post chemotherapy, while increased staining of cleaved Caspase-3 was observed in granulosa cells of growing follicles. Decreased nuclear staining of FOXO3A was seen in oocytes of PMFs in ovaries treated with alkylating agents compared with untreated ovaries. Marked fibrosis and

neovascularization was observed in ovaries exposed to alkylating agent chemotherapy 4-6 months earlier, but was not seen as acute changes in ovaries exposed more recently.
Limitations, reasons for caution: We were unable to perform molecular analysis on human ovarian samples as we had access to paraffin embedded not fresh-frozen samples. Therefore, the study was restricted to histological evaluations.
Wider implications of the findings: This study provides evidence that chemotherapy induces follicle activation and loss *in vivo* in ovaries of patients treated with alkylating agents. Prevention of this increased follicle activation may therefore be a potentially successful and highly targeted method of fertility preservation, which would not interfere with the effectiveness of chemotherapy.
Trial registration number: Helsinki #8065-10-SMC

P-409 Fertility preservation and oocyte quality in women with breast cancer and ovarian tumors: a prospective analytical study.

C. Fabiani[1], A. Guarino[1], E. Licata[1], G. Paciotti[1], C. Meneghini[1], R. Rago[1]

[1]ASL ROMA 2 - Sandro Pertini Hospital, REPRODUCTION PHYSIOPATOLOGY and ANDROLOGY, roma, Italy

Study question: Does the type of cancer disease influence the oocyte quality and ovarian response to stimulation for fertility preservation (FP) in female oncology patients?
Summary answer: Fewer mature oocytes are retrieved in ovarian and breast cancer patients than infertile patient, the number of dysmorphic oocytes is higher with a recurrent abnormality.
What is known already: Cancer survival has improved significantly and maintaining fertility is an important factor for the quality of life and for the management of cancer patient. Breast cancer is the most frequent cancer in women, and ovarian cancer, specially border-line one, is increasing in young patients. Currently mature oocyte cryopreservation is a standard technique for fertility preservation. The negative impact of cancer therapy on fertility is well known. However the data on the pattern of ovarian response after ovarian stimulation in oncology patients are limited. Few studies analyzed the effect of the type of malignancy on oocyte quality, in cancer patients.
Study design, size, duration: This is a prospective analytical study performed in the IVF unit at the Sandro Pertini Hospital in Rome between 2016 and 2019. The aim of this study is to investigate the effect of cancer diseases on number, above all on quality of oocyte and on dysmorphic oocyte ratio, in women with breast cancer and ovarian tumors compared to women age-matched who undergone ICSI treatment for tubal or male factor infertility.
Participants/materials, setting, methods: A total of 64 patients recently diagnosed with breast cancer (Group A) and 14 patients (Group B) with ovarian tumors were referred for counseling on FP. A total of 168 patients under 38 age underwent ICSI treatment for tubal or male infertility is the control group (Group C). Baseline characteristics are age, body mass index (BMI) and antimulleran hormone (AMH) value. The primary outcome was number and quality of retrievd oocyte from ovarian pick-up (OPU).
Main results and the role of chance: Baseline characteristic are comparable. Despite similar ovarian stimulation protocol, similar mean stimulation duration (Group A: 10.72; Group B: 10.4; Group C: 11.05), the recombinant FSH cumulative dose was significantly higher in breast patients (Group A: 2103.61 U.I.; Group C: 1514.77 U.I.) and the mean oestradiol peak at triggering was significantly lower due to the administration of letrozole in this patients (Group A: 597.16; Group C: 1131.49). Also the number of MII was significantly lower in cancer patients (Group A: 68.7%; Group B: 72.1%; Group C: 78.8%), the number of immature oocytes dose was significantly higher in breast cancer (Group A: 21.7 %; Group C: 13.5%), while the ratio of dysmorphic oocyte was significantly higher in cancer patients, expecially in ovarian cancer ones (Group A: 9.6% ;

Group B 16.5%; Group C: 7.7%). In Group A and B dysmorphic analyzed oocyte have a particular abnormality: a perivitelline space (SPV) with granularity.
Limitations, reasons for caution: Limitations concern the paucity of specific cancer group, especially ovarian tumors and BRCA mutated breast cancer patients. We still have not a follow up data to evaluate the competence of vitrified MII oocytes for oncology patients and we cannot report information on spontaneous conceptions and births.
Wider implications of the findings: Fertility outcomes in oncology patients have not been adequately studied due to the small number of patients with cancer undergoing FP. Few studies investigated the pattern of follicular growth to better characterize the outcome of ovarian stimulation not only in oocyte number and maturity, but also in oocyte quality.
Trial registration number: not applicable

P-410 Infertility and access to parenthood after an adolescent and young adult (AYA) cancer: a second 'obstacle course'?

M. Vialle[1], J. Saïas-Magnan[2], P. Bottin[2], A. Dezamis[3], C. Metzler-Guillemain[2], A.D. Bouhnik[4], J. Mancini[4], B. Courbiere[2,5]

[1]Centre Norbert Elias UMR 8562, Ecole des Hautes Etudes en Sciences Sociales EHESS- Centre National de la Recherche Scientifique CNRS, Marseille, France ; [2]Hôpital de la Conception - AP-HM, Department of Reproductive Medicine / CECOS, Marseille, France ; [3]Institut Paoli Calmettes, Department of Clinical Psychology, Marseille, France ; [4]Sciences Economiques et Sociales de la Santé & Traitement de l'Information Médicale SESSTIM, Institut National de la Santé et de la Recherche Médicale INSERM U125- Aix-Marseille Université- Institut de Recherche pour le Développement IRD UMR 259, Marse ; [5]Aix Marseille Univ, Avignon Univ- CNRS- IRD- IMBE, Marseille, France

Study question: What are the experiences of the medical care of fertility and access to parenthood for French adults in age to procreate who have had an AYA cancer?
Summary answer: Become parent after an AYA cancer is still a difficult pathway: patients report information and medical support gaps, feel guilty or are sometimes blamed.
What is known already: The medical literature has so far mainly shown the important effects of cancer treatments on fertility, the positive results of fertility preservation methods, or the uncertain conditions for maintaining or regaining fertility after cancer. Research in the humanities and social sciences has more specifically analysed the difficulties experienced when cancer is diagnosed and during treatment. Few have studied the post-cancer experiences of access to parenthood according to fertility conditions. The few existing surveys are quantitative, but none are based on in-depth qualitative interviews.
Study design, size, duration: This study was conducted between December 2018 and November 2019 and was carried out by a multidisciplinary team of sociologists and doctors. A qualitative survey was performed through in-depth interviews with 22 women and 14 men, who were adolescents or young adults at the time of cancer diagnosis and in remission for at least one year. Three types of cancer were studied: breast, testicles and malignant hematological diseases.
Participants/materials, setting, methods: Respondents were recruited from different locations and by different means: oncology or reproductive departments, snowball sampling, testimony call. Interviews were conducted by a sociologist face to face, by visioconference or telephone. The interviews covered, in a retrospective and chronological way: the personal, conjugal and professional history, the occurrence of cancer and its impact, especially in relation to treatment. The effects on fertility, desire for children and access to parenthood were discussed throughout the narrative.
Main results and the role of chance: A total of 36 interviews ranging in length from one to three hours were conducted with 22 women and 14 men, aged between 22 and 45 years. Among them, 8 women had breast cancer and 14 had malignant hematological disease; 6 men had testicular cancer and 8 had malignant hematological disease. Among women, 9 underwent a fertility preservation before cancer treatment, 2 after and 9 did not have preservation. Among the men, 13 did sperm cryopreservation and 1 did not. Among the 22 women interviewed, 8 had a child since the end of their cancer treatment, conceived naturally or by assisted reproductive technologies (ART) with their cryopreserved or donated oocytes; 6 of 14 men had or were expecting a child, conceived naturally or by ART with their cryopreserved or donated sperm. A few knew if they were fertile or infertile at the time of interview, but most were unaware of their fertility condition. This diversity of situations makes it possible to analyse a variety of experiences of medical care after cancer. However, despite this diversity, difficulties linked information or medical support gasps are systematically reported, appearing at different stages of the pathway towards parenthood according to the respondents.

Limitations, reasons for caution: This qualitative study is based on a limited number of interviews and a sample of people with limited characteristics. A study with a larger sample of people with broader characteristics would allow to reinforce or discuss the results. A selection bias is present, related to the volunteering process to participate.
Wider implications of the findings: The results showed the importance of a broader diffusion to the medical community and patients of the post-cancer existing 'self-reconstruction' difficulties, related to the treatment consequences on fertility, sexuality and couple life and the lack of information and medical support towards parenthood.
Trial registration number: Not applicable

P-411 Hydrogel derived from decellularized bovine ovarian extracellular matrix supports human follicle survival in vitro

M.C. Chiti1, L. White[2], J. Vanacker[1], E. Ouni[1], A. Des Rieux[3], M.M. Dolmans[1,4], C. Amorim[1]

[1]Institut de Recherche Expérimentale et Clinique, Pôle de Recherche en Gynécologie- Universitè Catholique de Louvain, Brussels, Belgium ;
[2]University of Nottingham, Wolfon Centre for Stem cells- Tissue Engineering and Modeling, Nottingham, United Kingdom ;
[3]Louvain Drug Research Institute, Advanced Drug Delivery and Biomaterials Unit-Université Catholique de Louvain, Brussel, Belgium ;
[4]Cliniques Universitaries St. Luc, Départemnt de Gynecologie, Brussel, Belgium

Study question: Is a thermosensitive hydrogel derived from decellularized bovine ovarian extracellular matrix (boECM) able to support human follicle survival and development after 7 days of in vitro culture?
Summary answer: When combined with alginate, this thermosensitive hydrogel constitutes what appears to be an efficient three-dimensional (3D) matrix for in vitro culture of human ovarian follicles.
What is known already: To successfully assemble a working artificial ovary, we need to create a 3D matrix able to accommodate isolated follicles and cells. While encouraging results have been achieved with fibrin matrices, the next step is designing an ECM-derived scaffold more closely resembling human ovarian ECM in its biochemical composition. This new generation of biomimetic scaffolds might well prove to be a breakthrough for ovarian follicle survival in an artificial ovary prototype.
Study design, size, duration: Two hydrogels (boECM1, boECM2) were analyzed for dsDNA, collagen and glycosaminoglycans (GAGs), and compared to bovine ovarian tissue. Human ovarian tissue (n=3 patients) was then digested to isolate ovarian follicles and encapsulate them inside 4 selected hydrogel combinations: 1) 100% boECM2; (2) 90% boECM2 + 10% alginate; (3) 75% boECM2 + 25% alginate; (4) 100% alginate (control). Follicle count, viability and growth were evaluated on day 0 (D0) and D7 after in vitro culture.
Participants/materials, setting, methods: Ovarian biopsies were obtained from fertile patients (n=3) with no ovarian pathology, and live/dead assays were performed to evaluate follicle survival before in vitro culture. Follicle recovery rates (n follicles encapsulated on D0/n follicles recovered on D7) were assessed after one week. Follicle growth was measured by comparing mean follicle diameters between D0 and D7 of in vitro culture. On D7, follicle viability was determined using a live/dead assay kit.
Main results and the role of chance: While dsDNA was significantly reduced in both boECM1 and boECM2 ($p<0.0001$) compared to native tissue, the greatest reduction ($p<0.01$) was observed in boECM2. There was no difference in collagen content between groups. GAG content was significantly higher ($p<0.01$) in native tissue than in boECM1, but not boECM2. Indeed, a significantly higher concentration of GAGs was found in boECM2 (P-value <0.05). A total of 114 isolated human follicles were encapsulated in boECM2-derived hydrogels and in vitro cultured for 7 days. On D7, overall follicle recovery rates were: 0%, 23%, 65% and 85% in groups 1 to 4 respectively, rising proportionately with increased alginate content. There was no difference in follicle viability between group 2 and 3 and the control group (group 4) (87%, 97% and 87% respectively) but follicle viability was not applicable in group 1 as no follicles were recovered. On D7, statistically significant follicle growth was accordingly detected in all groups except group 1 (P-value <0.05, P-value <0.01, P-value <0.001 respectively). Moreover, similar growth rates were found compared to the control group on D7.
Limitations, reasons for caution: This was a pilot study.
Wider implications of the findings: boECM2 combined with alginate may prove to be a promising new scaffold material for creation of an artificial ovary for women in remission from cancer, but at risk of malignant spread from reimplantation of their tissue.
Trial registration number: not applicable

P-412 In depth follow up of childhood development in two generations of spermatogonial stem cell transplantation derived offspring in a mouse model

J. Serrano[1], R. Van Eekelen[1], C.M. De Winter-Korver[1], S.K.M. Van Daalen[1], C.L. Mulder[1], A.M.M. Van Pelt[1]

[1]Amsterdam UMC- University of Amsterdam, Centre for Reproductive Medicine, Amsterdam, The Netherlands

Study question: What is the effect of transplantation of *in vitro* propagated spermatogonial stem cell (SSCT) on neonatal health and development in the derived offspring?
Summary answer: Systematic preclinical safety testing of SSCT derived offspring reveals no major differences in congenital abnormalities, birthweight, physical development and reflex ontogeny of the derived offspring.
What is known already: Pediatric cancer treatments improved greatly in recent years leading to increased life expectancy, but infertility is a late effect. Spermatogonial stem cells (SSCs) enable long-term male fertility through a tight balance between self-renewal and differentiation in the testis. To preserve fertility in prepubertal male cancer patients, a testicular biopsy is offered prior to gonadotoxic treatment. SSC *in vitro* propagation followed by auto-transplantation is proposed to restore spermatogenesis allowing natural conception. As several assisted reproductive techniques are linked to increased congenital abnormalities, low birthweight or developmental deviations, detailed pre-clinical follow-up of development of SSCT offspring is warranted before clinical application.
Study design, size, duration: Mouse neonatal SSCs were propagated *in vitro* and subsequently transplanted into sterile males (n=30). Control and fertile transplanted males (n=3 per group) were bred with control females (n=27) for one (control) and two generations (SSCT) of offspring, powered for congenital abnormalities (n=144 control, n=124 F1 SSCT, n=117 F2 SSCT). To assess childhood development, the pups were checked (double blinded) for congenital abnormalities, physical and behavioral development during the first 28 days of life.
Participants/materials, setting, methods: SSCs were isolated from neonatal DBA/2J mice and propagated *in vitro*. Sterile males (W/W-v) received SSCT to recover fertility. Control (DBA/2J) and transplanted (W/W-v) males were placed in breeding with control females (DBA/2J). At birth, the pups were checked for congenital abnormalities, birthweight and length. During the first 28 days, birth defects, ear opening, eye opening, complete fur growth, incisor eruption were checked, along with behavioral reflex testing of negative geotaxis, grasp and righting reflexes.
Main results and the role of chance: Overall, the health and development of naturally conceived SSCT derived pups during the first 28 days of life was similar to control pups, both in the first and second generations. However, statistically significant physical differences were found in the birthweight of second-generation pups, with a 0.068g decrease from 1.18 grams in control to 1.11 grams in SSCT derived offspring (95%CI: [-0.134; -0.003]). Furthermore, the eruption of the upper incisor occurred 1.16 days earlier in SSCT derived pups of the second generation (95%CI: [-2.161; -0.167]). No statistically significant differences were found between control and SSCT derived offspring, in both generations, for the remaining physical and behavioral assessments: birth length, eye and ear opening, lower incisor eruption, fur growth, righting reflex, grasping reflex and negative geotaxis. The study was powered for congenital abnormalities, which was a rare event (n=8), with no statistically significant differences found between groups in either generation (control n=1/142, SSCT F1 n=3/121, SSCT F2 n=4/113). However, the estimated odds ratios were relatively high at 3.57 (95%CI: [0.13; 293.33]) for F1 and 4.19 (95%CI: [0.60-82.95]) for F2.
Limitations, reasons for caution: Although powered for congenital abnormalities, the sample size of this study was insufficient to determine the impact of SSCT in the incidence in the offspring, given the rarity of congenital abnormalities.

Wider implications of the findings: Given the overall normal development of SSCT derived offspring, and after improvement of *in vitro* propagation of human SSCs and development as an advanced therapeutic medical product (ATMP), ethical approval should be requested for introduction of SSCT in a phase 1 clinical trial, alongside follow up of the children.
Trial registration number: Not applicable.

P-413 Modified RNA Encoding for Anti-Müllerian Hormone Has Fertoprotective Potential in Human Ovary Exposed to Cyclophosphamide

L. Man, M.D.- M.Sc.[1], E. Kallinos[1], Z. Rosenwaks[1], D. James[1]

[1]Weill Cornell Medical College, Center for Reproductive Medicine, New York City, U.S.A.

Study question: Does the administration of modified RNA encoding AMH confer a fertoprotective effect on the primordial follicle pool in the context of cyclophosphamide?
Summary answer: Administration of modified RNA AMH conferred a fertoprotective effect from cyclophosphamide, preserving the primordial follicle pool in both mouse ovary and human ovarian cortical xenografts.
What is known already: The risk of ovarian failure post-chemotherapy is determined largely by the type, amount of chemotherapy, and the age of the patient at treatment (Meirow, et al., 2010). Several studies have investigated the fertoprotective potential of a wide range of compounds in rodents, non-human primates, and patients (Spears, et al., 2019). In mice, recombinant or adenovirus-encoded AMH has been shown to protect the ovary from cyclophosphamide (Cp)-induced follicle loss (Kano, et al., 2017, Sonigo, et al., 2019).
Study design, size, duration: Cross-sectional study.

Murine model: intraovarian injection (saline/murine Mod-RNA-AMH) followed by an intraperitoneal (IP) injection 24 hours later (saline/Cp). A total of 4 arms, 6 ovaries in each.

Xenotransplantation model: human ovarian tissue transplanted into immunocompromised mice, intra-graft injection (buffer/human recombinant-AMH/human Mod-RNA-AMH) followed by an IP injection 24 hours later (saline/Cp). A total of 4 arms, 4 grafts in each.

Ovaries/grafts were harvested 2 weeks after the first chemotherapy injection.
Participants/materials, setting, methods: In the murine model, we used 6-7-week-old C57/B6 females.

In the xenograft model, we co-transplanted human ovarian cortical tissue from a 12-year-old organ donor, with endothelial cells, into NOD *scid* gamma (NSG) mice.

Cp was administered at the dose of 60mg/Kg, and the protocol was repeated a week later.

After harvest of the ovaries/xenografts, the ratio of follicles of all growth stages was measured in histologic sections.
Main results and the role of chance: In the murine model, we found the retention of primordial follicles similar to the controls: saline-intraovarian/saline-IP, 49±12.10, Mod-RNA-AMH/saline, 53.33±7.81, compared to Mod-RNA-AMH/Cp, 47.17±13.61. A 50% decrease was noted with saline/Cp Tx: 26.5±9.01. In the human xenografts, the retention of early primordial follicles was markedly improved with Mod-RNA-AMH pre-treatment. Buffer intra-graft/Cp IP 9.41±10.91% primordial follicles versus 37.48±17.12% with Recombinant-AMH, and 56.24±39.44% with Mod-RNA-AMH. Notably, the percentage of primordial follicles was similar to grafts treated with buffer/saline: 51.67± 4.04%.
Limitations, reasons for caution: Human ovarian tissue available for research is restricted. Repeating the experiment with more replicates will strengthen the results. Moreover, demonstrating the benefit to human xenografts at later time points will provide further support for the positive effect conferred by AMH.
Wider implications of the findings: Due to its high efficiency, transient protein expression, and the fact that it does not elicit a substantial innate immune response, Mod-RNA is an optimal mode of delivery. Administration before chemotherapy may confer a pronounced fertoprotective effect with minimal expense and intervention.
Trial registration number: na

P-414 impact of cancer treatment on ART outcomes: study of male cancer survivors

S. Shibasaki[1,2], Y. Takeshige[1,2,3,4], H. Hattori[1,2], Y. Nakamura[1,2], N. Aono[1,2,3,4], Y. Nakajo[1], N. Okuyama[2,3], T. Tai[1,3], M. Toya[1], T. Hashimoto[2,3], H. Igarashi[1], K. Kyono[1,2,3,4]

[1]Kyono ART Clinic Sendai, Department of Gynecology, Sendai, Japan ; [2]Human Ovariantissue Preservation Enterprise, Department of Gynecology, Tokyo, Japan ; [3]Kyono ART Clinic Takanawa, Department of Gynecology, Tokyo, Japan ; [4]Kyono ART Clinic Morioka, Department of Gynecology, Morioka, Japan

Study question: Does chemotherapy and/or radiation therapy in male cancer patients affect the fertility potential of sperm, embryonic development, or clinical outcomes?
Summary answer: There was no significant difference in embryonic development or clinical outcomes between the pre-cancer treatment group and the post-cancer treatment group.
What is known already: It is well known that cancer treatment, particularly chemotherapy and radiation therapy, for male cancer patients have negatively affected spermatogenesis. For this reason, sperm cryopreservation is recommended before cancer treatment to preserve fertility. However, it is not clear whether chemotherapy and radiation therapy affect embryonic development and clinical outcomes of ART.
Study design, size, duration: This study included the patients who used ART from January 1997 to June 2019. We defined 25 patients who underwent 45 ICSI cycles with cryopreserved ejaculated sperm before cancer treatment as group A. Of 109 patients who visited our clinic after cancer treatment, 31 cancer survivors who underwent 70 ICSI cycles with ejaculated sperm were defined as group B. A total of 63 frozen embryo transfers were performed (group A: 27, group B: 36 cycles).
Participants/materials, setting, methods: Of the cancer survivors, sperm could not be collected in 42 patients and ICSI was performed in 31 patients. Only semen analysis was performed for the rest. The cancer treatment was performed by chemotherapy and/or radiation therapy. Semen parameter, embryonic development, clinical outcomes were compared between groups A and B. Chi-squared test, Mann-Whitney U test, and Fisher's exact test were used for statistical analysis. $P<0.05$ was considered statistically significant.
Main results and the role of chance: The major cancer types in group A and B were testicular tumor (40.0%, 25.8%) and hematopoietic malignancy (28.0%, 51.6%). The mean age of females at the ovum pick-up in group B (37.1±4.5) was significantly higher than in group A (35.3±4.0) ($P<0.05$). There were no significant differences in the anti-Mullerian hormone levels or antral follicle counts, or baseline FSH levels. The mean age of males at the sperm collection in group B (39.9±7.9) was significantly higher than in group A (35.9±6.4) ($P<0.05$). In group B, the mean period from the end of cancer treatment to the start of ART was 10.8±9.7 years. The median of sperm concentration in group A [37.7×10^6 (20.5-78.9)] was significantly higher than in group B [5.5×10^6 (0.9-26.4)] ($P<0.05$). Two cases in group A showed azoospermia after cancer treatment. There were no significant differences in fertilization rates [63.5% (167/263), 65.7% (229/326)], and blastocyst formation rates [48.7% (73/150), 49.3% (75/152)] between groups A and B. Similarly, there were no significant differences in the pregnancy rates of frozen-thawed embryo transfer [59.3% (16/27), 50.0% (18/36)] and live-birth rates [44.4% (12/27), 41.7% (15/36)] between groups A and B.
Limitations, reasons for caution: In this study, the ART outcome was compared between the patients with sperm frozen before cancer treatment, and the only patients with sperm obtained after the treatment, which might cause a certain bias in grouping. We could not have enough information about cancer treatment, which should be shared by oncologist.
Wider implications of the findings: Considering the effects of gonad toxicity from chemotherapy treatment, sperm cryopreservation before cancer treatment is basically recommended. However, if sperm can be collected after a withdrawal period, ART treatment outcomes might be comparable. Since the number of target patients was still small, further study would be necessary.
Trial registration number: not applicable

P-415 No sign of actin polymerization or Hippo pathway inhibition in fragmented human ovarian tissue

S. Aagaard Lunding[1], S.G. Kristensen[2], L. Hardardottir[2], H.Ø. Olesen[2], A. Nyboe Andersen[1], C.Y. Andersen[2], S.E. Pors[2]

[1]Rigshospitalet, The Fertility Clinic, Copenhagen, Denmark ;
[2]Rigshospitalet, Laboratory of Reproductive Biology, Copenhagen, Denmark

Study question: Does tissue fragmentation of human ovarian cortex result in polymerization of the actin cytoskeleton and subsequent activation of follicle growth through Hippo pathway inhibition?
Summary answer: Tissue fragmentation of human ovarian cortex did not result in actin polymerization nor did it result in follicle activation by inhibition of the Hippo pathway.
What is known already: The Hippo pathway has been associated with regulation of early ovarian follicle growth in mammals including humans. Studies of murine ovaries suggest that changes in the actin cytoskeleton, caused by fragmentation, result in inhibition of the Hippo pathway by dephosphorylation of YAP and in turn may activate follicle growth by transcription of growth factors (eg. CCN's) and apoptosis inhibitors. In humans, *in vitro* and *in vivo* studies of fragmented ovarian tissue demonstrated upregulation of growth factors and growth of preantral follicles. However, the connections between fragmentation, the actin cytoskeleton and follicle activation in humans are yet to be confirmed.
Study design, size, duration: Donated frozen ovarian cortex from six women (34-37 years), undergoing ovarian tissue cryopreservation for fertility preservation between 2001 and 2011 prior to gonadotoxic therapy, were thawed for *in vitro* and xenotransplantation study. From each woman one cortex piece of 5x4x1mm was fragmented into 20 cubes of 1x1x1mm and another intact piece served as control tissue. Both fragmented and control tissue were incubated for either 0, 10, 30, 60, 120 or 240 minutes prior to examination.
Participants/materials, setting, methods: Actin polymerization was assessed with western blot of the ratio of F-actin to G-actin in fragmented and control ovarian tissue. Inhibition of the Hippo pathway was assessed with western blot of the ratio of phosphorylated YAP (pYAP/YAP) and gene expression analysis of the downstream growth factors CCN2, CCN3 and CCN5 in fragmented and control ovarian tissue. Fragmented and control tissue were xenografted to immunodeficient mice for six weeks before histological assessment of follicle growth.
Main results and the role of chance: Both F-actin and G-actin were detectable in all samples, but no significant difference was found in the ratio in fragmented tissue compared with control tissue for each timepoint (p=0.8). Both YAP and phosphorylated YAP (pYAP) were expressed in all samples. At the three selected timepoints (0, 60 and 120 minutes) there were no difference in the ratio of YAP/pYAP in fragmented and control tissue (p=0.6). Moreover, CCNs were expressed in all tissue samples. Only CCN5 was on average 0.56-fold lower in control tissue compared with fragmented tissue (p=0.0026). However, when assessing CCN5 in the fragmented tissue at the different timepoints, expression of CCN5 did neither increase nor decrease over time (p=0.8). Thus, fragmentation did not induce upregulation of CCN5 gene expression. Histological assessment of the xenografted ovarian tissue revealed fewer follicles in the fragmented tissue compared with control tissue, 239 versus 975 preantral follicles, respectively. A logistic regression model accounting for paired samples showed that the proportions of growing follicles, defined as all non-primordial follicles, in the exposed tissue (34.7%) and the control tissue (27.4%) were not different (p = 0.56).
Limitations, reasons for caution: Donated ovarian tissue were only available from six women, which limits the statistical power. Initially, ovarian cortex is cut into pieces prior to cryopreservation and some activation could have been induced in the control tissue. Furthermore, the unequal follicle distribution throughout the cortex warrants caution when interpreting the findings.
Wider implications of the findings: We were not able to confirm that fragmentation of human cortical tissue results in actin polymerization and subsequent follicle activation through disturbance of the Hippo pathway. Thus, these *in vitro* and *in vivo* results may indicate that ovarian tissue fragmentation is an ineffective method to activate follicle growth in humans.
Trial registration number: Not applicable

P-416 Ovarian stimulation for fertility preservation in young women: is there a right time to start?

R. Quintana Berto[1], A. Santolaria Baig[1], N. Garcia Camuñas[1], J. Subirá Nadal[1,2], P. Polo Sanchez[1], J.M. Rubio Rubio[1]

[1]La Fe University Hospital, Women's Health Area, Valencia, Spain ;
[2]IVI-RMA Castellon-Valencia, Reproductive Endocrinology, Castellon, Spain

Study question: Is there an optimal time to start an ovarian stimulation in young women who initiate an oocyte cryopreservation (OC) cycle for fertility preservation (FP)?
Summary answer: Starting OC cycles out of the early follicular phase (EFP) – or random-start protocol – may provide better ovarian response and oocyte yield.
What is known already: OC is the preferred method for FP compared to other treatments. Traditionally, stimulation protocols start during the EFP but this methodology sometimes requires more time depending on patient's ovarian cycle. However, in certain settings – cancer, for instance – we do not have enough time for delaying other therapies in order to preserve women's fertility. Some authors have argued that is possible to achieve a synchronized follicular development and an optimal oocyte retrieval despite starting the stimulation out the EFP based on the different follicles waves. Random-start ovarian stimulation protocols are a feasible alternative to conventional cycles in such scenery.
Study design, size, duration: This is a retrospective study performed from January 2013 to January 2020 at a tertiary university hospital. Our research was focused in the first OC cycle of young women (< 25 years old) which are expected to have a better cycle response due to their clinical characteristics. Data was retrieved from patients' electronic medical record.
Participants/materials, setting, methods: We collected data from epidemiology, stimulation and oocyte retrieval from a total number of 78 OC cycles. Two groups were stablished depending on the phase in which the treatment began: EFP n=63 and random-start n=15. Continuous variables were summarized by the median and standard deviation for a descriptive analysis. After evaluating the normal distribution of both groups, we performed a nonparametric statistical analysis to compare them.
Main results and the role of chance: Both groups were comparable in terms of Body Mass Index (BMI), Anti-Müllerian Hormone (AMH) or Antral Follicular Count (AFC).

Total dosing of FSH was similar in both groups with a mean of 2401,441 ± 1044,6 IU in the EFP group and 2295 +/- 636,90 IU in the random-start grouP- (p=0.941).

The total number of follicles at triggering day was comparable in both groups. However, there was a higher number of follicles >16 mm in the random-start group (12 ± 5) compared with the EFP group (7,47 ± 5) (p=0,011). Estradiol values at the trigger day were similar, as well as Follicular to Oocyte Index (FOI) and Follicular Output Rate index (FORT).

Nevertheless, the oocyte retrieval was more successful in the random-start group with a mean number of 11,72 (±7,25) oocytes in the EFP patients and 17,43 (±9,84) in the random-start patients (p=0.018). Even though the maturity rate was comparable in both groups, the number of metaphase II oocytes was also higher in the random-start group (p= 0,017).
Limitations, reasons for caution: The data from this study was retrospective and from a single center. Further studies including more patients would ensure a stronger statistically significant difference.
Wider implications of the findings: Random-start protocol for OC cycles provides an advantage in terms of timing. In settings in which an urgent ovarian stimulation is needed, starting it without delays not only allows to attempt fertility preservation for patients who have important time constraints, but also, does not compromise oocyte retrieval.
Trial registration number: Not applicable

P-417 Effect of BRCA genetic status on ovarian stimulation response for fertility preservation in breast cancer patients. A retrospective cohort study

L. Perez Martin[1], C. Alonso Mayo[1], S. Caballero Sanz[1], F.J. Amor Valera[1], D. Trobo Marina[1], F.M. Pérez Milán[1]

[1]Hospital General Universitario Gregorio Marañón, Reproduction Unit, Madrid, Spain

Study question: Do BRCA1 and BRCA2 mutation carriers diagnosed with breast cancer have an increased risk of poor ovarian response to ovarian stimulation for fertility preservation?
Summary answer: No association was observed between the presence of a BRCA gene mutation and ovarian response to ovarian stimulation in terms of number of oocytes retrieved.
What is known already: Breast cancer is the second most common malignancy diagnosed worldwide. 5-year survival rate extents to more than 80% due to early detection with screening programmes and the recent advances in its treatment. Successful treatment often requires the use of gonadotoxic chemotherapeutic agents, so fertility preservation is now advised to most premenopausal patients. Predisposing mutations are present in around 10-15% of cases, being BRCA genes the most commonly involved. There have been reports suggesting a poorer response to ovarian stimulation of BRCA mutation carriers, and recent studies showed lower serum AMH levels compared to non-carriers.
Study design, size, duration: This is a retrospective cohort study. All breast cancer patients who underwent fertility preservation in our unit from January 2010 to December 2019 were eligible to be included. Our aim was to compare the number of oocytes retrieved between BRCA mutation carriers and tested-negative controls. Secondary outcomes were number of metaphase II oocytes retrieved, rate of low or suboptimal ovarian response (<6 and < 9 oocytes, respectively) and cancelation rate due to insufficient response.
Participants/materials, setting, methods: All breast cancer patients tested for BRCA mutations who underwent a fertility preservation treatment were included in the study. We compared the number of oocytes retrieved in exposed and non-exposed patients using appropriate statistical tests. Effect size was estimated by relative risk, which was adjusted considering potential confounders by multivariate analysis (logistic regression). The study was conducted in Gregorio Marañón General University Hospital (Madrid, Spain), and was approved by the internal institutional committee.
Main results and the role of chance: We included 113 patients. BRCA mutations were present in 29 (25.7%). No differences were observed between groups regarding age, smoking habit, previous infertility and/or pregnancy, antral follicle count (AFC), initial and total dose of FSH consumed during ovarian stimulation and cotreatment with LH and/or letrozole.

No association was detected between BRCA status and number of oocytes retrieved (mean difference: 0.65; 95% CI: -2.29—3.59; p>0.05; log rank test p value >0.05). Multivariate analysis did not show association after adjusting by age, AFC, smoking habit and total FSH dose (regression coefficient: -0.99; CI 95%: -3.62—1.64).

BRCA status showed no effect on number of metaphase II oocytes retrieved (mean difference: 1.71; 95% CI -0.70—4.12; log rank test p value >0.05).

Cancelation rate due to insufficient response was similar in both groups (6.1% vs 9.3%; p >0.05). Risk of low and suboptimal response was also similar (RR: 0.70 CI 95%: 0.28—1.74; and RR: 0.96 CI 95%: 0.57—1.60; respectively). The impact of BRCA genetic status on low and suboptimal response was not affected by cofactors such as age, smoking habit, AFC and total FSH dose (adjusted OR: 0.99 CI: 0.87—1.83; and OR: 0.39 CI 95%: 0.08—1.83, respectively).
Limitations, reasons for caution: BRCA status was unavailable in many cases. The low number of patients included rendered a low power to conclude about the main objective, despite observed frequency of BRCA mutations being higher than expected. Pre-treatment AMH levels were unknown in most patients, so ovarian reserve could only be assessed by AFC.
Wider implications of the findings: As more BRCA mutation carriers are aware of their genetic status, more couples are seeking preimplantation genetic testing, which ideally requires a large number of oocytes and embryos. According to our findings, BRCA mutation carriers do not require oocyte cryopreservation to maximize chances before they decide to have children.
Trial registration number: Not applicable

P-418 Ovarian reserve before and after chemotherapy in triple negative breast cancer patients

J. Han[1,2], K. Hye In[1], K. Sung Woo[1,2], K. Hoon[1,2], K. Seung-Yup[1,2], S. Chang Suk[1,2], K. Seok Hyun[1,2], M.C. Young[1,2]

[1]Department of Obstetrics and Gynecology, Seoul National University Hospital, ; [2]Department of Obstetrics and Gynecology, Seoul National University College of Medicine,

Study question: Is there any difference in ovarian reserve after chemotherapy between triple negative breast cancer (TNBC) patients and other breast cancer patients?
Summary answer: Decreased ovarian reserve after chemotherapy is more obvious in TNBC group than other group. Early referral before chemotherapy is crucial especially in TNBC patients.
What is known already: Triple Negative Breast Cancer (TNBC) is a cancer that is estrogen receptor (ER) negative, progesterone receptor (PR) negative and human epidermal growth factor receptor 2 (HER2) negative, based on immunohistochemistry (IHC). Some studies suggest that women with BRCA1 or BRCA2 mutation have fewer oocytes in their ovaries and large portion of TNBC patients were proven to have BRCA mutation. But there is no report about association between TNBC and ovarian reserve.
Study design, size, duration: In this retrospective study, data from 138 breast cancer patients who referred for fertility preservation at a single tertiary center were examined from January, 2017 to December, 2018. All options were explained by specialist of endocrinology, and patients selected the method of fertility preservation. Most patients (n=122) chose GnRH agonist injections only, and other patients (n=16) wanted to perform oocyte or embryo cryopreservation.
Participants/materials, setting, methods: Subjects were classified into two groups, TNBC group (n=33) and other group (n=105) in which at least one of ER, PR, HER2 is positive. Clinical characteristics and markers of ovarian reserve (AMH, FSH, E2) of the two groups were compared before, 6 months, and 1 year after chemotherapy.
Main results and the role of chance: Baseline characteristics including age were not significantly different between two groups. In TNBC group, initial AMH levels were significantly lower than other group (3.25 ± 0.61 vs. 3.85 ± 1.04, p<0.001). After 1 year of chemotherapy, FSH levels were higher in the TNBC group (22.98 ± 13.08 vs. 11.15 ± 5.38, p=0.051).
Limitations, reasons for caution: Limitations of this study is that difference in drug regimen and duration of chemotherapy between two groups was not considered thoroughly. Further prospective studies with larger, homogenous cohorts are needed.
Wider implications of the findings: In this study, TNBC patients showed trend to have lower ovarian function before chemotherapy and slower recovery of ovarian function after chemotherapy. Therefore, urgent referral for fertility preservation should be considered especially in TNBC patients.
Trial registration number: not applicable

P-419 A streamlined andrology workflow for elective sperm freezing before chemotherapy is pertinent to timely preservation of male fertility

Z. Huang[1], J. Mathew[2], C. Ho[2], S. Chew[2]

[1]Institute of Molecular and Cell Biology- National University Health Systems, Obstetrics and Gynaecology, Singapore, Singapore Rep. of ; [2]National University Health Systems, Obstetrics and Gynaecology, Singapore, Singapore Rep. of

Study question: Does a streamlined andrology workflow help improve time-to-treatment for men who require elective sperm freezing before chemotherapy?
Summary answer: A standardized workflow with instructions and checklist for all clinicians to refer for elective sperm freezing before chemotherapy is efficient and reduce time to treatment.
What is known already: Men who require elective sperm freezing to preserve their fertility prior to chemotherapy to treat their medical conditions (e.g. cancer or debilitating medical conditions) are often referred to multiple clinics and specialists (referring physicians, fertility specialist and andrologist), undergo a multitude of investigations and go through many consent forms before receiving the appropriate treatment. This causes additional financial costs and further delays as well as precious time lost before these men can receive life-saving medical treatments. Many men become confused by conflicting instructions, frustrated by numerous appointments and lack accurate information about elective sperm freezing.

Study design, size, duration: Retrospective analyses on all the elective sperm freezing cases performed in 2018 was done to assess, 1. the duration required from time of referral to time of sperm freezing, 2. costs bore by these men and 3. types of cases referred. An institution-approved checklist and counselling form designed by the andrology service for elective sperm freezing is implemented from January 2019 and a prospective analysis of the referral process and outcomes was performed.

Participants/materials, setting, methods: Participants: Men referred from all disciplines for elective sperm freezing

Setting: The andrology service attends to men with a wide range of psychosexual and fertility issues; limited appointment slots available.

Method: An approved standardized checklist deployed in 2019 with indications, requirements and counselling form which a clinician (from any discipline) can access on the hospital internal web-portal to reference, download and employ in their clinics for direct onward referral to do elective sperm freezing for these men.

Main results and the role of chance: Elective sperm freezing requests comprises 20% the andrology service's workload. With the limited appointment slots and usually lengthy consults for psychosexual issues and complex andrological issues, it can result in long waiting times, increased number of clinic visits, increased costs and delays to life-saving treatment for these men just to access the service. Typically it takes up to 3 clinic visits before the men can schedule their elective sperm freezing prior to January 2019. Additionally, relevant investigations before sperm freezing such as sexually transmitted infections screen must be done as mandated by the Ministry of Health, Singapore - however prior to 2019, this was haphazard and not all men have their screen performed routinely - resulting in further delay to elective sperm freezing and initiating their medical treatment (range 4 -14 days). The referring physicians from multiple disciplines (medical-oncology, haematology, endocrinology, urology) had to delay commencing vital medical treatments for these men until their fertility preservation plans were completed. With the implementation of the streamlined workflow and checklist in January 2019, the referring physician can follow the checklist, counsel patients and refer directly for elective sperm freezing with no delay, waiting time or need to see the andrologist anymore.

Limitations, reasons for caution: The analysis is largely descriptive and applicable only in a tertiary referral hospital with a broad range of disciplines and high number of complex cases.

Wider implications of the findings: This resolves the unnecessary delay and extra costs for men to have elective sperm freezing done. The standardized checklist and counselling form will create a model of care for other clinical services to adopt. This is to avoid delay in commencing life-saving medical-treatment due to the need for fertility preservation.

Trial registration number: not applicable

P-420 Reproductive outcomes after IVF treatment in a cohort of Danish women transplanted with cryopreserved ovarian tissue

I.M. Dueholm Hjorth[1], S.G. Kristensen[2], M. Dueholm[3], P. Humaidan[4]

[1]The Regional Hospital in Horsens and Aarhus University Hospital, Department of Obstetrics and Gynecology, Aarhus C, Denmark ;

[4]Skive Regional Hospital and Faculty of Health- Aarhus University, The Fertility Clinic and Department of Clinical Medicine, Skive and Aarhus, Denmark

Study question: How were the reproductive outcomes, ovarian stimulation regimens and predictive factors for successful fertility treatment in women undergoing ovarian tissue cryopreservation (OTC) and transplantation (OTT)?

Summary answer: Although low, reproductive outcomes after OTT are more favorable in younger patients swiftly referred to IVF treatment, followed by frozen-thaw embryo transfer.

What is known already: The reproductive outcomes after OTT are diverse as some women conceive spontaneously, whereas others fail to conceive even after repeated IVF treatment. Knowledge on the causes of this variability, including predictive factors for success is lacking, and limited data exists as to which ovarian stimulation and embryo transfer regimens are the most optimal for this group of patients.

Importantly, negative outcomes are generally underreported.

Study design, size, duration: Retrospective study in a cohort of 28 patients, undergoing OTT at Aarhus University hospital in Denmark followed by IVF treatment during the period 2012 to 2017.

Participants/materials, setting, methods: A cohort of 28 women undergoing IVF-treatment in Danish fertility clinics after OTC and OTT. The study included evaluation and analysis of patient characteristics, including diagnosis prior to OTC, details of the OTT surgery, ovarian stimulation regimens and reproductive outcomes, including number of follicles, oocytes, embryo transfers, pregnancy, and live birth. The possible impact of time to fertility treatment was also evaluated.

Main results and the role of chance: In 19 patients responding to ovarian stimulation, a median of 3.0 cycles per patient (range: 1-14 cycles) was performed and 2.0 mature oocytes were retrieved per cycle. Eleven women (39%) achieved 15 pregnancies of which 60% were lost during first or second trimester, resulting in 5 patients (17,9%) having one or more live births, and 7 healthy children being born. In breast cancer patients (mean age at OTC=33 years), the pregnancy (PR) and live birth rates (LBR) were 35.0% and 5.0% per embryo transfer, respectively. For all other diagnoses (mean age at OTC=26.6 years), PR and LBR were 50.0% and 37.5% per embryo transfer, respectively. None of 12 women aged ≥35 years at OTT achieved a live birth. A total of 1.42 fertilized oocytes per cycle, was obtained using the long GnRH agonist protocol compared to 0.71 fertilized oocyte per cycle in GnRH antagonist cycles (p=0.004, Mann-Whitney). Frozen-thaw embryo transfer resulted in more pregnancies than fresh embryo transfer (P<0.05). There were no significant differences in age at OTC, diagnosis or transplantation site between patients who had oocytes retrieved and non-responders to stimulation, but in non-responders, the mean time from OTT was 15.7 months compared to 9.9 months in responders (p<0.05).

Limitations, reasons for caution: Although this study includes the largest single center Scandinavian cohort of OTC-OTT patients undergoing IVF treatment, the sample is still low, limiting the statistical power. Moreover, since live birth was rare, parameters related to this outcome may be masked.

Wider implications of the findings: Based on the present results, the long GnRH agonist down-regulation protocol, followed by freeze-all and frozen-thaw embryo transfer should be recommended and multiple OTT procedures and repeated IVF-treatment may be necessary to achieve a live birth. Patients may benefit from being referred to fertility treatment soon after OTT.

Trial registration number: 3-3013-2790/1

P-421 Spermatogenesis enhancement in neonatal mouse frozen - thawed testis after 3- dimensional culture with growth factors.

A. Alrahel[1], M. Movahedin[2], Z. Mazaheri[3], F. Amid[4]

[1]Reproductive Biotechnology Research Center- Avicenna Research Institute- ACECR-Tehran- Iran., Reproductive Biotechnology Research Cente, tehran, Iran ;
[2]Anatomical Sciences Department- Faculty of Medical Sciences- Tarbiat Modares University- Tehran 14115331- Iran, Anatomical Sciences Department, Tehran, Iran ;
[3]Basic Medical Science Research Center- Histogenotech Company, Basic Medical Science Research Center- Histogenotech Company, Tehran, Iran ;
[4]Anatomical Sciences Department- Faculty of Medicine- Tehran University of Medical Sciences-, Anatomical Sciences Department, Tehran, Iran

Study question: Are growth factors (GF) provide profound impact on spermatogenesis after 8 weeks of in-vitro 3- dimensional culture?

Summary answer: The level of TnP1 gene expression and ACRBP were significantly higher in the fresh culture group with growth factors compared to control groups.

What is known already: Aggressive chemotherapy may lead to permanent male infertility. Three-dimensional(3D) in-vitro culture can operate as an effective strategy for studies on spermatogenesis and male infertility treatment. Sperm-like cells derived from the human and mice spermatogonial stem cells after frozen-thawed has already been carried out by researchers. In this study, 3D culture of testicular tissue by GF were studied in 4 groups of immature mice testes after 8 weeks to evaluate the progress of the spermatogenesis process.

Study design, size, duration: The testes were removed from 5 NMRI neonatal male mice (six days old) and repeated 3 times for further accuracy in each group. The testis tissue fragments were transferred to the hexahedrons, incubated in a culture incubator and cultured for 8 weeks
Participants/materials, setting, methods: The fragments of testes tissue are placed in the freezing culture. The tissue was examined from the aspect of morphology.PLZF, SCP3, ACRBP antibodies were assessed to identify spermatogonia, spermatocyte and sperm-like cell respectively. Four studied groups are as follow: Culture of fresh testicular tissue fragments on agarose with and without growth factors for 8 weeks ,the culture of frozen-thawed neonatal mouse testicular tissue fragments on the agarose with and without growth factors for 8 weeks.
Main results and the role of chance: The findings showed that the size and diameter of seminiferous tubules were increased compared to control groups. Different types of germ cells including spermatogonia and spermatocyte cells were observed in Fresh and frozen-thawed testicular tissue.
The expression level of ACRBP was significantly increased in the fresh culture group with growth factors and in the frozen-thawed culture group with growth factors (P≤0.05).
Limitations, reasons for caution: Further studies are needed, where the culture medium enriched with several supplements or growth factors, for better results.
Wider implications of the findings: The slow programmed freeze of the 3D agarose testicular tissue culture appears to be a useful method to maintain long-term preservation, especially for children with cancer before initiating treatment with chemotherapy or radiotherapy.These results will encourage researchers to set up a culture system for in vitro spermatogenesis.
Trial registration number: not applicable

P-422 Translating male cancer patients' needs into a professional development intervention that improved fertility preservation knowledge and referral among oncology healthcare providers

W.M. Buckett, M.B.B.Ch.-M.D.[1], B. Herrero[2], G. Raskovic[3], M.C. Brabant[4], P. Chan[5]

[1]MUHC Reproductive Centre, Obstetrics and Gynecology- McGill University, Montreal, Canada ;
[2]MUHC, Obstetrics and Gynaecology, Montreal, Canada ;
[3]MUHC, Oncology, Montreal, Canada ;
[4]MUHC, Obstetrics and Gynecology, Montreal, Canada ;
[5]MUHC, Urology, Montreal, Canada

Study question: How do male cancer patients want to learn about fertility preservation and how can this need be addressed improving care and referral rates?
Summary answer: Cancer patients perceived their oncology healthcare providers as the most trusted source from fertility preservation. Targeted seminars for oncology healthcare professionals improved knowledge and referral.
What is known already: Clinical practice guidelines for fertility preservation recommend clinicians to discuss the potential impact of cancer treatments on future fertility with reproductive-aged cancer patients, and be prepared to refer them to a reproductive specialist, if appropriate. However, multiple publications consistently show that pre-treatment fertility counselling is disseminated to only a minority of newly diagnosed cancer patients. Effective and co-ordinated strategies to overcome this and improve quality of life after cancer are urgently needed. One barrier is the lack of understanding of cancer-related infertility and available resources amongst both patients and their oncology practitioners.
Study design, size, duration: Co-ordinated and targeted regional strategy comprising: (1) Cancer patient surveys (March-July 2016) to determine fertility preservation needs; (2) Assessment of efficacy of educational seminars to oncology health care professionals (January 2017-December 2018); and (3) Evaluation of discussion of the effect of cancer care on subsequent fertility in men aged under 50 years and, where appropriate, referral rates (January 2018-July 2019)
Participants/materials, setting, methods: Male cancer patients (n=45) completed surveys about cancer and fertility and to choose most trusted sources for information - oncology healthcare professional (HCP); other HCP; peers; educational material; websites. Seminars were given at 7 different regional sites. Oncology HCPs (n=109) completed a pre- and post-surveys and differences were analyzed. Targeted chart review of men with a new diagnosis of cancer under 50 was undertaken to evaluate fertility preservation discussion and overall referral rates were measured.
Main results and the role of chance: The median age of patient respondents was 30 years and 69% were in a relationship. The majority (89%) of patients perceived oncology HCPs as the most trusted source to learn about fertility preservation and 11% preferred to learn from another channel of information (videos, brochures, websites). Following the survey and in order to fulfill the need expressed by respondents, a series of seminars were organized to bring awareness and knowledge to healthcare providers about fertility preservation and how to access the service. The mean pre-session knowledge score was 2.08, 2.46 and 2.06 for nurses, physicians and allied HCPs respectively, whereas the mean post-session knowledge score was 3.73 ($p<0.05$) for all. Documented evidence of discussion was 15% and referral rate for fertility preservation was 7.7% (104/1345) pre-intervention. The discussion rate was 35% and the referral rate 21% (379/1807) post-intervention ($p<0.001$). The reasons for non-discussion and non-referral were assessed.
Limitations, reasons for caution: The study samples size are small, and the fact that the seminars were performed in university-based hospitals limit the generalization of these findings. Furthermore, the evaluation of discussion and referral rates overlap the period of the educational intervention.
Wider implications of the findings: Oncology HCPs are perceived as the most trusted source of health information and advice among young male adults with cancer. Therefore, increasing knowledge of healthcare providers in fertility preservation could enable proactive and open discussions with patients, thus enhancing the quality of counselling and improving access to care.
Trial registration number: Not applicable

P-423 Oncofertility cares provided to patients: results from a systematic review of literature revealed a low adhesion to fertility preservation services due to accessibility barriers

J. Daolio[1], L. De Panfilis[2], M. Perin[2], M.C. Bassi[3], L. Mangone[4], M.T. Villani[1], A. Nicoli[1]

[1]Azienda Unità Sanitaria Locale - IRCCS di Reggio Emilia, Departement of Obstetrics & Gynecology, Reggio Emilia, Italy ;
[2]Azienda Unità Sanitaria Locale - IRCCS di Reggio Emilia, Unit of Bioethics, Reggio Emilia, Italy ;
[3]Azienda Unità Sanitaria Locale - IRCCS di Reggio Emilia, Medical Library, Reggio Emilia, Italy ;
[4]Azienda Unità Sanitaria Locale - IRCCS di Reggio Emilia, Unit of Epidemiology, Reggio Emilia, Italy

Study question: What kind of barriers could hinder the use of fertility preservation services?
Summary answer: Barriers in knowledge, attitude and organization of oncofertility cares could be present at patient, health providers and organizational levels limiting the adherence to service.
What is known already: International guidelines on oncofertility cares recommend to counsel patients of childbearing age about the risk of infertility following cancer treatment and options available to preserve fertility. Patients without fertility preservation choices before treatments have negative psychological consequences during the course of treatments and, in case of survival, on quality of life. Poor adherence to guidelines is acknowledged due to the presence of barriers in daily clinical practice regarding healthcare providers and information provided to patients hindering the access to fertility preservation services (FPS). In our realty, only 16,7% of patients were counseled for FPS between 2015-2017.
Study design, size, duration: This study was conducted from August 2019 to November 2019 as part of a major healthcare pathway about oncofertility services. In the first phase, we conducted a comprehensive systematic review of literature with the keywords "fertility preservation", "cancer", "education", "engagement"; in the second phase, results will be used by an expert team of Embryologists and Bioethicists to define educational interventions to overcome barriers in our network.
Participants/materials, setting, methods: The electronic search was conducted in Medline, Embase and Cinahl, and led to identify a set of 1540 items. The selection was confined to articles in English language only. Three authors screened individually all the items by title and abstract, and, after removing

duplicates and discussing about discrepancies, a selection of 320 articles was finally considered for the evaluation of contents.
Main results and the role of chance: The analysis by text revealed 4 key items on which the educational interventions could be focused: healthcare providers, patients, patient's engagement and implementation of educational FPS programs aimed at identifying criticisms on oncofertility decision-making counseling before treatments. Both healthcare providers and patients challenge with FPS barriers concerning communication, inappropriate support for a conscious decision-making process or lack of knowledge about fertility preservation strategies, etc. These represent core items on which building educational programs aimed to increase the discussion rate on FPS between clinicians and patients, by ensuring a personalized care path to patients in terms of time, use of available resources, quality and continuity of care, and a good quality of life. Suggested tools are the development of a multidisciplinary team, a script-based approach, the partners or relatives involvement at the time of counseling, the release of informative material and the training of professional figures working between oncologic and reproductive care services (nurses or midwives).
Limitations, reasons for caution: It is important to keep on sensitizing all multidisciplinary healthcare professionals involved in cancer care to avoid the underestimation of FPS barriers.
Wider implications of the findings: The evaluation of effectiveness of FPS awareness-raising interventions in terms of patient engagement can increase the number of FPS accesses, improve the knowledge of cancer therapies and the quality of the clinician/patient relationship. The implementation of multidisciplinary FPS programs can also increase the adherence to national guidelines on oncofertility cares.

P-424 In vitro nanoparticle-mediated delivery of MicroRNA 143 and MicroRNA 206 on spermatogonia and cancer cell apoptosis

A. Shams[1], M. Koruji[2], R. Shabani[3], M. Asghari[4], M. Karimi[5]

[1]Iran univesity of medical sciences, reproductive biology, tehran, Iran ;
[2]Iran univesity of medical sciences, anatomy, tehran, Iran ;
[3]iran university of medical sciences, anatomy, tehran, Iran ;
[4]Tabriz university of medical sciences, statistics, tabriz, Iran ;
[5]Iran univesity of medical sciences, nanotechnology, tehran, Iran

Study question: to assess the efficiency of PLGA-miR 143/206 transfection on apoptosis in mouse leukemia cancer cells (El4) and spermatogonial stem cells (SSCs)
Summary answer: we were able to induce apoptosis on cancer cells without any significant damage to spermatogonial stem cell by using smart transfection.
What is known already: A promising method to preserve fertility in children with cancer is via testicular biopsy before the onset of cancer treatment, followed by isolation, proliferation, maintenance and transplantation. One of the methods for the decontamination of cancerous cells from testicular cell suspensions can be smart nanoparticles. Smart gene delivery via Nanoparticles can be targeted and concurrently minimize damage to healthy cells in cancer treatments.Many microRNAs (MiRs) are used to induce apoptosis in cancer cells.Many studies have shown the effect of MiRs 143 and 206 on induction of apoptosis in many cancer cells. ransfection of MiRs via nanoparticles has been very promising.
Study design, size, duration: This study was in vitro animal experiment and it was done on 50 neonate mouse. This study was conducted over a period of 9 months
Participants/materials, setting, methods: mouse spermatogonia and cancer cell were used. To obtain a suitable miR dose that can induce apoptosis in cancer cells, while not harming SSCs, several doses were evaluated. Cells were treated separately at 3 doses of each miR (for miR 143, doses of 25, 50 and 75 nmol and for miR 206, doses of 50, 100 and 150 nmol) at 24, 48 and 72 hours. Viability and apoptosis were investigated by MTT and Annexin Kits
Main results and the role of chance: Based on MTT assay results, the optimal dose of miR 143 was 75 nmol (61.24%±2.85 SSC and 45.57%±0.78 EL4) (P≤0.05), and for miR 206, the optimal dose was 150 nmol (53.82%±6.7 SSC and 28.14%±3.01 EL4) (P≤0.05). The optimal time was 48h. these doses, the survival rate of the EL4 cells was below IC50 and SSC survival was above 50%. Annexin V staining also confirmed the selected doses (for miR 143 total apoptosis was 6.93%±2.8 SSC and 38.2%±13.2 EL4 (P≤0.05), and miR 206 was (14.6%±5.5 SSC and 38.3%±23.7 EL4) (P≤0.05).
Limitations, reasons for caution: The biggest limitation of this study was the failure to perform it on human specimens
Wider implications of the findings: Taken together, this study suggests that MiR -therapy may lead to the development of novel therapeutic strategies for cancer, and apoptotic MiRs may be a potential therapeutic agent for human tumors and is worthy of further investigation.
Trial registration number: 96-01-30-29861

P-425 Does letrozole supplementation during ovarian stimulation for fertility preservation impact early luteal progesterone levels following GnRH agonist trigger

I. Lalami[1], M. Peigné[1], C. Vinolas[2], F. Krief[2], I. Cédrin[1], M. Grynberg[1]

[1]Hôpital Jean Verdier, Department of Reproductive Medicine and Fertility Preservation, Bondy, France ;
[2]Hôpital Jean Verdier, Department of Reproductive Medicine and Fertility Preservation-, Bondy, France

Study question: To investigate early luteal progesterone levels following GnRH agonist (GnRHa) trigger after controlled ovarian stimulation (COS) in cancer patients with or without letrozole supplementation (COSTLES).
Summary answer: Following GnRHa trigger, early luteal phase progesterone levels are significantly lower in COSTLES when compared with stimulation performed without aromatase inhibitor.
What is known already: Oocyte vitrification after COS is the first line and most effective method for fertility preservation (FP) prior to cancer treatment. However, COS leads to supraphysiologic serum estradiol levels that could be potentially harmful in estrogen-sensitive diseases such as breast cancer. To protect patients from the potential adverse effects of elevated estradiol levels during COS, specific FP protocols using aromatase inhibitors (letrozole) have been developed recently. However, data on luteal progesterone levels following COS are lacking despite rising evidence of the role of progesterone in breast tumorigenesis.
Study design, size, duration: This retrospective study was conducted from July 2014 to December 2019. Serum progesterone levels following GnRHa trigger measured in 84 breast cancer patients undergoing COSTLES were compared to those obtained in 162 FP patients stimulated without letrozole administration.
Participants/materials, setting, methods: This study was performed in a public tertiary hospital. All women underwent COS with GnRH antagonist protocol. In COSTLES, the aromatase inhibitor was started 2 days before recombinant FSH administration and continued until GnRHa trigger. Final oocyte maturation was induced by injection of 0.2 mg of triptorelin, 36 hours before oocyte pick-up in both groups of patients. Serum hormonal levels of estradiol, LH and progesterone were measured in the morning following the injection of triptorelin.
Main results and the role of chance: Patients in COS without letrozole and COSTLES groups were comparable in terms of age (31.7±0.4 vs. 32.7±0.5, respectively), BMI (23.6±0.5 vs. 23.4±0.4 kg/m²), antral follicle count (22.2±1.0 vs. 22±1.7 follicles) and serum anti-Müllerian hormone levels (3.1±0.2 vs. 2.6±0.8 ng/mL). They received comparable total amount of exogenous FSH (3167.3±251.9 vs. 2981.2±237.2 IU). As expected, on the day following GnRHa administration serum estradiol levels were lower in COSTLES cycles (650.3±57.7 vs. 2451.4.0±144.0 pg/mL, p<0.01). However, GnRHa-induced LH surge was significantly higher in patients having received aromatase inhibitors (71.9±4.6 vs. 51.2±2.6 UI/L, p<0.01). In addition, serum progesterone levels were significantly lower in the COSTLES group (8.6 ± 0.7 vs. 10.5 ± 0.5 ng/mL, p< 0.03). Otherwise, the mean number of oocytes recovered (14.2±0.7 vs. 14.1±0.9 oocytes, respectively) and vitrified at metaphase 2 stage (10.1±0.6 vs. 10.0±0.7 oocytes) did not differ significantly between COS without letrozole and COSTLES.
Limitations, reasons for caution: Serum progesterone levels were available only once, during the very early luteal phase.
Wider implications of the findings: The higher LH surge following GnRHa administration in COSTLES protocol may be in relation with a weaker negative

feed-back of estradiol on the hypothalamic-pituitary axis. However, the lower serum progesterone levels might suggest a suppressive effect of letrozole in its production. Further analysis is required to confirm the mecanisms.
Trial registration number: not applicable

P-426 Gonadotrophin stimulation and risk of relapse in breast cancer

A. Fredriksson[1], E. Rosenberg[2], Z. Einbeigi[3], C. Bergh[1], A. Strandell[1]

[1]Sahlgrenska University Hospital, Reproductive Medicine, Gothenburg, Sweden ; [2]Sahlgrenska University Hospital, Gynaecology, Gothenburg, Sweden ; [3]Southern Älvsborg Hospital, Department of Medicine- Oncology, Borås, Sweden

Study question: Is gonadotrophin stimulation as part of IVF associated with an increased risk of relapse in breast cancer?
Summary answer: Controlled ovarian hyperstimulation (COH) in connection with IVF in women with previous breast cancer was not associated with an increased risk of breast cancer relapse.
What is known already: Breast cancer is the most common malignancy among women in the world and the leading cause of cancer death among females. The use of COH with gonadotrophins in order to rescue the fertility by cryopreservation of oocytes or embryos prior to cancer treatment is currently the most established fertility preservation method for women with breast cancer. To date, there are only a few small retrospective hospital-based controlled studies evaluating the risk of breast cancer relapse in patients undergoing fertility preservation with or without COH showing no evident risk of relapse in breast cancer after the use of chemotoxic agents.
Study design, size, duration: This was a retrospective, population-based, matched cohort study comprising a total of 5857 women, previously treated for breast cancer of whom 337 were exposed to COH. Exposure for COH and outcomes as relapse and death were identified for all patients from 2003 to 2014 by assessing national registries holding data on IVF, births, prescription of drugs, causes of death and cancer diagnoses. Relapse, when non-registered, was calculated based on typical diagnoses and procedures, indicating relapse.
Participants/materials, setting, methods: Women aged 20-44 years, previously diagnosed with breast cancer and exposed to COH, were matched for age at breast cancer diagnosis +/- five years, tumour size and lymph node involvement to a non-exposed control group. In a subsequent secondary analysis the entire cohort was assessed with adjustments for N- and T-stages.

The risk of r2elapse in breast cancer was estimated as crude hazard ratios (HRs) and 95% confidence intervals using Cox proportional hazards models.
Main results and the role of chance: In the matched cohort relapse occurred in 27 of 337 (8.0%) women having undergone COH compared with 71 of 334 (21.3%) among the non-exposed (HR=0.60; 95% CI 0.37-1.00; p=0.051). In the secondary analysis with adjustments for T- and N stages the risk remained low after COH exposure; 27/337 (8%) in the exposed cohort compared with 1176/5520 (21.3%) in the control group (HR=0.54; 95% CI 0.34-0.84; p=0.006). In the exposed cohort nine breast cancer related deaths (9/27; 8%) occurred compared with 555 in the non-exposed control group (555/5220; 10.1%). The coding template for assessing relapse from diagnoses and procedures in regions where relapse was not a registered variable, compared with a reference region, resulted in a sensitivity of 95% and specificity of 87%.
Limitations, reasons for caution: A substantial degree of missing data on important prognostic variables was a limitation. Further, data on confounding factors were not completely covered. Another limitation was that the variable 'relapse' had been introduced only in one region and had to be calculated from other variables.
Wider implications of the findings: In this large, retrospective, matched cohort study we found no risk of relapse in breast cancer among women who had been exposed to gonadotrophins as part of IVF. This is reassuring but probably confounded by selection to IVF of a group of women with a more favourable prognosis.
Trial registration number: Not applicable

P-427 Clustering of primordial follicles during reproductive ageing

A. Schenck[1], G. Greggains[1], M.V. Rodriguez[1], B. Davidson[2], P. Fedorcsak[1]

[1]Oslo University Hospital, Department of Reproductive Medicine, Oslo, Norway ; [2]Oslo University Hospital, Department of Pathology, Oslo, Norway

Study question: What is the spatial distribution of primordial follicles the human ovarian cortex during the reproductive lifespan?
Summary answer: Follicles lie clustered in the human ovarian cortex; average cluster radius is ~270µm. At older age, degree of clustering increases and the cluster size decreases.
What is known already: In mice, the distribution of follicles is clustered, and the degree of clustering is increased in aged mice. In human, primordial follicles distribute unevenly in the ovarian cortex, but the pattern of distribution has been unknown.
Study design, size, duration: Observational study using ovarian tissue samples derived from patients undergoing fertility preservation treatment at an academic hospital.
Participants/materials, setting, methods: Ovarian tissue samples derived from 14 patients (aged 20.8 – 35.2, mean 28.1 years) were obtained after unilateral oophorectomy. Cortical fragments were processed for quantitative histological assessment, including recording of two-dimensional coordinates of primordial follicles and stage of follicle development. The spatial distribution of follicles was tested and cluster radius was calculated. Loss of follicles was modeled with computer simulation, comparing alternative models of follicle loss dynamics.
Main results and the role of chance: Primordial follicles form clusters with a radius of ~270 µm in the ovarian cortex, which is increasingly apparent with ageing. At older age, follicle density declines and the distance to the nearest neighbouring follicle increases, the cluster radius decreases, but the degree of clustering increases. Computer simulation of follicle loss dynamics indicate the close-range follicle-to-follicle signalling may contribute to the emergence of clusters during reproductive ageing.
Limitations, reasons for caution: The tissue was obtained for diagnostic purposes. The small size of the fragments may limit the validity of assumptions of the spatial statistical analysis. All tissue samples were sectioned in the same orientation, limiting comprehensive three-dimensional analysis.
Wider implications of the findings: Clustering may impede precise estimation of total follicle count, the imprecision increasing with age. Excessive dissection of ovarian tissue fragments on ~ 0.5 mm scale may disrupt clusters and interfere with close-range follicle-to-follicle signalling, causing rapid graft exhaustion.
Trial registration number: not applicable

P-428 Semen quality and cryopreservation in patients with brain tumors.

D. Rivet-danon[1], C. Jean[1], A.S. Gille[1], C. Chalas[1], C. Patrat[1], V. Drouineaud[1]

[1]Assistance Publique – Hôpitaux de Paris AP- HP Centre- Université de Paris, Service de Biologie de la Reproduction - CECOS, Paris, France

Study question: Do initial sperm parameters of a patient with brain tumor make cryopreservation possible?
Summary answer: Overall, initial mean sperm parameters are normal except for progressive motility in pineal region tumors and make possible cryopreservation in the vast majority of cases.
What is known already: Baseline data on semen quality and cryopreservation in patients presenting brain tumors are mainly based on small sample sizes and results of various studies are controversial. Melatonin is a neurohormone secreted by the pineal gland. Literature data show that melatonin affects secretion of both gonadotropins and testosterone, and can influence sperm quality. Moreover, men having reduced sperm motility present lower levels of melatonin in semen than patients with normal sperm parameters. Furthermore, in vitro addition of melatonin in semen shows an increase of sperm progressive motility.
Study design, size, duration: This was an 8 years retrospective and observational study including patients with brain tumors, referred for sperm cryopreservation before a potentially gonadotoxic treatment, to the Paris Cochin University Hospital sperm bank (Centre d'Etude et de Conservation des Œufs et du Sperme humains, CECOS). The location of brain tumors plus clinical and histological data were collected as well as sperm parameters before freezing and after thawing. Fertile sperm donors were recruited between 2014 and 2016.

Participants/materials, setting, methods: Two hundred and fourteen brain tumor patients aged 14-58 years old and 92 fertile sperm donors were included. Sperm parameters were analyzed before freezing and after thawing, according to the World Health Organization's (WHO) 2010 guidelines. Sperm parameters and the quality of sperm straws were compared on one part between patients with brain tumors, in particular according to the location of the tumor, and on other part between patients and fertile sperm donors.

Main results and the role of chance: Among the 214 patients, brain tumor location was recorded in 183 patients: pineal gland (26), hypothalamic-pituitary axis (7) and other periphery brain regions (150).

In all patients, each mean initial sperm parameter was normal according to the WHO 2010 criteria (total sperm count: 326.5 ± 433.2 x 10^6, sperm concentration: 95.9 ± 108.16 x 10^6/ml, progressive motility: 32.7 ± 14.8%), except sperm vitality which was low (53.2 ± 19.2%).

However, mean progressive motility (p<0.001), vitality (p<0.001), morphology (p=0.03) and number of motile spermatozoa per straw (NMSPS) (p=0.008) were significantly lower in brain tumor patients than in donors, respectively.

In pineal brain tumor patients, mean sperm progressive motility was low according to the WHO 2010 criteria (27.8 ± 13.4%) and significantly lower than in the case of hypothalamic-pituitary tumors (27.8% vs 45.0%; p=0.009). All mean sperm parameters of patients with pineal tumor were significantly reduced compared to those of fertile donors (total sperm count, p=0.02; sperm concentration, p=0.005; progressive motility, p<0.001; vitality, p<0.001; morphology, p=0.01; NMSPS, p=0.01, respectively).

Severe oligozoospermia (sperm concentration <1 x 10^6/ml) was significantly more frequent in patients with pineal tumor than in periphery locations (p=0.007).

More than 90% of patients could bank sperm regardless of tumor location.

Limitations, reasons for caution: The abstinence period was high in patients with brain tumors and could explain the low sperm vitality and motility observed. The disease itself and/or brain surgery and/or the associated altered general state in those patients probably influenced the long abstinence delay.

Wider implications of the findings: Patients with brain tumors showed suitable sperm parameter allowing cryopreservation in most cases, even in pineal gland tumor patients. Importantly, sperm straws could be used for Assisted Reproductive Technologies (ART) if necessary. Those results confirm the importance of sperm cryopreservation in those patients before a potentially high gonadotoxic treatment.

Trial registration number: not applicable

P-429 Fertility preservation outcomes among adolescent transgender boys before testosterone treatment compared with adolescent cisgender girls

H. Amir[1], A. Oren[2], E. Klochendler Frishman[3], O. Sapir[3], Y. Shufaro[3], F. Azem[1], A. Ben-Haroush[3]

Study question: What are the fertility preservation (FP) outcomes among adolescent transgender boys before testosterone treatment compared with adolescent cisgender girls?

Summary answer: FP outcomes from assisted reproductive technology (ART) among adolescent transgender boys are excellent compared to adolescent cisgender girls.

What is known already: ART enables young transgender men to have genetically related children and overcome gender-affiliation hormone (i.e. testosterone) therapy-related fertility impairment. Although medical FP outcomes in young cancer patients who preserve fertility before exposure to anticancer therapy are well known, there are no data on FP outcomes among transgender boys before initiating testosterone therapy.

Study design, size, duration: This retrospective cohort study included 11 adolescent transgender boys and 39 adolescent cisgender girls who underwent FP between January 2017 and April 2019 and September 2013 and April 2019, respectively.

Participants/materials, setting, methods: Eleven transgender boys (mean age 16.4y) and 39 cisgender girls (mean age 15.5y) were referred to FP at IVF units of two tertiary university-affiliated medical centers. The transgender boys (study group) were referred before initiating testosterone treatment and the cisgender girls (control group) were referred due to cancer diagnosis before starting anticancer treatment. Control ovarian stimulation was carried out by the GnRH antagonist protocol. Statistical analyses compared ART data and FP outcomes between two groups.

Main results and the role of chance: The values of the accepted ovarian reserve markers, follicle-stimulating hormone (FSH: 5.7±1.9 mIU/mL) and antral follicle count (AFC: 20.4±5.5) of all the adolescent transgender boys were within the normal range. The transgender boys were slightly older compared to the cisgender girls (16.4±1 vs 15.5±1.3 years, respectively, $P = 0.03$). The amount of FSH used to stimulate the ovaries was significantly lower among the transgender boys compared to the cisgender girls (2308±945 IU vs 4372±1877 IU, respectively, $P < 0.001$), but the duration of ovarian stimulation was similar for both groups (12.2±3.6 and 10.1±2.8 days, respectively, $P = 0.092$). There were no significant differences between the transgender boys and cisgender girls in peak estradiol levels (2660±2532 pg/mL vs 1269±975 pg/mL, respectively, $P = 0.053$), the number of retrieved oocytes (30.5±11.4 vs 22±13.2, respectively, $P = 0.062$), the number of MII oocytes (24.9±11.7 vs 18.8±11.2, respectively, $P = 0.122$), and the maturity rates (80±10.5% vs 85.4±14.6%, respectively, $P = 0.118$).

Limitations, reasons for caution: Our control group consisted of oncology patients in whom the ovarian reserve and the ovarian stimulation response may be affected by the underlying disease and it may, therefore, not be representative of the general healthy population.

Wider implications of the findings: Adolescent transgender boys have a normal ovarian reserve and an excellent response to ovulation stimulation before initiating testosterone treatment. Oocyte cryopreservation is, therefore, a feasible and effective way for them to preserve their fertility for future biological parenting.

Trial registration number: Not required

P-430 Passive slow freezing is an easy, cost-effective and efficacious alternative freezing method for slow controlled cryopreservation of ovarian tissue.

S. Lierman[1], A. Bus[2], S. Andries[2], P.E.J. Bols[2], K. Tilleman[1]

[1]University Hospital Ghent- Fertility and Stem cell Team, Department for Reproductive Medicine, Ghent, Belgium ;
[2]Laboratory for Veterinary Physiology and Biochemistry- Gamete Research Centre, Faculty of Pharmaceutical Biomedical and Vetrinary Science- University of Antwerp, Antwerp, Belgium

Study question: Is there a difference in follicle activation after xenotransplantation of passive slow frozen ovarian tissue compared to standard controlled frozen tissue?

Summary answer: Human primordial follicles have similar developmental capacity in a xenotransplantation model after passive slow rate freezing (PSF) compared to the control slow rate freezing (CSF).

What is known already: For the moment, CSF is the established method for the freezing of cortical fragments of ovarian tissue (OT). CSF requires expensive computerized equipment and the process is time-consuming. There is a risk for technical failures with the potential loss of precious material. Other techniques like tissue vitrification are promising. However, the technique is expensive and laborious. PSF is a technique that is successfully used in freezing of in vitro cell cultures and testicular tissue of different animal species including human (Goossens et al., 2013). Until today no studies have described PSF for human ovarian tissue.

Study design, size, duration: Xenotransplantation was performed in the pouch between the musculus obliquus and peritoneum of Balbc/nude mice (n=24). On each side of the incision at the linea alba, a PSF and a CSF frozen-thawed OT-piece of the same patient was introduced. After 2,4 and 6 weeks transplantation, mice were euthanized by cervical dislocation and grafts were collected, fixed in 4% buffered formalin and embedded in paraffin for HE staining. All xenotransplantation experiments were performed in duplo.

Participants/materials, setting, methods: In total, 48 OT strips from 4 transgender patients were frozen using L-15+0.45% HSA+DMSO (1.5M). For

CSF a programmable freezer was used (2°C/min:4°C to –9°C; seeding at –9°C; –0.3°C/min to –40°C and to –140°C by 10° C/min). PSF was performed using an isopropyl alcohol container (Mr. Frosty, Nalgene) and stored at –80 °C overnight at ≈ -1°C/min. Follicle activation and the fibrotic surface area by Masson Trichrome staining were analyzed. Fisher's exact-test was performed.

Main results and the role of chance: The grafting recovery rate was 95.8% (46/48 OT-strips). Both freezing procedures, PSF versus CSF, showed similar amounts of primordial follicles after 2 hours of warming before transplantation (53.0% (1690/3188) versus 54.7% (1309/2393) (P=0.220)).

After 2 weeks of transplantation, a clear and significant activation of primordial follicles in both cryopreservation methods was seen compared to the non-transplanted tissue. For PSF (85.3% (290/340) versus 47.0% (1498/3188) and CSF (72.7% (288/396) versus 45.3% (1084/2393), (P<.0001).This activation shift was significantly higher in PSF compared to CSF (85.3% (290/340) versus 72.7% (288/396) (P<.0001). After 4 weeks, the PSF technique showed a higher percentage of secondary follicles in the growing follicle pool in comparison to CSF 37.6% (65/173) versus 6.8% (4/59) (P<0.001).

After 6 weeks, the proportion of secondary follicles was not significantly different between the two methods (CSF 47.5% (19/40) versus PSF 38.5% (15/39)).

The percentage of fibrosis in the xenograft was comparable for PSF versus CSF for the 2 and 4 weeks (10.25±0.37 versus 10.50±0.37) and (9.42±0.47 versus 10.02±0.37). After 6 weeks transplantation, graft tissue from the PSF showed a higher percentage fibrotic area compared to the tissue of the CSF (13.56±0.48 versus 11.55±0.46, (P=0.003)).

Limitations, reasons for caution: Although the follicle activation and growth in xeno transplanted human OT after PSF is similar to CSF, PSF has not yet been used in transplantation in human. The true competence of the PSF frozen tissue still needs proof of concept in human.

Wider implications of the findings: Passive slow freezing (PSF) shows a significant higher follicle activation after xenotransplantation than the conventional method of freezing (CSF). PSF could be an easy and cost-effective alternative to CSF for fertility preservation of human ovarian tissue.

Trial registration number: This research is conducted with the approval of the local ethics committee 2015/0124 – B670201523543), Ethical Committee on Animal Experimentation (ECD18/12).

P-431 Early follicle activation, repair and death after human ovarian tissue transplantation using adipose tissue-derived stem cells

L. Cacciottola[1], G. Courtoy[2], C. Hossay[1], J. Donnez[3], M.M. Dolmans[1]

[1]Institut de Recherche Expérimentale et Clinique- Université Catholique de Louvain, Gynecology Research Unit, Brussels, Belgium ;
[2]Institut de Recherche Expérimentale et Clinique- Université Catholique de Louvain, Imaging Platform, Brussels, Belgium ;
[3]Society for Research into Infertility, Av. Grandchamp 143, Brussels, Belgium

Study question: Does ovarian tissue transplantation (OTT) using adipose tissue-derived stem cells (ASCs) yield better follicle outcomes shortly after transplantation than the standard procedure?

Summary answer: Improved survival, reduced activation and better maintenance of repair mechanisms were observed in primordial follicles 3 days after grafting using ASCs compared to standard OTT.

What is known already: OTT has gained ground as a valid fertility restoration approach thanks to its established effectiveness. Nevertheless, more than 50% of follicles are lost after transplantation due to two main mechanisms: prolonged hypoxia and massive follicle activation, the latter known as the 'burn out' effect. ASCs have been shown to shorten the hypoxic/ischemic period by boosting revascularization in human xenografts, thereby increasing follicle survival. It is also known that hypoxia-related signaling is able to modulate several pathways involved in cell survival and follicle activation, like the PI3K/pAKT and Hippo pathways.

Study design, size, duration: Twenty nude mice (Swiss Nu/Nu) were grafted with frozen-thawed ovarian fragments from 5 patients. Ten of them underwent OTT in 2 steps using ASCs, as previously described by Manavella et al. (ASCs+OT group), and the remaining ten using the standard procedure (OT group). In each group, grafts were retrieved on days 3 (n=5) and 10 (n=5). One fragment was taken from each patient to serve as non-grafted controls.

Participants/materials, setting, methods: Prospective experimental study conducted in an academic gynecology research laboratory.

Retrieved xenografts were analyzed by histology (follicle count and classification), immunohistochemistry (caspase-3 for apoptosis and LC3B for autophagy) and immunofluorescence (analysis of follicle activation pathways): (i) FOX01 cytoplasm translocation for PI3K/pAkt pathway activation; and (ii) YAP nuclear translocation for Hippo pathway activation. Immunostained cellular localizations were determined in primordial follicles by image acquisition using the Axio Imager with ApoTome at 63x magnification.

Main results and the role of chance: The ASCs+OT group showed significantly higher follicle density and lower follicle atresia than the OT group over time. Nevertheless, ASCs did not appear to modulate apoptosis, as the rate of caspase-3+ follicles was higher in both groups after 3 days compared to non-grafted controls (2-step/ASCs+OT group: 24.3 %; OT group: 25%; non-grafted controls: 3.75%; p<0.05). Regarding autophagy, average LC3B staining concentrations were similar in the ASCs+OT group and non-grafted controls, but significantly lower in primordial follicles in the OT group, indicating less active cell repair.

FOX01 localization was mainly nuclear in oocytes of primordial follicles in non-grafted controls. A significant shift to cytoplasmic localization (follicle activation marker) was observed in the OT group on day 3, while the ASC+OT group showed no difference from non-grafted controls.

YAP localization was largely cytoplasmic in granulosa cells of primordial follicles in non-grafted controls, but shifted significantly to nuclear (follicle activation marker) in both grafted groups 3 days after OTT. ASCs appeared to confer a protective effect on primordial follicles by suppressing the PI3K/pAKT pathway. However, there was no evidence of Hippo pathway modulation by ASCs.

Limitations, reasons for caution: These findings warrant long-term studies investigating maintenance of the primordial follicle pool over time, with a view to clinical application in patients undergoing OTT.

Wider implications of the findings: The present study provides further insights into the mechanisms of action involved in follicle activation and cell repair, underlining the beneficial impact of ASCs in grafted ovarian tissue. We also demonstrated that ASCs exert positive effects on the ovarian reserve by protecting primordial follicles.

P-432 TurnerFertility study: preliminary data on fertility preservation by ovarian tissue cryopreservation in young girls with Turner syndrome

S. Nadesapillai[1], M. Schleedoorn[1], R. Peek[1], D. Braat[1], J. Van der Velden[2], K. Fleischer[1]

[1]Radboud University Medical Center, Obstetrics and Gynaecology, Nijmegen, The Netherlands ;
[2]Radboud University Medical Center, Pediatric Endocrinology, Nijmegen, The Netherlands

Study question: Which girls with Turner syndrome (TS) could benefit from fertility preservation by ovarian tissue cryopreservation (OTC), based on the presence of follicles in relation to karyotype, clinical and hormonal data?

Summary answer: Girls with TS who have favourable predictive parameters (e.g 46,XX cell line, a measurable AMH or spontaneous puberty) could benefit from fertility preservation by OTC.

What is known already: Infertility due to premature ovarian insufficiency is a major concern for girls with TS and their parents. Physicians are often asked about possible options to preserve their fertility. However, evidence for successful fertility preservation by OTC/autotransplantation in these girls is lacking and many questions remain. Without evidence on the effectiveness of OTC it cannot routinely be offered to girls with TS.

Study design, size, duration: A national prospective exploratory intervention study. Ovarian cortex will be obtained after unilateral ovariectomy from 100 girls with TS aged 2-18 years. Patients will be included between 2017 and 2020.

Participants/materials, setting, methods: All girls with TS who have completed the diagnostic work up of TS were included. After unilateral ovariectomy, one fragment of the ovarian cortex was used to determine the number of follicles by serial sectioning and staining. Karyotyping of ovarian cells, lymphocytes, buccal

cells and urine cells was performed by Fluorescence in situ hybridization (FISH). Blood samples obtained before ovariectomy and during the yearly clinical visit after ovariectomy will provide information on hormonal parameters.

Main results and the role of chance: Currently, we have received 98 informed consent forms and 66 girls (age 3-19) had an unilateral ovariectomy. Oocytes were found in 27% of the girls (n=18; age 5-17). In this group, 5 girls were prepubertal, 12 girls had a spontaneous thelarche (age 10-17) and 4 girls had a spontaneous menarche (age 13-16). Hormone values and the chromosome pattern were found to be predictive parameters for the presence of follicles. In this cohort, the chance of finding follicles in girls with a 46,XX cell line is three times higher than in girls without a 46,XX cell line. Until now, there was only 1 girl with 45,X cells in lymphocytes and buccal cells (n=25) who had follicles and a measurable AMH. FISH was used to karyotype the ovarian cortex cells of 5 patients with a mosaicism and revealed that 42 of the 46 oocytes that were analysed had a normal X-chromosomal content. Granulosa cells were largely 45,X, but showed different levels of X chromosome mosaicism, not only between patients but also between individual follicles of the same patient. Despite the presence of a low percentage (10–45%) of 46,XX ovarian stromal cells, normal macroscopic ovarian morphology was observed.

Limitations, reasons for caution: The final analysis will be performed when the dataset of 100 TS girls is completed. Further research is necessary to determine the functionality of the follicles in the ovaries of TS girls and to elucidate if OTC is an effective method for fertility preservation in TS.

Wider implications of the findings: A combination of clinical, hormonal and karyotypic data could provide predictive parameters to define which girls with TS might benefit from fertility preservation. These parameters could help physicians during fertility preservation counselling to determine if OTC is an option for a certain girl with TS.

Trial registration number: NCT03381300

P-433 Experience with 54 cryopreserved ovarian tissue grafts in a single centre: the devil in reporting details!

G. Rozen[1], F. Agresta[2], D. Gook[1], S. Siii[3], K. Stern[1]

[1]Royal Women's Hospital and Melbourne IVF, Reproductive Services, Melbourne, Australia ;
[2]Melbourne IVF, Reproductive clinic, Melbourne, Australia ;
[3]South West Healthcare- 25 Ryot Street- Warrnambool- 3280, Obstetrics and Gynaecology, Victoria, Australia

Study question: Following transplantation of cryopreserved ovarian tissue, what are IVF outcomes per cycle and are there factors related to this technique which impact on success.

Summary answer: Mature oocytes which resulted in pregnancies were largely harvested from non-ovarian grafts. Longer duration of ovarian activity correlated with increased tissue volume and follicle density.

What is known already: Transplantation of cryopreserved ovarian tissue has a unique role for fertility preservation and over 140 live births have now been published. Nevertheless, uncertainties remain regarding its efficacy, with success of this technique reported inconsistently and mostly reported per patient, rather than per cycle started or embryo transferred as is used in conventional IVF. This hampers identification and optimisation of factors which may predict success, such as grafting sites and tissue volumes.

Study design, size, duration: We analysed a case series of reproductive outcomes throughout the IVF treatment process following ovarian tissue transplantations at our centre (2006-2019), with tissue frozen in the years 1996-2018. This included 54 grafting procedures in 40 patients, following a diagnosis of premature ovarian insufficiency. Results of modified low-dose stimulation and oocyte retrieval, including both oocyte cryopreservation and IVF cycles were reviewed.

Participants/materials, setting, methods: Ovarian tissue was harvested from 40 patients at risk from gonadotoxic treatment at median age of 26 years (range 18-39). Almost 30% of patients had their tissue frozen elsewhere. Nine of 31 patients (29%) had prior cytotoxic treatment. Following a diagnosis of premature ovarian insufficiency, ovarian tissue was grafted to pelvic sites including the ovary and adjacent pelvic side walls, as well as the anterior abdominal wall, on average five years following extraction.

Main results and the role of chance: Fifty-four grafting procedures were performed in 40 women. For patients whose tissue was cryopreserved in our centre, ovarian activity resumed in 90% of grafts, and in 64% when cryopreserved elsewhere. This was after a mean period of 5.3 months. Follicle density and tissue volume grafted appear to be the strongest predictors of ovarian activity duration over 12 months, however this does not reach statistical significance. Stimulated cycles in 25 patients with low-dose modified recombinant FSH protocol from 2012, yielded an oocyte from 68% of follicles (32% rate of empty follicles) and 75% of these were retrieved from non-ovarian grafts. Mature oocytes were retrieved from mean follicular size 13.5mm (range 6-20 mm). The overall 2PN fertilisation rate was 64%. A total of 25 fresh and frozen embryos were transferred in 15 women, yielding a clinical pregnancy rate 28% (7/25) and live birth rate of 20% (5/25). There was additionally a single, ongoing spontaneous pregnancy. All pregnancies occurred in patients aged under 32 years at cryopreservation and only one of the successful patients had prior chemotherapy exposure.

Limitations, reasons for caution: Trends alone can be observed from this data as the numbers are small.

Wider implications of the findings: This case series adds to international understanding of this technique's results. It encourages detailed and consistent reporting, as ongoing research is needed to improve efficacy. These results support offering ovarian cryopreservation to young women who are undergoing fertility threatening treatment, with optimism for future pregnancy.

Trial registration number: not applicable

P-434 Dynamic in vitro culture of human ovarian cortical tissue improves follicle growth and the expression of genes involved in follicle activation and progression.

R. Talevi[1], M.M. Pallotta[1], V. Barbato[1], M. Di Nardo[1], V. Costanzo[1], R. Ferraro[2], G. Mondrone[3], K.S. Adiga[4], T. Capriglioine[1], G. Catapano[5], R. Gualtieri[1]

[1]Università degli studi di Napoli Federico II, Dipartimento di Biologia, Napoli, Italy ;
[2]Genesis Day Surgery, IVF center, Caserta, Italy ;
[3]IVF RED srl, research, Caserta, Italy ;
[4]Kasturba Medical College Manipal Academy of Higher Education, Clinical Embryology, Manipal, India ;
[5]Università della Calabria, Ingegneria Meccanica- Energetica e Gestionale, Rende CS, Italy

Study question: Does dynamic (D) versus static culture of human ovarian cortical tissue (HOCT) better support follicle growth and expression of genes involved in follicle activation and progression?

Summary answer: D vs static culture of HOCT improves follicle progression to the secondary stage and the expression of genes involved in follicle activation and progression

What is known already: Oxygen availability, disruption of solutes gradients and application of physiological fluid mechanical stress, through dynamic culture *in vitro* of HOCT have been shown to enhance follicle growth and health. Several pathways, e.g. Hippo, Wnt, and P3K/AKT, are modulated by fragmentation and subsequent culture of HOCT *in vitro*.

Study design, size, duration: Biopsies of HOCT were fragmented into 1×1×0.5mm strips and cultured, in groups of ten, in gas-permeable dishes (PD) and in D condition for 6 days. At the end of culture, the following endpoints were assessed: 1) follicle quality and stage; 2) follicle viability; 3) expression of genes involved in follicle activation and growth. This study was approved by our local ethical committee.

Participants/materials, setting, methods: Biopsies were obtained from five consenting patients (aged 27.2±5.8) during laparoscopic surgery for benign gynecological conditions, fragmented using a tissue chopper and cultured 6 days in PD and D conditions. Follicle health and stage were assessed through histology, and live-dead far-red/Hoechst 33342 labeling. Total RNA was extracted to analyze the expression of BMP15, BMP7 (Wnt pathway), INHA (follicle growth), FOXO3, FGF2 (P3K/AKT pathway), MST2, YAP1 (Hippo signaling).

Main results and the role of chance: Overall, 2300 follicles were analyzed. At day 0 most follicles were primordial (primordial, 78.7%; primary, 18.3%; secondary, 3%), with high viability (78.8%) and good quality (grade 1, 43.6%; grade 2, 29.2%; grade 3, 27.2%). At day 6, D was superior to PD culture in terms of follicle progression (primordial, 27.8 vs 40%; primary, 50 vs 45.3%; secondary, 22.2 vs 14.7%; $p<0.01$) and quality (grade 1, 43.6 vs 33.6%; grade 2, 27.4 vs 24.6%; grade 3, 29 vs 41.8%; $p<0.01$). Viability was not significantly different

between samples (day 0: 78.8%; PD: 67.9%; D: 65.3%). At day 6 of in vitro D versus PD culture, the expression of genes involved in follicle activation (FGF2; p<0.001) and progression (BMP7, p<0.05; BMP15, P<0.01) increased, whereas the expression of the inhibitors of cell proliferation (INHA, FOXO3; p<0.001) decreased. The expression of MST2 and YAP1, components of the Hippo pathway, was different between the two in vitro culture systems. In particular, MST2 was uP-regulated and YAP1 was down-regulated (p<0.05) after D versus PD culture.

Limitations, reasons for caution: This is an In vitro study carried on a limited number of patients

Wider implications of the findings: Dynamic vs static culture, which enhances the number and health of secondary follicles, and expression of genes involved in cell proliferation and follicle growth, could represent a new tool for in vitro folliculogenesis

Trial registration number: not applicable

P-435 Can progesterone primed ovarian stimulation (PPOS) be introduced in non-medical fertility preservation? Results from vitrified oocytes from the oocyte donation program.

M. Devesa Rodriguez De La Rua[1], N.P. Polyzos[1], E. Clua[1], D. Rodríguez[1], S. García[1], L. Coll[1], F. Martínez[1]

[1]Dexeus Mujer, Obstetrics- Gynecologý and Reproductive Medicine, Barcelona, Spain

Study question: Does the type of LH peak suppression (PPOS vs. GnRH antagonist) have any effect on oocyte competence, embryo development and live birth rates in recipients of vitrified donated oocytes?

Summary answer: PPOS protocol results in equally competent oocytes / embryos and comparable live birth rates as compared with GnRH antagonist (ganirelix) in recipients of vitrified oocytes.

What is known already: It has been reported that progesterone is effective in LH peak suppression in oocyte donation and IVF cycles, with no differences in the number of retrieved oocytes or embryo quality. Although some studies have found lower pregnancy rates in recipients of oocytes coming from a PPOS cycle suppressed with medroxyprogesterone acetate, results with desogestrel did not reveal significant differences. However, no study has analyzed results coming specifically from vitrified oocytes. Assessing outcomes from vitrified oocytes coming from donation cycles suppressed with progesterone in comparison to GnRH antagonist, would allow applying the same protocol to non-medical fertility preservation.

Study design, size, duration: Retrospective cohort study carried out from 2016 to 2018 in a University affiliated private fertility clinic.

Donors: age between 18-35 years, regular menstrual cycles, BMI 18-28 Kg/m^2 and no relevant medical history. LH suppression with desogestrel (PPOS): n=83. LH suppression with ganirelix: n=83.

Recipients: age <50 years, reception of vitrified oocytes coming from oocyte donation cycles suppressed either with desogestrel (n=83) or with ganirelix (n=83).

Participants/materials, setting, methods: Donors: pretreatment with oral contraceptives, stimulation carried out with gonadotrophins and downregulated with oral desogestrel (75mg daily, from stimulation day 1 until day of trigger) or subcutaneous ganirelix (0.25 mg/day, flexible protocol).

Recipients: endometrial preparation with oral estradiol valerate (2mg/8 hours) and vaginal progesterone (200 mg/8 hours). Embryo transfer was performed on third or fifth day of embryo development. Treatment was continued until the day of βhCG and, if positive, until 10th week of pregnancy.

Main results and the role of chance: Donors: There were no significant differences concerning mean age, BMI, AMH, AFC, number of mature (21.05 ± 7.52 vs. 23.05 ± 9.28) and vitrified oocytes (12.93 ± 6.66 vs. 15.17 ± 9.92) between desogestrel and ganirelix cycles, respectively.

Recipients: Age and BMI did not differ significantly between both groups of recipients. The number of thawed oocytes was significantly lower in the desogestrel group compared to the ganirelix group (9.89 ± 4.05 vs. 10.69 ± 3, p=0.02). Warming survival rates (80.1% vs. 81.1%), fertilization rates (71.3% vs. 75%) and embryo development rate (53.1% vs. 52.1%) didn't differ significantly between desogestrel and ganirelix groups, respectively.

Embryo transfer rate did not differ significantly between the groups (91.6% in desogestrel vs. 88% in ganirelix). Endometrial thickness and estradiol levels the day of fertilization showed no significant differences but progesterone levels were significantly higher in recipients of ganirelix protocol (8.19 ± 3.08 vs. 10.15 ± 7.05, p=0.03).

Mean number of transferred embryos showed no significant differences (1.29 ± 0.62 in desogestrel vs 1.13 ± 0.6 in ganirelix, p=0.09). No statistically significant differences were found in clinical pregnancy rates (48.2% in desogestrel vs. 53% in ganirelix) and live birth rates (37.3% in desogestrel vs. 43.4% in ganirelix).

Limitations, reasons for caution: Retrospective study carried out in oocyte donors that vitrified oocytes, which is a suitable model to suggest outcomes in non-medical fertility preservation, but the study did not analyze fertility preservation cycles specifically. Further well conducted clinical trials and long-term safety studies are needed.

Wider implications of the findings: According to our findings, no significant differences were observed in oocyte competence, embryo development and live birth rates from vitrified oocytes coming from desogestrel or ganirelix suppressed cycles. Therefore, non-medical fertility preservation cycles could be suppressed with progesterone instead of GnRH-antagonists, maintaining the efficacy, increasing patient convenience and decreasing costs.

Trial registration number: not applicable

P-436 Choosing a triggering agent in oocyte preservations cycles - A comparison between gonadotropin-releasing hormone agonist (GnRH-a) and recombinant human chorionic gonadotropin (r-hCG).

E. Haikin Herazberger[1], S. Knaneh[1], D.B.Y. Ben Yosef[1], H. Amir[1], A. Reches[1], Y. Kalma[1], F. Azem[1], N. Samara[1]

[1]Tel-Aviv university, IVF Unit- Department of Obstetrics and Gynecology- Tel-Aviv sourasky Medical centere- Tel-Aviv- Israel, Tel aviv, Israel

Study question: Is there a difference in outcomes of oocyte preservation cycles according to the type of triggering agent?

Summary answer: GnRH-a significantly increases the mature oocyte rate in medically indicated cycles, with no similar effect in social fertility preservation cycles.

What is known already: Fertility preservation is no longer reserved for patients with malignancy before medical intervention. More and more women seek to extend their fertility options due to personal choices. One main advantage of an antagonist protocol is that it provides the option to trigger ovulation with GnRH-a, which lowers the risk of ovarian hyperstimulation syndrome (OHSS). However, it also lowers pregnancy and live birth rates in fresh embryo transfer cycles due to an inadequate luteal phase. In fertility preservation luteal phase is irrelevant. We set out to compare other relevant outcomes according to triggering type in this subgroup of patients.

Study design, size, duration: This retrospective cohort study was performed at a tertiary university-affiliated medical center. Overall, 226 fertility preservation cycles between May 2013 and September 2018 were included in the analysis, of which 126 cycles were triggered with GnRH-a and 100 cycles with r-hCG. Medical indications accounted for 130 cycles and social indications accounted for 96 cycles.

Participants/materials, setting, methods: Fertility preservation indications were extension of fertility or fertility protection preceding chemotherapy, radiotherapy, or endometriosis surgery and fragile X carriers at risk for premature ovarian insufficiency. Triggering with GnRH-a (Decapeptyl 0.2 mg) or r-hCG (Ovidrelle 250 microgram) was administrated when the leading follicle was ≥17 mm with adequate estradiol levels. Mature oocyte rates were calculated as the number of MII oocytes/total retrieved oocytes per cycle. A cut-off of 80% indicated good oocyte maturation rate.

Main results and the role of chance: No significant differences were observed between patients triggered by GnRH-a compared to r-hCG in terms of gonadotropin dosage and BMI (p=0.95 and 0.62, respectively). The majority of patients with social indication were triggered with GnRH-a (63.5%). Patients with medical indications were divided equally between GnRH-a and r-hCG (p=0.043). The average age of the GnRH-a patients was significantly lower than that of the r-hCG patients (p<0.01), and the estradiol blood levels of the former were higher than those of the latter (p=0.04). There was no significant difference in oocyte maturation rate between triggering by GnRH-a or r-hCG (p= 0.48). Comparison of the percentage of GnRH-a- and r-hCG-triggered cycles with an MII rate >0.8 revealed a slightly higher percentage for the GnRH cycles, however,

difference was not statistically significant. (59.6% versus 47.1%, p=0.08). Data were then analyzed according to both indication for fertilization therapy and triggering agent. GnRH-a significantly increased the likelihood of a high maturation rate by 3.55 (1.30-9.66) among treatment cycles for medical indications, while there was no significant effect of the triggering agent in treatment cycles for social indication.

Limitations, reasons for caution: This cohort analysis is based on retrospective data collection, with potential biases inherent to that design. Pregnancy rates and live birth rates were not evaluated, and future studies on these aspects are warranted.

Wider implications of the findings: The results affirm that triggering with GnRH-a and r-hCG have similar ART outcomes in women planned to no fresh embryo transfer. GnRH-a triggering administration should be considered first choice in fertility preservation for reducing the risk of OHSS and for greater likelihood of good maturation rates in medically indicated cycles.

Trial registration number: not applicable

P-437 Epigenetic factor regulation; microRNA-9 and microRNA-218 related to cell proliferation and apoptosis, by tissue engineering-fibrin encapsulation: Preliminary study on ovarian tissue cryopreservation for fertility preservation

P. Thuwanut[1], W. Sereepapong[1], K. Pruksananonda[1], C. Suebthawinkul[1], P. Tuntiviriyapun[1], C. Taweepolcharoen[1], P. Sirayapiwat[1]

[1]Department of Obstetrics and Gynecology, Faculty of Medicine- Chulalongkorn University, Bangkok, Thailand

Study question: Could fibrin encapsulation regulate alteration of epigenetic factors related to cell proliferation and apoptosis; microRNA-9 and microRNA-218, during ovarian tissue cryopreservation procedure?

Summary answer: The tissue engineering technology by fibrin encapsulation tended to down-regulate microRNA-218 (cell apoptosis) while uP-regulate microRNA-9 (cell proliferation) during ovarian tissue cryopreservation.

What is known already: Application of biodegradable matrix i.e. hydrogel or fibrin for mammalian cell encapsulation has been extensively considered one of potential strategies which offer utility of cell-based system regulation under complex microenvironment. Recently, this fascinating technology was introduced to reproductive medicine research i.e. immature testicular tissue fragment encapsulation or mesenchymal stem cell encapsulation in 3D ovarian cell construction. This novel approach allows molecule cocktails; angiogenic, growth factors, hormones or essential nutrients delivered to cell or tissue leading to cell/graft survival during culture, cryopreservation and transplantation. This technology, however, mainly presents in animal research whereas in terms of human ovarian studies are limited.

Study design, size, duration: The cortical pieces of ovarian tissues collected from two patients during July-August, 2019 (there cortical pieces per patient) were allocated into three sub-groups; I) fresh (F), II) ovarian tissue without fibrin gel encapsulation (Non-FG) and III) ovarian tissue encapsulated with 10% fibrin gel (FG). The cortical pieces from each designed group (Non-FG and FG) were processed for slow freezing procedure and evaluated for relative microRNA (microRNA-9 and microRNA-218) and mRNA (Bcl-2 and FOXO1) expression levels.

Participants/materials, setting, methods: Total of six cortical strips (0.5 x 0.5 x 1.0 mm; width x length x thickness) from premenopausal patients (age 39 and 48 years old; diagnosed with breast cancer and uterine fibroid) were allocated as mentioned in study design. Ovarian tissues were cryopreserved by -1°C/minute slow freezing (4°C to -80°C and plunged into -196°C). Fresh and post-thawed samples were analysed for relative microRNA (reference to U6) and mRNA (reference to GAPDH) expression levels using qRT-PCR.

Main results and the role of chance: The present findings preliminary indicated that the fresh ovarian cortical strips present the highest relative microRNA-9 expression level (2.97 ± 1.43; mean ± SD). Nonetheless, the lower relative microRNA-218 (2.06 ± 2.27; mean ± SD), Bcl-2 (4.42 ± 0.38; mean ± SD) and FOXO1 (7.23 ± 5.43; mean ± SD) expression levels compared the post-thawed samples were observed. Regarding to the recent advance in tissue engineering technology, the uP-regulation of microRNA related to cell proliferation (microRNA-9) was notably revealed in the post-thawed ovarian cortex encapsulated with fibrin gel which was 1.95 times higher than non-FG samples (FG = 1.13 ± 0.19 vs Non-FG = 0.58 ± 0.22; mean ± SD). Contrastingly, the genetic and epigenetic controls comprehended with form of programmed cell death; Bcl-2, FOXO1 and microRNA-218 were markedly lower or down-regulated in the ovarian tissue-fibrin encapsulated group (Bcl-2; Non-FG = 7.31 ± 1.52 and FG = 5.51 ± 1.16; FOXO1; Non-FG = 9.42 ± 3.01 and FG = 7.98 ± 0.43; microRNA-218; Non-FG = 2.39 ± 0.99 and FG = 0.63 ± 0.25; mean ± SD).

Limitations, reasons for caution: The present research findings preliminary document outcomes from a small number of participants following oophorectomy procedure. Additionally, the limitation of retrieved ovarian tissue size and number theoretically leads to the restriction of research or study design expansion and recapitulation in all aspects.

Wider implications of the findings: Our preliminary research outcomes speculate that the novel technology focused on tissue engineering with biodegradable gel matrix may be applicable for ovarian tissue cryopreservation and fertility preservation. Furthermore, the cortical striP-fibrin encapsulation may subsequently lead to the restriction of cell apoptosis during ovarian tissue cryopreservation and transplantation.

Trial registration number: 384/62

P-438 The use of LH for preserving reproductive health in cancer patients

S. Marcozzi[1], R. Vicenti[2], G. Orlando[3], C. Centonze[3], M. Macciocca[2], F. Di Rella[4], M. De Felici[1], R. Fabbri[2], F.G. Klinger[1]

[1]University of Rome Tor Vergata, Dep. of Biomedicine and Prevention, Rome, Italy ; [2]S.Orsola-Malpighi Hospital- University of Bologna, Department of Medical and Surgical Sciences DIMEC, Bologna, Italy ; [3]Merck Serono spa, Medical Affairs Department, Rome, Italy ; [4]National Cancer Institute- IRCCS Foundation G. Pascale, Medical Oncology-Department of Senology, Naples, Italy

Study question: Is luteinizing hormone (LH) able to protect ovarian reserve against cyclophosphamide (CPM)-induced damage in women?

Summary answer: LH appears able to significantly reduce primordial follicle (PMF) loss in ovarian strips treated *in vitro* with phosphoramide mustard (PM), the active metabolite of CPM.

What is known already: Cancer therapies cause a severe reduction of PMFs, often inducing premature ovarian insufficiency (POI) in female patients. For this reason, several compounds have been analyzed as adjuvant therapies to protect the ovarian reserve without interfering with cancer treatment on tumor cells. We recently demonstrated, *in vitro*, the protective effect of LH against ovotoxicity induced by cisplatin on the ovary of prepuberal mice. These results suggest a possibility for to use of LH prior or in concomitance with an anticancer treatment in order to preserve oocytes in human patients, therefore preventing the early onset of menopause and/or infertility.

Study design, size, duration: The ovarian tissues were collected from three patients (age-pathology : 25 yrs-Ewing's sarcoma, 15 yrs-medulloblastoma and 14 yrs-Hodgkin lymphoma) who have cryopreserved their ovarian tissue before receiving anticancer treatment. For each patient, eight ovarian strips were thawed and randomly assigned to the experimental conditions (two strips each): Control (CTRL), PM, PM+LH-200mIU and PM+LH-500mIU. LH was added 1 hour before the treatment with PM. Samples were analyzed after 24 and 48 hrs of treatment.

Participants/materials, setting, methods: Ovarian strips were cultured for 24-48 hours at 37°C and 5% CO_2, in α-MEM supplemented with 40% human serum with/out 10mM PM and/or 200mIU/ml LH or 500mIU/ml LH. The samples were processed for:

–Histology, for PMFs and primary follicles (PFs) analysis;

–Western blotting, for the expression of protein involved in DNA damage and apoptosis;

–Real-Time PCR, for the expression of genes involved in apoptosis and inflammation.

Main results and the role of chance: Histological analysis showed that in the untreated group, the follicle density varied from 450.45 to 921.38 PMFs/mm^3 and from 94.45 to 430.30 PFs/mm^3 between the three patients analysed. Therefore, relative follicular density (%) was performed to analyse statistical differences between the control and treated groups. Notably, whereas relative PMFs density (%) was significantly reduced in PM *vs* CTRL either after 24 and

48 hrs, this reduction was partially counteracted by both LH dosages tested (24 hrs: CTRL=74.47±5.12; PM=42.31±5.66; PM+LH-200mIU=70.77±3.72; PM+LH-500mIU=59.19±9.49 - 48 hrs: CTRL=68.15±1.75; PM=25.96±16.91; PM+LH-200mIU=42.62±11.79; PM+LH-500mIU=56.35±12.96). No significant differences were observed in relative PFs density (%). Real-Time PCR and Western blotting revealed no significant differences, between groups, in the expression of molecules involved in apoptosis (NOXA, PUMA, Bax, Bak and Bcl2), DNA damage (γH2AX), probably due to the already occurred loss of the follicles, and in the expression of IL6, a pro-inflammatory cytokine.
On the contrary, treatment with PM is able to significantly increase IL1β gene expression, another pro-inflammatory cytokine; interestingly, pre-treatment with LH, at both tested dosages, counteracted this increase (24 hrs treatment: CTRL=1.00±0.01; PM=2.03±0.04; PM+LH-200mIU=1.37±0.04; PM+LH-500mIU=1.50±0.03 and 48 hrs treatment: CTRL=1.00±0.12; PM=1.75±0.09; PM+LH-200mIU=1.30±0.10; PM+LH-500mIU=1.63±0.20).**Limitations, reasons for caution:** Main limitation of this preliminary study includes its small sample size (only ovarian cortex from three subjects were used) that needs to be improved. The present study did not elucidate the molecular mechanisms involved in LH ovoprotection against PM
Wider implications of the findings: These preliminary results showed that LH is able to preserve PMFs in human ovarian cortex exposed to PM *in vitro*. These findings encourage the possibility to use the hormone as a treatment to prevent the premature onset of menopause and/or infertility in women undergoing anticancer treatments.
Trial registration number: Not applicable

P-439 Production of ovine fertilizable oocytes using innovative in vitro (iv) technologies applied to preantral follicles growth.

C. Di Berardino1, G. Capacchietti[1], N. Bernabò[1], M. Crociati[2], M. Monaci[2], L. Sylla[2], B. Barboni[1]

[1]Faculty of Bioscience and Agro-Food and Environmental Technology- University of Teramo, Unit of Basic and Applied Biosciences, Teramo, Italy ;
[2]University of Perugia, Department of Veterinary Medicine, Perugia, Italy

Study question: Considering the early pool of gametes potentially able to generate offspring, what actions should be taken to optimize *iv*F thus increasing fertilizable oocytes availability?
Summary answer: The standardization of long-term gonadotropin stimulation is a key step to implement *iv*F in order to promote both reproductive targets, oogenesis and follicle steroidogenesis activation.
What is known already: Increasing in childhood cancer survivors points up an urgent need in fertility preservation (FP) strategies to overcome the negative impact of cancer treatments on reproductive cell cycle. Because of a concern exists on the possible re-introduction of malignant cells following ovarian transplantation, *in vitro* (*iv*) culture of early stage follicles still remains a potential alternative to obtain fertilizable oocytes that contribute to biological offspring. Since technologies advances are required to transfer *iv* Follicologenesis (*iv*F) from bench to bedside, monovulatory large mammal becomes ideal translational models to validate cultural conditions enhabling synergic follicles-oocyte *iv* development.
Study design, size, duration: The present research aimed to study the influence of 2 different gonadotropins (oFSH *vs* Pregnant Mare's Serum Gonadotropin/PMSG) on *iv*F cultures of single ovine preantral follicle (PA). The *iv*F outcomes obtained by using the specie-specific (oFSH) or the trans-species chorionic gonadotropin (PMSG) were analyzed after 14 days of culture by comparing follicle/oocyte growth, timing and percentage (%) of antrum differentiation as well as % of Methaphase II (MII) oocytes after *iv* Maturation (IVM).
Participants/materials, setting, methods: Preantral follicles, mechanically isolated from slaugterhoused prepubertal ovaries, were incubated as 3D single follicle culture and exposed to 25 ug oFSH or to different PMSG doses (from 0,4 to 40 IU/ml). In order to compare the degree of meiotic competence, MII oocytes obtained adopting an advanced IVM, consisting of cumulus oocytes complexes co-cultured with walls antral follicle-derived somatic cells, were analyzed.
Main results and the role of chance: The PMSG influence on *iv*F performances was strictly dose-dependent. More in detail, 4 IU was the concentration of PMSG able to enhance follicular diameter increment (Δ%: 63.7±28.9 *vs* 43.4±19.3 and 52.7±33.4, respectively for 4, 0.40, 40 IU; $p<0.05$). Conversely, any significant increase in antrum differentiation upon PMSG treatment (4, 0.4, 40 IU) was observed. The chorionic gonadotropin was more effective than oFSH in promoting *iv*F outcomes. Indeed, preantral follicles stimulated with 4 IU PMSG displayed a significantly greater growth than those exposed to oFSH (Δ%: 63.7±28.9 vs 52±31; p=0,038). Moreover, PMSG promoted a complete meiotic competence in the majority of collected oocytes (58.3% MII, 2.8% GVBD, 38.8% GV). Of note, the MII oocytes were all isolated by early antral follicles with Δ%>40 ($p<0.01$). On the contrary, only a very small fraction of the oocytes isolated from oFSH-treated follicles was able to resume meiosis and no one reached the MII stage (83,30% GV, 16,70% GVBD; $p<0.001$).
Limitations, reasons for caution: -
Wider implications of the findings: These proof-of-concept PMSG experiments establish a way for new protocols optimizing *iv*F and allow to identify a trans-species hormone to functionalize biomaterials. Both strategies might support follicle development in large animal models and humans with the hope of translating this technology for fertility preservation purposes.
Trial registration number: not applicable

P-440 Fertility preservation in adolescent males: Setting up a national service.

M. Horan[1], L. Hartigan[1], H. Groarke[1], L. Glover[1], M. Wingfield[1]

[1]Merrion Fertility Clinic- Dublin and The National Maternity Hospital Dublin, Obstetrics & Gynaecology, Dublin, Ireland

Study question: Does a multi-disciplinary approach to sperm cryopreservation in adolescent males enable quality care?
Summary answer: Within 18 months of inception, an efficient national care pathway has been established with successful cryopreservation and positive patient feedback.
What is known already: The incidence of both childhood and adolescent cancer is increasing throughout Europe. Around 200 children and young adolescents are diagnosed with cancer in the Republic of Ireland every year. Thanks to advances in medicine and surgery, survival rates in this group are now greater than 80%. As a result, there is increased emphasis on the long-term effects of cancer treatment. Studies from other units outside of Ireland have shown that semen cryopreservation was possible in most adolescent cancer cases regardless of age or disease diagnosis, however to date, no formal service for CAYA male sperm cryopreservation exists in Ireland.
Study design, size, duration: We developed a National CAYA Fertility Preservation Consortium with fertility specialists at our clinic and paediatric oncology specialists at the National Children's Hospital. The infrastructure and combined expertise through this collaborative consortium allowed us to provide a sperm cryopreservation service for adolescent boys, with the option of producing samples at either site. We performed a retrospective review of all adolescent male patients referred for consideration of sperm cryopreservation in a 16-month period.
Participants/materials, setting, methods: Patients were identified through the National Paediatric Haematology/Oncology Programme. Clinical and demographic data was recorded on patients. Disease diagnosis was provided by the primary oncologist or rheumatologist in the setting of benign disease. We evaluated patient demographics and semen parameters. Sperm parameters analyzed were volume, sperm concentration and motility. Number of failed samples, number of straws stored per patient, and number of visits required for each patient to produce a sufficient sample was also recorded.
Main results and the role of chance: This project addressed deficiencies and current barriers in the provision of fertility preservation services to children in Ireland.

Fifteen patients, aged between 12 and 17 years old, were referred to our service for consideration of sperm cryopreservation between August 2018 and December 2019. Of these, 93% (14/15) presented with malignant disease. One patient was referred for sperm cryopreservation prior to commencing gonadotoxic treatment for non-malignant disease. 93% of the male patients elected to come to our fertility clinic rather than provide their samples at the National Children's Hospital.

Of the 15 patients referred, 12 attempted sperm production. Eight of these patients (67%) had sperm successfully cryopreserved. The youngest patient in our study was 12 years old and successfully cryopreserved four straws. Four patients (36%) did not achieve sperm cryopreservation: 1 patient failed to collect

any sample, 2 patients had no sperm in the sample produced. Unfortunately 1 patient had very poor semen quality that was not suitable for freezing, this was following one cycle of chemotherapy. Five patients attended the clinic twice to attempt specimen production. Of the 8 patients who successfully had sperm cryopreserved, only 1 patient had semen analysis results entirely within WHO 'normal' limits.

Limitations, reasons for caution: The study cohort was limited in size. We currently have no long term data on the rate of straw utilisation in our cohort of patients, given that this is a very new service.

Wider implications of the findings: Prior to this study, the number of adolescent males availing of cryopreservation in Ireland was unknown. This study will enable collection of data and the establishment of a national database. Success thus far will improve awareness of this service among oncologists in Ireland.

Trial registration number: N/A

P-441 Sperm cryopreservation in adolescents with cancer.

F. Filippi[1], E. Somigliana[1,2], M. Reschini[1], C. Meazza[3], M. Podda[3], C. Guarneri[1], D. Giacchetta[4], M. Massimino[3], L. Restelli[1], M. Terenziani[3]

[1]IRCCS Fondazione Ca' Granda Policlinico di Milano, IVF Unit, Milano, Italy ; [2]Università degli Studi di Milano, Dept. Clinical sciences and Community Health, Milano, Italy ; [3]IRCCS Istituto Tumori di Milano, Pediatric Unit, Milano, Italy ; [4]Ospedale Santi Paolo e Carlo, Assisted Reproduction Techniques Unit, Milano, Italy

Study question: Is sperm banking underused in adolescents with cancer?

Summary answer: Semen cryopreservation prior to initiate gonadotoxic therapies is insufficiently used in adolescents with cancer.

What is known already: Sperm cryopreservation was the first validated technique for fertility preservation. It is simple, promptly available, cheap and safe. Even if only a minority of subjects who stored their semen will ever thawed them, there is a general consensus that sperm cryopreservation could be cost-beneficial and that it should be systematically offered to men with cancer prior to initiate gonadotoxic treatments. However, evidences on sperm cryopreservation in adolescents and young men are sparse. They generally show that sperm banking is feasible but also indirectly suggest that the proportion of those actually storing their semen may be hindered.

Study design, size, duration: Men undergoing semen cryopreservation at the Infertility Unit of the Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico of Milan, Italy between January 1986 and December 2018 were retrospectively reviewed. Information were obtained from patients' charts.

Participants/materials, setting, methods: Inclusion criteria were as follows 1) Age 14-21 years, 2) diagnosis of malignancy. Subjects those performing surgical sperm collection were excluded. The analysis focussed on the following information: age at semen preservation, semen parameters at the time of preservation and oncological diagnosis.

Main results and the role of chance: Overall, 317 subjects satisfied our selection criteria. Cancer diagnoses were as follows: lymphomas (n=159, 50%), leukemia (n=21, 7%), testicular cancer (n=60, 19%) and others (n=77, 24%). The frequencies of referred cases according to age was not consistent ($p<0.001$) with the theoretical uniform distribution of referrals (ie with a similar number of cases per group of age): a clear sharp and constant increase with age emerged. This unbalanced distribution remained also when restricting the analysis to boys older than 16 years ($p<0.001$) or to those older than 18 years ($p=0.01$), suggesting that discrimination for age persisted also in older boys. The total number of cases referring before 1999, between 1999 and 2008 and between 2009 and 2018 were 88, 98 and 131, respectively. An improvement of the distribution of cases per age group emerged over time (Chi square for trend, $p=0.002$). However, within each historical period, distribution per age group remained inconsistent with the theoretical uniform distribution ($p<0.001$ for all). No statistically significant differences were identified in semen quality between the different age groups. The proportion of boys who could not freeze their specimen because of the absence of viable spermatozoa was also similar.

Limitations, reasons for caution: Number of boys who failed to make a collection was not recorded. Secondly, we cannot exclude that our results may reflect a local low sensitivity towards fertility preservation. Thirdly, we hypothesized a uniform distribution model for the referrals, assuming therefore that the frequency of cancer is constant over the years.

Wider implications of the findings: The frequency of adolescents who bank their semen prior to initiate gonadotoxic therapies is lower than it should be. Future research is needed to delineate the barriers and to develop interventions that could overcome them. Meanwhile, physicians engaged in oncology should dedicate more attention on fertility preservation in young boys.

Trial registration number: not applicable

P-442 Females' fertility preservation for cancer patients: lessons learned of ten years' experience in a French center

A. LE BRAS[1], V. Windal[1], V. Puy[1], L. Hesters[1], V. Gallot[2], B. Alexandra[2], M. Grynberg[2], C. Sonigo[2], N. Frydman[1]

[1]Hospital A. Béclère, Reproductive Biology Unit CECOS, Clamart Cedex, France ; [2]Hospital A. Béclère, Department of Reproductive Medicine and Fertility Preservation, Clamart Cedex, France

Study question: For female cancer patients who underwent fertility preservation, what are the outcomes of oocyte- or embryo-thawing after Controlled Ovarian Stimulation or *in vitro* maturation ?

Summary answer: Regardless of FP technique, live births were obtained for all of the emergency *in vitro* fertilization procedures in former cancer patients.

What is known already: Cryopreservation of embryos was considered the best FP method before the development of vitrification. Whereas vitrification has improved the success rate for cryopreserved oocytes in female cancer patients, no live births have ever been reported using in vitro matured oocytes.

Study design, size, duration: This was a single-center, retrospective study from January 2009 to December 2018 in France. We reviewed the biological and clinical outcomes of female patients treated for cancer who returned to use their oocytes or embryos that were cryopreserved using Controlled Ovarian Stimulation (COS) or In Vitro Maturation (IVM).

Participants/materials, setting, methods: After a cancer diagnosis, four possible cryopreservation procedures were used: either frozen oocytes or frozen embryos, after either COS or IVM treatment cycles. Among the 667 patients who underwent emergency FP before gonadotoxic cancer treatments, 40 returned to thaw their oocytes or embryos. We compared the clinical and laboratory data of freeze/thaw cycles for these four groups in these 40 patients.

Main results and the role of chance: Following emergency FP, 40 patients (6%) returned to attempt a pregnancy with a mean time lapse of 3.3 ± 1.5 years. Most were cured of breast cancer (n = 31). One hundred and thirty-four oocytes were used in 25 thawing cycles (7 after IVM-FP and 18 after COS-FP). Eighty-seven embryos were used in 24 thawing cycles (14 after COS-FP and 10 after IVM-FP). Eight pregnancies (3 from frozen oocytes, 5 from frozen embryos) resulted, three of them from fertilized, mature oocytes after IVM. All babies were delivered at term with normal perinatal characteristics. We report the first births in previous cancer patients using vitrification of *in vitro* matured oocytes for FP.

Limitations, reasons for caution: Some confounding factors such as smoking, alcohol consumption, and toxic environmental exposure at the time of cryopreservation are missing. Only a few patients have returned to attempt pregnancy after being cured from cancer. We have no information about natural pregnancies in patients who have had FP.

Wider implications of the findings: The present study is one of only a few published series conducted in patients treated for cancer comparing the outcomes of thaw cycles according to the FP procedure chosen at the time of diagnosis. We report the first pregnancy obtained from matured oocytes after IVM.

Trial registration number: NA

P-443 Effects of high concentrations of Resveratrol on human sperm cryopreservation

E. Porcu[1], L. Notarangelo[1], L. Cipriani[1], G. Damiano[1], P.M. Ciotti[1], N. Calza[1], S. Zuffa[1], M. Nadalini[2], E. Nardi[3], E. Borini[2], A. Borini[2]

[1]Infertility and IVF Unit, University of Bologna-Sant'Orsola Hospital, Bologna, Italy ; [2]9.baby, Family and Fertility Center, Bologna, Italy ; [3]University of Bologna, Department of Medical and Surgical Sciences, Bologna, Italy

Study question: Can high concentrations of resveratrol as antioxidants in sperm cryopreservation be useful for post thawing viability and morphology?
Summary answer: High concentrations of resveratrol do not improve vitality and post-thaw morphology in sperm cryopreservation.
What is known already: It was demonstrated that the cryopreservation of human semen produces reactive oxygen species (ROS), which cause important sperm damages such as lipid peroxidation of the cell membrane and DNA damage. Several studies have examined the role of in vitro supplementation of antioxidants, such as resveratrol, to protect sperm DNA from ROS oxidative damage and improve post-thawing sperm quality.
Study design, size, duration: The effects of Resveratrol will be examined based on the assessment of sperm motility and morphology. Prospective study: 100 waste seminal samples of patients undergoing a IVF cycle at the University of Bologna Infertility and IVF Center and 9.baby Center, Bologna from March to December 2019. Three groups were considered: Group A = post thawing control group; Group B = post thawing 30 µM/L Resveratrol; Group C = post thawing 50 µM/L Resveratrol.
Participants/materials, setting, methods: One hundred patients selected for normozoospermia and mild or moderate oligoastenoteratozoospermia. Patients age ranged from 23 to 53 years with a mean value of 38.18±6.00. Diagnosis of normozoospermia and mild or moderate oligoastenoteratozoospermia was made considering not only the cellularity of seminal fluid samples but also the total and progressive motility and morphology of spermatozoa. Sperm cryopreservation was performed using Test Yolk Buffer, Resveratrol and Sherman freezing Protocol.
Main results and the role of chance: Semen standard analysis showed that in the pre-freezing group the parameters related to total motility, progressive motility and morphology were 48,70 ± 8,63, 24,45 ± 14,70 and 19,73 ± 9,32 respectively. In the control group, total motility, progressive motility and morphology were respectively 26,30 ± 7,09, 12,30 ± 8,39 and 13,60 ± 6,59. In the 30 µM/L Resveratrol group the total motility, progressive motility and morphology were respectively 22,77 ± 6,72, 9,47 ± 6,48 and 13,05 ± 6,41. In the 50 µM/L Resveratrol group total motility, progressive motility and morphology were respectively 19,05 ± 6,54, 6,87 ± 5,71 and 11,83 ± 6,09. Thawing results showed that, 30 µM/L and 50 µM/L of resveratrol produce pejorative effects on motility and morphology ($P < 0.0001$) of sperm after thawing, compared to the control group.
Limitations, reasons for caution: The scientific community opinion is still controversial about the use, in vivo and in vitro, of antioxidants in IVF cycles.
Wider implications of the findings: In IVF cycles, the occurrence of oxidative events during in vitro culture and in cryopreservation processes is well demonstrated; the use of antioxidants during these phases must be further investigated.
Trial registration number: None

P-444 Mitochondrial activity in prepubertal and adult ovaries

R. Masciangelo[1], M.C. Chiti[1], A. Camboni[1], C.A. Amorim[1], J. Donnez[2], M.M. Dolmans[3]

[1]Université Catholique de Louvain, Pôle de Recherche en Gynécologie- Institut de Recherche Expérimentale et Clinique, Bruxelles, Belgium ;
[2]Société de Recherche pour l'Infertilité, Avenue Grandchamp 143, Bruxelles, Belgium ;
[3]Cliniques Universitaires Dt. Luc, Départment de Gynécologie, Bruxelles, Belgium

Study question: Are mitochondrial content and activity in prepubertal ovarian follicles different from adult ovarian follicles?
Summary answer: Differences in the number, activity and morphology of mitochondria of prepubertal patients were evidenced.
What is known already: Mitochondria generate most of the energy of cells through oxidative phosphorylation, possible thanks to generation of mitochondrial membrane potential. Reduced efficiency of oxidative phosphorylation and energy production in oocytes is related to poor embryo development. Moreover, it is known that mitochondria play a central role in ovarian aging via their major contribution to cell survival and apoptosis and that maternal age is associated with increased oxidative stress in oocytes, resulting in mitochondrial dysfunction. The role of mitochondria in determining oocytes' developmental capacity is increasingly evident, nevertheless, literature on mitochondrial function in prepubertal follicles at early stages of growth is scarce.
Study design, size, duration: Ovarian tissue was collected from 7 prepubertal girls (age 1-10 years) and 6 adult women (age 20-35 years). Primordial and primary follicles were isolated from frozen-thawed prepubertal and adult ovarian tissue. Frozen-thawed ovarian tissue from the same patients was also evaluated by immunohistochemistry and transmission electron microscopy.
Participants/materials, setting, methods: Mitochondrial activity in isolated follicles was explored by MitoTracker CM-H2XRos, which is a mitochondria-specific fluorescent and cell-permeant probe, selectively sequestered only in mitochondria with active $\Delta\Psi m$, depending on their oxidative activity. Mitochondrial content was investigated in prepubertal and adult ovarian tissue by TOMM20 immunostaining, a peptide receptor located on the surface of the outer mitochondrial membrane. Transmission electron microscopy was performed to evaluate mitochondrial morphology.
Main results and the role of chance: Prepubertal follicles showed higher fluorescence intensity by MitoTracker ($p=0.03$), compared to adult follicles. This result suggests that mitochondrial activity is enhanced in prepubertal patients compared to adult patients. Quantification of TOMM20 immunostaining, based on the intensity and extent of the signal, revealed significantly stronger TOMM20 staining in prepubertal follicles than adult follicles ($p=0.01$), indicating the presence of more mitochondria in prepubertal follicles. Last, TEM allowed to identify ultrastructural differences in the morphology of mitochondria: in prepubertal follicles, mitochondria were heterogeneously dispersed throughout the cytoplasm in small clusters and were mostly elongated in shape, rather than round as in adult mitochondria. Moreover, cristae in prepubertal mitochondria were mostly longitudinal rather than archiform and, in some cases, shaped in the form of a fingerprint.
Limitations, reasons for caution: The present study evaluates follicle maturation and competence in prepubertal patients, by assessing mitochondria function and activity. Nevertheless, these parameters only provide indirect information and additional cellular organelles should be studied to further corroborate these results.
Wider implications of the findings: With this study, we provided for the first time information on the function, content and morphology of mitochondria from prepubertal patients. We revealed that in prepubertal follicles mitochondria are more abundant and that mitochondrial activity is enhanced, suggesting that intrisic maturation changes will occur in ovarian follicles with aging.

P-445 Elective fertility preservation: do women come back as much as they freeze?

M. Miguens[1], A.M. Quinteiro Retamar[2], A. Coscia[2], D. Acosta[2], G. Vega Balbuena[1], N. Allende[2], S. Papier[2]

[1]cegyr, fertility, buenos aires, Argentina ;
[2]cegyr, clinical, buenos aires, Argentina

Study question: What is the return rate for counseling in patients who had chosen to do elective fertility preservation and the proportion of women who used their stored eggs?
Summary answer: A quarter of patients who preserved their fertility return around two years after for counseling and only 12,58% of the total performed an IVF cycle.
What is known already: Increasing numbers of women are seeking elective oocyte cryopreservation (EOC). This is due to the improving success rates of the oocyte vitrification technique over the years and also social freezing is promoted to single women as a way of preserving their fertility potential. Recent studies have found usage rates are less than ten percent. Studies have proven that vitrified oocytes can be fertilized, implant and achieve normal pregnancies after a short period but the chance of having desired outcomes in long term cannot be predicted by physicians based on real-life experience.
Study design, size, duration: A cross-sectional retrospective study of 469 women who did an EOC between 2009 and 2018 in a single-center at Buenos Aires, Argentina.
Participants/materials, setting, methods: Women who did an EOC between 2009 and 2018 were included. The primary outcomes were the return rate to the clinic for counseling and the proportion of women who used their storage eggs. Other analyzed variables were mean age at the moment of the freezing, mean number of oocytes vitrified per patient, the average time it took

patients to return and ongoing pregnancy rate in the patients who used their oocytes. All analyses are descriptive.
Main results and the role of chance: The total of cryopreserved oocytes over the years was 3376 being the average 7,2 per patient (from 1 to 32). The mean age at the moment of the EOC was 37,17 years (19 to 45). The 24,95% (n: 117) of the total of patients returned for counseling with a mean age of 39,57. The average time it took women to return was 2 years. From this group, 27,35% (n:32) have decided to perform a second oocyte retrieval cycle (main reason was a low number of eggs vitrified in the cycle before -median: 4-) and around a half-used their stored eggs for an IVF treatment (50,43% n:59) which is a 12,58% of the total of patients included. The thawed oocyte viability rate was 72%, the fertilization rate was 66% and the ongoing pregnancy rate was 32.2% (n:19).
Limitations, reasons for caution: The main limitation of this study was its retrospective design based on data from a single center which may be subject of bias.
Wider implications of the findings: The cycles of oocyte cryopreservation, in our clinic, have increased at least 800% since 2009. Even though, our rate is a little above compared with the literature, is still a low number. Prospective cost-effectiveness and long-term success analysis are needed to determine if it's worth it or not.
Trial registration number: Not applicable

P-446 Ascorbic acid protects against ovarian dysfunction induced by mono (2-ethylhexyl) phthalate in fetal mouse ovaries in vitro via reducing the oxidative stress

C. Sui[1], C. Liu[1]

[1]Tongji Hospital- Tongji Medical College- Huazhong University of Science and Technology, Reproductive Medicine Center, Wuhan, China

Study question: Whether ascorbic acid protects fetal ovaries from the injury effect induced by mono (2-ethylhexyl) phthalate (MEHP) and what is the mechanism.
Summary answer: Supplement of ascorbic acid can rescue the injury effect induced by MEHP in fetal mouse ovaries in vitro via reducing the oxidative stress
What is known already: Di-(2-ethylhexyl) phthalate is considered to be toxicant to female reproduction, potentially by its active metabolite MEHP. Toxicological studies affirmed oxidative stress is one possible pathway for MEHP-adjuvant effect. Ascorbic acid is known to be an antioxidant and a powerful reducing agent and plays an important role in attenuating oxidative damage to the reproductive system.
Study design, size, duration: Fetal mouse ovaries exposed to different concentration of MEHP (0 M, 10^{-4} M, 10^{-5} M, 10^{-6} M) were treated with or without ascorbic acid (100nM) in vitro for 6 days. Then the ovarian follicle constitution and the oxidative stress parameters of ovaries in each treatment were detected respectively to evaluate the influence of MEHP and ascorbic acid.
Participants/materials, setting, methods: Ovaries from post-natal day 4 Kunming mice were recruited and assigned to different groups randomly. After treated with MEHP alone or a combination of MEHP and ascorbic acid for 6 days, ovaries were collected to histologically qualify the follicle numbers, and the ovarian malonaldehyde (MDA) levels were tested. Besides, ovarian mRNA related to Redox (Sod-1, GSS, CAT) were examined using quantitative reverse transcription polymerase chain reaction.
Main results and the role of chance: MEHP accelerated primordial follicle activation by increasing the proportion of primary and secondary follicles in ovaries at the concentration of 10^{-4} M. The expression of SOD was increased significantly in ovaries treated with 10^{-4} M MEHP ($p<0.05$). Moreover, MEHP increased the MDA level in the ovaries at 10^{-4} M ($p<0.01$) and 10^{-5} M ($p<0.05$). When ovaries exposed to 10^{-4} M MEHP, supplement of ascorbic acid rescued the follicular constitution, and normalized the MDA level. Ascorbic acid also reversed the increasing expression of SOD and GSS in the ovaries, which was caused by MEHP.
Limitations, reasons for caution: This study only demonstrated the protective effect of ascorbic acid to ovaries in vitro. Whether ascorbic acid functioned as a powerful agent to rescue the MEHP-induced ovarian injury will need in vivo studies to explore.
Wider implications of the findings: Ascorbic acid ameliorated the disruption of folliculogenesis induced by MEHP via its antioxidant capacity. Supplement of ascorbic acid might be a potential therapy for MEHP-induced ovarian injury.
Trial registration number: not applicable

P-447 Fertilisation outcomes after cryopreservation of human immature and in vitro matured oocytes

M. Petrushko[1,2], V. Piniaiev[3], T. Yurchuk[2]

[1]ART Clinic of Reproductive Medicine, Embryology, Kharkiv, Ukraine ;
[2]Institute for Problems of Cryobiology and Cryomedicine of the NAS of Ukraine, Cryobiology of reproductive system, Kharkiv, Ukraine ;
[3]ART Clinic of Reproductive Medicine, Gynecology, Kharkiv, Ukraine

Study question: What are maturation and fertilization outcomes of GV oocytes in vitro matured prior and after vitrification?
Summary answer: Oocytes in vitro matured prior vitrification have higher maturation, fertilization and blastocyst formation rate than oocyte matured after vitrification.
What is known already: Emergency of fertility preservation for patients who are in danger of losing their ovarian function or donation programs apply oocyte preservation for further usage in assisted reproductive technologies in spite of being at different maturation stage (germinal vesicle stage (GV), MI, MII). There is lack of data concerning oocyte cryopreservation efficiency and timing of in vitro maturation regards to cryopreservation procedure.
Study design, size, duration: GV oocytes (n=108) were cryopreserved prior and after *in vitro* maturation oocytes and their survival, fertilisation and blastocyst formation rates were analyzed. All manipulations have been carried out between January 2017 and November 2019.
Participants/materials, setting, methods: This single-center cohort study included 31 patients diagnosed with polycystic ovary syndrome (PCOS) and poor responders (mean age of women was 34.3±4.2 years). GV oocytes were randomly selected for *in vitro* matured (IVM) prior (group 1) and after vitrification (group 2). After thawing MII oocytes were fertilized by ICSI and cultured up to day 5. All manipulations with gametes were performed according with written consent of patients.
Main results and the role of chance: It has been shown maturation rate was 73.2 *vs* 52.0% in group 1 and 2 respectively. Overall no differences were found for survival rate of MII oocyte matured prior cryopreservation and cryopreserved GV oocyte (97.6 % vs 96.2 %; $P>0.05$). Fertilisation and blastocyst formation rate were higher in group 1 (77.5 % and 38.7%) than in group 2 (38.5% and 20.0%). These differences are significant between the groups ($P<0.05$).
Limitations, reasons for caution: Limited number of GV oocytes in the study group. Further studies are recommended and should include also group advanced age patients.
Wider implications of the findings: These results revealed that using immature oocytes at GV stage and long-term preservation can increase the number of embryos available for transfer into the uterus of patient with PCOS and poor responders.
Trial registration number: not applicable

P-448 Fertility preservation in adolescent women: should we expect the same response?

A. Santolaria Baig[1], R. Quintana Berto[1], N. García Camuñas[1], J. Subirá Nadal[1,2], P. Polo Sánchez[1], J.M. Rubio Rubio[1]

[1]La Fe University Hospital, Women's Health Area, Valencia, Spain ;
[2]IVI-RMA Castellón-Valencia, Reproductive Endocrinology, Castellón, Spain

Study question: Are oocyte cryopreservation (OC) cycles in adolescent women (<20 years old) comparable to OC cycles in ages we expect the best response (20-25 years)?
Summary answer: OC cycles in adolescent women have similar results compared with ages we expected the best response.Fertility preservation(FP) is a feasible option in this age group.
What is known already: Women from 20 to 25 years old are expected to have the best response to OC cycles for FP, based on the age-related distribution of AMH. Few studies are published in adolescents (<20 years), even though FP in this group of patients is increasing nowadays. Some authors hypothesized that adolescent have differences in their stimulation cycles regarding the oocyte

maturity or dosing requirements of gonadotropins.The last publications obtained similar results in stimulation in adolescents and in women of other age groups, but with a higher likelihood of cancellation.

Study design, size, duration: This is a retrospective study performed from January 2013 to January 2020 at a tertiary university hospital. Our research was focused in OC cycles of adolescent women (between 13 and 20 years of age) and the group we expected the best response according to AMH levels (20-25 years). Data were retrieved from patients electronic records.

Participants/materials, setting, methods: We collected data from epidemiology, stimulation and oocyte retrieval from 49 cases in adolescent women and 104 cases in the 20-25 years group. Numerical variables were summarized by the median and standard deviation and a comparation of both groups was performed with T Student test.

Main results and the role of chance: The main indication in adolescents for FP was Hodgkin lymphoma(36,73%) followed by gynecological pathology(24,48%). In the 20-25 years group the gynecological pathology was the main indication(26,92%), followed by Hodgkin lymphoma(22,11%) and breast cancer (9,6%).

Both groups were comparable in terms of epidemiological variables about ovarian reserve. In all ages, the most common stimulation protocol was short antagonist protocol.

Results from total days of stimulation, total number of follicles, follicles >16 mm and serum estradiol on the trigger day and FORT(Follicular Output Rate) index were similar in both groups. Regarding the gonadotropin dosing, adolescent used a mean FSHr dosed of 2219,46 IU(±909,88) compared with 2520,50 IU(±934,79) in women 20-25 years(p=0,07). However the initial dosing was higher in the 20-25 years group: 222,90 IU(±53,66) vs 246,39 IU(±52,53) (p<0,05). No significant differences were found between the groups for oocytes retrieval or the maturity rate. Adolescents retrieved a mean of 13,69(±10) oocytes with a maturity rate of 67,76%(±28,32) compared with 11,53(±8,15) oocytes and 75,42%(±23,45) in women 20-25 years. The Follicle to Oocyte Index (FOI) was also comparable in both groups.

There were more cancellations in the adolescent group:20,4 % of cycles in adolescents vs 6,7% in women 20-25 years(p=0,025).

Limitations, reasons for caution: The data from this study were retrospective and from a single center.

Wider implications of the findings: This study shows that OC cycles in adolescents have similar results to 20-25 years women, the age expected to have a better response.It is plausible to include adolescents in FP programs due to their good response. This is very reassuring because these patients are less likely to have completed childbearing.

Trial registration number: Not applicable

P-449 Developmental quality post-insemination of vitrified versus fresh oocytes from patients with low ovarian reserve

F. Bonald[1], M. Montagut[1], M. Clouet[2], V. Guitard[1], A. Chiron[1], D. Nogueira[3]

[1]Labosud Garonne, Reproductive Biology Laboratory, Toulouse, France ;
[2]Clinique Croix du Sud, Gynecology, Toulouse, France ;
[3]INOVIE Fertilité - Labosud Garonne, Reproductive Biology Laboratory - Clinique Croix du SUD, Toulouse, France

Study question: Does oocyte developmental quality is affected after vitrification in women with low ovarian reserve?

Summary answer: Embryonic developmental quality seems affected after vitrification compared to freshly collected oocytes from the same patient

What is known already: Oocyte vitrification in low ovarian reserve patients can be used for fertility preservation, to accumulate oocytes for optimizing the use of frozen-thawed-testicular and donor sperm, to augment the number of embryos in PGT cycles. Embryos from vitrified oocytes have similar implantation potential than freshly collected oocytes from infertile patients but the number of vitrified oocytes has an affect on delivery rates. Data on donors showed that in vitro development of embryos derived from vitrified-warmed donor oocytes is altered compared to their fresh sibling counterparts. Data on oocyte developmental quality after oocytes vitrification in patients with low ovarian reserve is lacking.

Study design, size, duration: A retrospective analysis performed between January 2016 and December 2018 including low ovarian reserve patients (AMH < 1.1 ng/ml by The Bologna criteria) (n=206). These patients underwent 1.6 ±0.9 previous ovarian stimulation cycles for oocyte vitrification, followed by a fresh oocyte retrieval where all oocytes previously vitrified were warmed for ICSI, as a strategy to increase the potential number of embryos available.

Participants/materials, setting, methods: Oocyte vitrification and warming were performed with the Cryotop method (Kitazato, Dibimed). Analysis on pre- and post-embryonic developmental quality and perinatal evaluation was performed after ICSI on 580 freshly collected oocytes (FO) and on 614 vitrified-warmed oocytes (VO) and fresh embryo transfer.

Main results and the role of chance: Patients had 36.4 ± 3.7-year-old, AMH of 0.7 ± 0.4 and FSH ± 10.3 4.1. The mean number of 2.8 ± 2.1 FO and 3.0 ± 2.2 VO were used for ICSI on the same day per patient. Although fertilisation rates were similar between FO and VO (64% vs 62%), embryonic developmental quality was affected on day 3 ($p < 0.01$) and day 5 ($p < 0.05$) of development being lower in vitrified oocytes compared to their fresh counterparts, which resulted in less embryos chosen for transfer in VO. A total of 161 patients underwent embryo transfer: 81 had 1.3 ± 0.5 embryos transferred from FO, while 49 received 1.3 ± 0.4 embryos from VO. Thirty patients received mix transfer (one FO and one VO). Implantation rates were 22% and 28% for FO and VO (NS), respectively. All embryos derived from vitrified oocytes that implanted progressed to delivery (n=14), while 3/17 (18%) and 3/8 (38%) embryos from freshly collected oocytes and mixed transfer miscarried. Perinatal outcomes from this preliminary evaluation showed no difference in gestational age and body weight of children between freshly collected (38.67 weeks and 3092 kg) and vitrified oocytes (39.07 weeks and 3298 kg) (NS).

Limitations, reasons for caution: Retrospective design of the study and limited sample size concerning the data on delivery rates.

Wider implications of the findings: In view of the lower in vitro developmental potential of embryos derived from vitrified oocytes in low ovarian reserve patients, accumulation of oocytes in patients undergoing ICSI cycles should be further evaluated. However, the preliminary data on perinatal outcomes seems to reassure the safety of this technology once implantation occurs.

Trial registration number: not applicable

P-450 Low value of AMH did not affect oocyte quality and pregnancy outcome in patients with severe endometriosis

A. Pacchiarotti[1]

[1]San Filippo Neri Hospital, IVF Unit, ROMA, Italy

Study question: The aim of this pilot study was to determine that low anti-müllerian hormone (AMH) serum levels due to severe endometriosis *did not affect IVF* clinical outcomes in young patients (<37)

Summary answer: young patients with low AMH level due to severe endometriosis displayed a diminished oocyte yield but not a reduction in embryo quality and pregnancy outcomes.

What is known already: diminished ovarian reserve is associated to reduced fertility and poor response to ovarian stimulation during *in vitro* fertilization (IVF) treatments

Study design, size, duration: A total of 50 IVF cycles of patients younger than 37 with severe endometriosis were retrospectively analyzed in a single center between November 2016 and July 2018 and compared to a control group of 84 patients with no story of endometriosis and normal AMH value. AMH value has been evaluated within three months before the stimulation. number and maturation of retrieved oocytes, embryo quality, and pregnancy outcomes were compared using Student's t-test and Fisher's test.

Participants/materials, setting, methods: A total of 50 IVF cycles of patients younger than 37 with severe endometriosis were retrospectively analyzed in a single center between November 2016 and July 2018 and compared to a control group of 84 patients with no story of endometriosis and normal AMH value. AMH value has been evaluated within three months before the stimulation. number and maturation of retrieved oocytes, embryo quality, and pregnancy outcomes were compared using Student's t-test and Fisher's test.

Main results and the role of chance: The number of oocytes retrieved per cycle and the percentage of mature oocytes (MII) were significantly (P<0.001) lower in IVF patients with severe endometriosis AMH value ≤ 1.1 ng/ml (Group A; 3.8±2.6 retrieved oocytes, 70% MII) compared to patients without endometriosis and AMH levels > 1.1 ng/ml (Group B; 6.9±4.6 retrieved oocytes, 83%

MII). On the other hand, embryo morphology, implantation rate (31% vs 33%; *P*=0.833) and pregnancy rate (50% vs 49%; *P*=1) were comparable in the two groups.
Limitations, reasons for caution: none
Wider implications of the findings: young patients with an impairment of the ovarian reserve due to severe endometriosis displayed a diminished oocyte yield but not a reduction in embryo quality and pregnancy outcomes. These results suggest that serum AMH levels should not be adopted as a criterion for discouraging those patients from undergoing IVF treatments.
Trial registration number: not applicable

POSTER VIEWING SESSION
NURSING AND MIDWIFERY

P-451 I trust the healthcare professional most: Exploring fertility knowledge among healthcare professional and lay population groups

B. Grace[1], J. Shawe[2], J. Sarah[3], S. Judith[1]

[1]University College London, Institute for Women's Health, London, United Kingdom ; [2]The University of Plymouth, Institute of Health and Community, Plymouth, United Kingdom ; [3]SPD GmbH, Clinical Research, Bedford, United Kingdom

Study question: What is the level of fertility knowledge amongst healthcare professionals compared to lay men and women in the UK?
Summary answer: Healthcare professionals in this study did not appear to have better knowledge than the lay population in this study.
What is known already: As the average age of first time parents continues to rise, health policies have highlighted the importance of optimising reproductive health through better knowledge and awareness. This study therefore aimed to assess current patterns of fertility knowledge, attitudes and practices; and identify improvement opportunities. In this study, fertility knowledge of lay men and women and HCPs was assessed using the same test instrument, which provided a new and unique perspective compared to previous studies.
Study design, size, duration: Mixed method research was conducted using a UK wide cross-sectional survey and semi-structed interviews. Results were obtained from 1,082 survey respondents which included 347 HCPs, 332 men, and 413 women, 115 of whom were trying to conceive. There was variation in age, level of education, ethnicity and training. Interviewees were purposively sampled to include men and women from the reproductive age range (18-45 years) and of varying ethnic and educational backgrounds.
Participants/materials, setting, methods: Survey participants were recruited nationwide via online newspaper and social media adverts. Of those who agreed to a follow-up interview, 35 were included this study. Healthcare professionals (HCPs) were recruited from professional bodies such as RCN, RCGP, RCP, doctors.org.uk. Interview data were transcribed and analysed using the framework method. Interviews lasted an hour on average. Favourable ethical opinion was given by University College London Research Ethics Committee.
Main results and the role of chance: Survey questions covered the following areas: demographics, basic definitions, male and female reproductive biology, age-related fertility decline and conception. The proportion of HCPs correctly answering the survey knowledge questions was 47.0%(95% CI= 41.6%,52.4%) compared to 47.3% for women(95% CI= 41.0%,52.2%); 50.9%(95% CI= 40.1%, 61.0%) for Women trying to conceive sub group; and 36.3% (95% CI= 30.8%,41.6%) for men. Chi-squared test confirmed statistically significant difference amongst groups. 98.8% of HCPs stated that they provide fertility advice in their role.

Although the internet and school education remained popular sources, HCPs were ranked as the most trusted source for seeking fertility and reproductive health information, however, they did not appear to have better knowledge than the lay population in this study. From interviews, there were inconsistencies among HCPs regarding where responsibility lies for providing the right information and support to patients on fertility awareness. Recommendations were made for additional training on the topic part of general HCP training.

"There is a lack of information. We do touch upon it but I think that with the current climate it's such a significant part of people's lives. I don't think there's enough emphasis on training clinical staff when it comes to fertility…" HCP3, Nurse.
Limitations, reasons for caution: One of the main methodological limitations of this study is the self-selection process, which has implications for generalisability. The results necessarily reflect the views of those who were willing to participate. For the lay population, the online recruitment method could result in potential bias towards respondents of higher socioeconomic status.
Wider implications of the findings: School education remains a consistent source of information but does not adequately cover fertility education. In addition to websites based on robust scientific evidence and centres specialising in sexual education; as an important source, there remains an important need for additional training for primary HCPs on reproductive health.
Trial registration number: N/A

P-452 The Gestational Diabetes Mellitus (GDM) and Risk Factors After Assisted Reproductive Techniques (ART)

N.N. Aypar Akbağ[1], M. Aluş Tokat[2], S. Fata[3], E. Ünsal Avdal[4], R.E. Okyay[3], Ö.E. Doğan[5]

[1]KaramanoğIu MehmetbeyUniversity, Gynecology Nursing, Karaman, Turkey ; [2]Work adres, Dokuz Eylul University Nursing Faculty, Izmir, Turkey ; [3]Dokuz Eylul University, Gynecology Nursing, Izmir, Turkey ; [4]Katip Çelebi University, Internal Medicine Nursing, Izmir, Turkey ; [5]Dokuz Eylul University, Gynecology Medicine, Izmir, Turkey

Study question: Do assisted reproductive techniques play a pivotal role in gestational diabetes mellitus (GDM) incidence and risk factors for GDM in pregnancies after ART?
Summary answer: The hormones stimulated in ART may cause lipid, carbohydrate metabolism disturbances. Obesity, age, polycystic ovary syndrome in addition to ART may increase incidence of GDM.
What is known already: External stimulation of hormones in assisted reproductive therapies is known to cause disharmony in lipid, carbohydrate and protein metabolism. However, it is stated in the literature that the increase in the incidence of GDM may be caused by some confounding factors such as age, obesity, polycystic ovary syndrome (PCOS) and multiple pregnancies developing after ART.
Study design, size, duration: The retrospective cohort study was performed between December 2018 and February 2019 by using the file information of women who had been treated at Dokuz Eylul University InVitroFertilization (IVF) Center and gave birth between 2006-2018. One hundred eigth women were reached.
Participants/materials, setting, methods: Women who treated at the IVF center between 2006-2018 were included. Giving birth after ART was inclusion criteria; Polycystic Ovarian Syndrome (PCOS), age 40 and over, Body Mass Index (BMI) 30 and over, glucose intolerance, previous GDM history and corticosteroid treatment were the exclusion criteria. The women were called from center and data was collected via telephone. A total 621 women registered in center, 108 women were reached.
Main results and the role of chance: The GDM was reported by 16.7% of women participating in the study. The results was interpreted as high incidence according to general incidence of GDM reported by American Diabetes Association's incidence of GDM (1-14%). Ovulation induction drugs used by all women were rFSH (recombinant Follicle Stimulating Hormone) (70.4%), Human Menopausal Hormone (HMG) (16.7%), FSH and HMG (13.0%). The mean drug starting dose was 257.98±110.95 and the total dose was 2797.47±1457.20 units. They used drugs for an average of 10.60±1.92 days. Progesterone use rate after transfer was 65.7%. Using rFSH, HMG, together rFSH and HMG (KW=1.162, p=0.281), drug starting dose (U=668.000, p=0.236), the total dose of drug (U=722.500, p=0.470), the duration of drug use (U=767.000, p=0.718), using or not using of progesterone after transfer (KW=0.204, p=0.652) did not increase the incidence of GDM.
Limitations, reasons for caution: Since the data were obtained from the sample treated in a wide period of time, problems related to the recall factor were experienced. Also, some women could not be reached from their registered numbers in the centers.

Wider implications of the findings: This study suggests that women who will receive ART should be screened for risk of GDM from the begining of pregnancy.The incidance can be higher in this group compared with natural pregnancy. Studies with larger sample should be performed for specific determimining the risk factors that can affect this process.
Trial registration number: not applicable

POSTER VIEWING SESSION
PSYCHOLOGY AND COUNSELLING

P-453 Eliciting couples' preferences for fresh versus elective frozen embryo transfer in IVF: a discrete choice experiment

B. Abdulrahim[1], G. Scotland[2], S. Bhattacharya[3], A. Maheshwari[4]

[1]Aberdeen Fertility Centre, University of Aberdeen, Aberdeen, United Kingdom ; [2]Institute of Applied Health Science, University of Aberdeen, Aberdeen, United Kingdom ; [3]School of Medicine- Medical Sciences and Nutrition, University of Aberdeen, Aberdeen, United Kingdom ; [4]Aberdeen Fertility Centre, NHS Grampian, Aberdeen, United Kingdom

Study question: What are the factors influencing couples' preferences for fresh versus elective frozen embryo transfer (ET) in in-vitro fertilisation (IVF)?
Summary answer: Accepting that elective frozen ET can delay treatment but reduces the risk of OHSS, couples' choices are driven by expected pregnancy and birth outcomes.
What is known already: Elective frozen embryo transfer results in livebirth rates which are on par with, or better than those following fresh embryo transfer. In terms of safety, elective embryo transfer reduces the risk of ovarian hyperstimulation (OHSS) and small for gestational age babies but increases the risk of pre-eclampsia and large for gestational age compared to fresh embryo transfer. Given the prevailing uncertainty around a universal policy of elective frozen embryo transfer for all couples undergoing IVF, user preferences are critical in informing clinical decision making.
Study design, size, duration: Discrete choice experiments (DCEs) are a preference elicitation technique for assessing the value that individuals derive from different aspects of a treatment or service. We asked both partners of 104 IVF naïve couples attending a tertiary referral centre to independently complete a questionnaire with nine hypothetical choices illustrating potential advantages and disadvantages of fresh versus frozen embryo transfers in terms of four attributes (live birth rate, miscarriage rate, neonatal complication rate and cost of treatment).
Participants/materials, setting, methods: Participants were informed that frozen ET would delay the transfer of embryos by 6-8 weeks but reduce the risk of OHSS. An opt-out (no IVF treatment) was included for each choice task. Logistic regression was used to analyse the choice response data and estimate preference weights for fresh and frozen ET and each treatment attribute. Willingness to pay (WTP) was calculated as the marginal rate of substitution between the cost attribute and each other attribute.
Main results and the role of chance: A total of 104 couples completed 208 questionnaires. Couples preferred both fresh and elective frozen embryo transfer (Odds ratio 27.65 and 27.7 respectively) compared to no IVF treatment with no strong preference for fresh over frozen.

Couples strongly preferred any IVF treatment options that increased the livebirth rate by 5% (OR 1.28; 95% CI; 0.070 - 0.424), reduced the miscarriage rate by 18% (OR 0.54; 95% CI; 0.788 - 0.454) and diminished neonatal complication rates by 10% (OR 0.59; 95% CI; 0.697 - 0.357).

Respondents were willing to pay an additional £2452 (95% CI; 596 - 4,308) and £7,168 (95% CI 5,053 – 9,283) for a 5% and 15% increase in the live birth rate respectively. They required compensation of £5,230 (95% CI; 3,320 -7,141) and £13,245 (95% CI; 10,110 – 16,380) for treatments that increased the neonatal complication rate by 10% and 25% respectively. Couples valued a 10% diminution in the risk of neonatal complications and a 10% increase in the livebirth rate equally.

Older women put a higher monetary value on increases in the livebirth rate than younger women. Partners tended to place a greater value on reductions in treatment associated risks than those intending to get pregnant.
Limitations, reasons for caution: DCEs can elicit intentions which may not reflect actual behaviour. The external validity of this study is limited by the fact that it was conducted in a single centre with generous public funding for IVF.
Wider implications of the findings: Couples undergoing IVF may be willing to forgo higher livebirth rates for reduced maternal and perinatal risks. Along with evidence from randomised trials, these preferences should be used to inform policy as well as individualised decision making in IVF.
Trial registration number: Not applicable

P-454 Pre-implantation genetic testing for aneuploidy; motivations, concerns and perceptions in a UK population

B. Jones[1], T. Bracewell-Milnes[1], M. Spearman[2], M. Jalmbrant[3], J. Green[4], O. Rabi[4], S. Saso[1], P. Serhal[4], J. Ben-Nagi[4]

[1]Imperial College London, Department of Surgery and Cancer, London, United Kingdom ; [2]University College London, Medicine, London, United Kingdom ; [3]Imperial College NHS Foundation Trust, Clinical psychology, London, United Kingdom ; [4]The Centre for Reproductive & Genetic Health, Fertility, London, United Kingdom

Study question: What are women's motivations and concerns in using pre-implantation genetic testing for aneuploidy (PGT-A), and what are their perceptions after undergoing it as part of in vitro fertilisation (IVF) treatment?
Summary answer: Most women use PGT-A to optimise the chance of successful embryo transfers, are satisfied after treatment, and would use it in future IVF cycles
What is known already: PGT-A facilitates embryo selection by allowing the opportunity to prioritise chromosomally normal embryos for transfer to the uterus. The transfer of embryos adjudged to be euploid using modern PGT-A methods is associated with higher implantation, ongoing pregnancy and delivery rates with reduced pregnancy loss compared to unscreened embryos, thus mitigating the negative clinical impact maternal age has upon reproductive outcomes. Despite the upward trend in women utilising PGT-A, there is little data about the women's motivations and concerns toward using the technology, and perceptions having gone through the process.
Study design, size, duration: This was a cross sectional survey which included 161 women who used PGT-A in a single fertility clinic in the UK between 2014-2018.
Participants/materials, setting, methods: An online questionnaire was created to assess motivations and concerns toward PGT-A as well as outcomes and perceptions following IVF using PGT-A. Motivating and concerning factors were quantified out of 10 depending on perceived significance (0=insignificant; 10=very significant). A mixture of closed and Likert scaled questions were used to assess perceptions to PGT-A after treatment. Descriptive statistical analysis was undertaken using mean +/- SD.
Main results and the role of chance: 333 women were invited to participate. The response rate was 48.3% (n=161). The most common reasons to use PGT-A was advanced maternal age (n=84;35.1%) and repetitive (≥2) unsuccessful IVF cycles (n=77;32.2%). The most significant motivating factors to undergo PGT-A were to improve the probability of having a baby per embryo transfer (9.22+/-1.8) and optimise the chance of implantation (8.85+/-2.52). The most significant concerning factors identified were not having any embryos to transfer (5.76+/-3.4) and the potential for damage to be caused to embryos (5.45+/-3.1). More than three quarters (n=122;77.2%) achieved at least one live-birth using IVF with PGT-A. Two thirds (n=81;66.4%) of those who had a livebirth planned to tell their children regarding the use of PGT-A, whereas a minority (n=10;8.2%) did not intend to. The majority of participants were satisfied/very satisfied with their experience with PGT-A (n=117;73.6%), whereas 15.7% (n=25) were dissatisfied/very dissatisfied. Of those that were dissatisfied/very dissatisfied, almost two thirds (n=16;64%) did not achieve a live-birth. In those who were satisfied/very satisfied, just 8.5% (n=10) did not have a successful live-birth. More than two thirds (n=108;67.9%) would use PGT-A in future IVF cycles, and more than three quarters (n=123;77.4%) would recommend it to family and friends.

Limitations, reasons for caution: The data from this study was retrospective and from a single centre.
Wider implications of the findings: PGT-A offers an opportunity to optimise reproductive outcomes. This study highlights that, in a UK population, perceptions amongst women who undergo PGT-A as part of IVF are mostly positive. We clearly identify that women are more satisfied following treatment if a resultant livebirth is achieved.

P-455 Prospective acceptability study of a psychological online self-help intervention for individuals with an unmet parenthood goal (UPG)

B. Rowbottom[1], S. Gameiro[1]

[1]Cardiff University, School of Psychology, Cardiff, United Kingdom

Study question: How acceptable is a psychological online self-help intervention for individuals with an UPG?
Summary answer: Overall the self-help intervention was found to be acceptable and useful, providing structured support for individuals with an UPG, with minor amendments suggested.
What is known already: Individuals who are unable to achieve the family they desire, remaining childless or having fewer children than desired, have an UPG. People with an UPG can experience adjustment problems, resulting in poorer mental health and well-being. An in-depth systematic review of how people adjust to an UPG (Gameiro and Finnigan, 2017) generated the Three Task Model (3TM). This proposes three psychological mechanisms that facilitate adjustment to an UPG: acceptance, meaning making and pursuit of new life goals, leading to better mental health and well-being. To date there is no widely used evidence-based interventions for individuals facing an UPG.
Study design, size, duration: A prospective qualitative acceptability study of an online self-help intervention based on the 3TM was carried out. Twelve participants were interviewed twice: first to obtain their initial reaction to the intervention (T1); and eight weeks later to collect their perspectives of the intervention once they had engaged with it (T2). The interviews focused on assessing participant's perceptions of how acceptable (willingness to use intervention) and important/useful (perceived benefits of using intervention) the intervention is.
Participants/materials, setting, methods: Each participant was interviewed via Skype and audio recorded. At T1, participants were asked to 'think aloud' to the researcher as they engaged with the intervention for the first time. A semi-structured interview then took place, followed by a short questionnaire. The interview and questionnaire were repeated at T2 to gather participants' perspective after engaging with the intervention. Interviews were transcribed and analysed using thematic analysis.
Main results and the role of chance: The analysis resulted in 8 main themes, organized under 3 higher order themes: acceptability, importance, and other.

Themes under acceptability reflected that participants considered the intervention acceptable due to being easy to use, comprehensive and appropriate. Nearly all participants used the intervention individually, with one using it verbally with their partner. Just under half engaged with it digitally, the rest printed out the activities. Barriers to acceptability included limited digital access, poor interactivity, and unclear organisation. A minority of participants felt some sections were difficult to understand and some language was not always appropriate.

Themes under importance showed that all participants felt the intervention was useful and helpful, given that it provided a structure to organise and clarify thoughts, whilst providing guidance to move through their loss. Around two thirds of participants initially felt concerned that engaging with the intervention might be challenging. However, a majority experienced no negative effect engaging with the intervention, with three participants reporting they felt upset at times.

Themes under other highlighted that participants saw their experience of adjusting to UPG as a journey and that the intervention could facilitate this. Finally, participants thought that connecting with others is important and that the intervention can support this.
Limitations, reasons for caution: The study had a small homogeneous sample of childless married infertile women and results may not reflect the views of people who have children (but desire more), whose parenthood goals were not achieved due to other reasons (e.g., lack of partner, partner who does not want children) and of men.
Wider implications of the findings: This study shows that a psychological intervention based on the 3TM is perceived to be acceptable and useful, suggesting it successfully responds to an unmet need for support from infertile women with an UPG. Future work will focus on improving the intervention as per participants' feedback and testing its efficacy.
Trial registration number: Not applicable

P-456 Promoting fertility awareness and preconception health using a chatbot: A randomized controlled trial

E. Maeda[1], A. Miyata[2], J. Boivin[3], K. Nomura[1], Y. Kumazawa[4], H. Shirasawa[4], H. Saito[5], Y. Terada[4]

[1]Akita University Graduate School of Medicine, Environmental Health Science and Public Health, Akita, Japan ;
[2]Dokkyo Medical University, Reproduction Center, Saitama, Japan ;
[3]Cardiff University, School of Psychology, Cardiff, United Kingdom ;
[4]Akita University Graduate School of Medicine, Obstetrics and Gynecology, Akita, Japan ;
[5]Umegaoka Women's Clinic, ART Center, Tokyo, Japan

Study question: What are the effects of using a fertility education chatbot on knowledge, intentions to improve preconception behaviour, and anxiety?
Summary answer: Providing fertility education using a chatbot improved fertility knowledge and intention to optimize preconception behaviour without increasing anxiety.
What is known already: Providing fertility information through educational brochures improves fertility knowledge and changes intentions regarding childbearing, but increases anxiety. Chatbots are automatic conversation programs that are increasingly used in health education, but not yet for fertility awareness.
Study design, size, duration: A three-armed randomized controlled trial was conducted using an online social research panel in Japan in March 2019. All 927 participants were randomized and exposed to one of three materials: a chatbot (intervention group, IG), a document about fertility and preconception health (control group 1, CG1), or a document about an irrelevant topic (control group 2, CG2).
Participants/materials, setting, methods: Participants were women aged between 20 and 34 years old who hoped to have (more) children in the future. The scores for the Japanese version of the Cardiff Fertility Knowledge Scale and intention to optimize eight preconception behaviours among those who did not exhibit that behaviour were assessed immediately before and after exposure to the material. The scores for the State-Trait Anxiety Inventory and the free-text feedback provided by chatbot users were assessed after exposure.
Main results and the role of chance: Baseline characteristics were well balanced between groups. A repeated-measures analysis of variance showed significant fertility knowledge gains after the intervention in the IG (+9.1 points) and CG1 (+14.9 points), but no significant change in the CG2 group (+1.1 points). Post-test increases in the intention to take folic acid, to receive human papilloma virus vaccination, to obtain a primary obstetrics and gynaecology doctor, to take oral contraceptives, and to try to get pregnant were significantly higher in the IG than in CG2 and were similar to that in CG1. Post-test state anxiety scores (mean ± SD) were significantly lower (less anxiety) in IG (43.2 ± 9.5) than in CG1 (47.5 ± 9.5) and CG2 (46.2 ± 9.0), all $P < 0.001$. Three themes emerged from user feedback about the chatbot: technical limitations (e.g., instability of the system such as freezing, low comprehension of users' words); pros and cons of using chatbot (e.g., easy and convenient versus robotism and coolness); and experiences of learning about fertility and preconception health.
Limitations, reasons for caution: The possibility of selection bias associated with the use of a social research panel and volunteer bias toward those more interested in fertility may limit the generalizability of these findings.
Wider implications of the findings: The improvement in fertility knowledge was smaller than that of participants who read a well-written booklet but applied on a large scale may still warrant implication. Further technical development of the chatbot and exploration of personal affinity for technology is required.
Trial registration number: UMIN Clinical Trials Registry (UMIN000035736)

P-457 The age of the patient at the time of decision making is the only factor associated with the future use of conditionally blocked donors

V. Muyshond[1], A. Tolpe[1], A. De Baerdemaeker[1], K. Tilleman[1]

[1]Ghent University Hospital, Reproductive Medicine, Gent, Belgium

Study question: Which patient characteristics are predictive for further use of a sperm donor after the donor has been conditionally blocked?

Summary answer: The younger a patient is when confronted with the use of a quarantined sperm donor, the more likely she will use it for future treatments.

What is known already: Harm to a fetus via transmission of disease is considered a severe adverse reaction and needs to be reported through a biovigilance system. Karyotype screening and carrier screening for cystic fibrosis and spinal muscular atrophy are mostly performed in sperm donors and although this reduces the risk for transmission of the latter diseases, it does not diminish the risk for transmission of other conditions (Isley L. et al. 2016). When a donor child is born with a condition, sperm donors are conditionally blocked, distribution of semen restricted. Patients are notified and decisions on further use of the donor are necessary.

Study design, size, duration: A retrospective descriptive analyses was performed of sperm donors imported from EU sperm banks that were blocked in the period from 01/01/2010 to 31/12/2019. From this patient population, a subgroup was selected based on the fact that these patients had already given birth to a child of this donor or were in treatment at the moment of the blocking. This subgroup of patients had to decide to further use the donor or not.

Participants/materials, setting, methods: In total 767 patients had been treated with donors (n=196) that were subsequently blocked. Patients who had to make a decision on further use of the donor were selected. Variables like country of residence, relation type, children conceived and number of children born, age patient at time of decision and the straws left were included. Mixed model binary logistic regression and Fisher's exact test was used for statistical analysis ($p \leq 0.05$).

Main results and the role of chance: Of the total population, 292 patients were informed about the condition of the donor and a selected sample size of 184 patients had to make a decision on further use of in total 104 blocked donors. 87/184(47%) of the patients decided not to use the donor for future treatments, compared to 57/184(31%) decided to further use and 40/184(22%) have not decided yet.

At the time of decision making, patients had on average 3.2 straws left of the donor and the average age of the patient was 36.23years. Of the 292 patients, 144 made an informed decision on the further use of the donor.

More than half of the lesbian couples chose to not further use the straws (55% (42/77)), 69%(29/42) of the heterosexual couples and 64%(16/25) of the single mothers decided not to use the blocked donor in further treatments (p=NS). Binary logistic regression analysis including multiple variables showed that only the age of the patient had predictive value for deciding not to further use the straws: the average age of a patient deciding not to use the donor (av±SD 37.77±5.45) is higher compared to the average age of a patient deciding to further use the donor (av±SD 33.88±4.67) (p=0.02).

Limitations, reasons for caution: Of the selected sample size, 22% of the patients did not yet decide on the future use of the donor. There might be more intrinsic factors related to the decision making of the patients that are not included in the analysis.

Wider implications of the findings: The future use of a donor is probably related to the fact that the genetic link between future siblings is important to the parent(s), regardless of the type of relationship the patient is in. However more research into decision making of patients in these cases is very much needed.

[9]AZ Sint-Jan, Center for Reproductive Medicine, Bruges, Belgium ;
[10]Cliniques universitaires Saint-Luc, Gynécologie- andrologie et fertilisation in vitro, Brussels, Belgium ;
[11]Antwerp University Hospital, Center for Reproductive Medicine, Antwerp, Belgium

Study question: What is the dropout rate for couples with remaining cryopreserved embryos and what are the reasons for postponing or discontinuing the transfer of cryopreserved embryos?

Summary answer: The dropout rate is 9.0% in patients with remaining cryopreserved embryos. Main reasons to discontinue their treatment are psychological/physical burden and impact on work.

What is known already: In fresh ART cycles, the physical and psychological burden associated with an ART treatment is the major reason for patients to delay or even discontinue their treatment. For IVF and ICSI, rates of discontinuation vary in Europe from 17 to 70%. In addition, discontinuation of ART treatment may contribute to compromised cumulative pregnancy rates in ART. In case of the presence of cryopreserved embryos, delaying treatment is probably less frequent given the lower burden of a natural or artificially prepared frozen embryo transfer cycle. Nevertheless, no data are available regarding rates and reasons for dropout in this population.

Study design, size, duration: This multicenter study included patients from 11 Belgian fertility centers between 2012 and 2017. Patients were considered dropouts (n = 1917) in case they underwent an unsuccessful fresh ("fresh group") or cryo ("in between group") embryo transfer and did not start a subsequent cryo cycle within one year.

Participants/materials, setting, methods: An online anonymous questionnaire, aiming to explore the reasons for dropout, was developed, approved by all the ethical committees and sent to the eligible patients. An unsuccessful embryo transfer was defined by no pregnancy, a biochemical pregnancy, an ectopic pregnancy or a miscarriage <12 weeks. Exclusion criteria were cryopreservation of embryos in case of preimplantation genetic testing, fertility preservation cycles and oocyte donation cycles.

Main results and the role of chance: The overall treatment dropout rate for couples with remaining cryopreserved embryos is 9.0%. The dropout rates in the "fresh" and "in between" group are 9.7% and 8.0%, respectively. The response rate for the online questionnaire was 15.8% (n = 304/1917). The most important reasons for dropout are psychological (50%) and physical (43%) burden, the impact on work (29%), age of the woman in treatment (25%) and the impact on relationship (25%). The decision of the couple to postpone or stop treatment is influenced by external factors in only 16% of the cases. Seventy-eight percent of respondents are satisfied with the care delivered by their fertility center, and 92% would recommend the center to peers. Out of suggested improvements to the respondents, psychological support before (41%), during (51%) and after (51%) treatment, as well as lifestyle counseling (44%) and receiving digital information (43%) are most frequently selected.

Limitations, reasons for caution: As questionnaires cannot fully capture emotional responses or feelings, open answer boxes were added to the 10-point Likert scale used for some of the questions. Although the response rate is quite high compared to similar studies in the field, the results should not be extrapolated to the entire dropout population.

Wider implications of the findings: Based on our data, patients highly recommend enhanced psychological support throughout the entire ART treatment, as well as lifestyle advice and digital communication regarding information relevant for the treatment. This stresses the need to better integrate these aspects of patient centered care in our daily ART practice.

Trial registration number: not applicable

P-459 What happens in the counsellor's room? A qualitative study on the aims of psychological intervention in Italy

Z. Donarelli[1], G. Lo Coco[2], S. Gullo[2], V. Oieni[1], A. Marino[3], A. Allegra[3]

[1]Andros Day Surgery Clinic, Psychology Unit, Palermo, Italy ;
[2]University of Palermo, Department of Psychology- Educational Science and Human Movement, Palermo, Italy ;
[3]Andros Day Surgery Clinic, Reproductive Medicine Unit, Palermo, Italy

Study question: What type of intervention, methods and goals guide the Mental Health Professionals' (MHPs) work with couples in infertility counselling?
Summary answer: Although Italian MHPs' interventions follow different approaches in infertility counselling, there is a consensus on aiming to strengthen personal generativity beyond the goal of pregnancy.
What is known already: Within the context of infertility, three types of counselling are commonly adopted (implication counselling, support counselling and therapeutic counselling) and ESHRE has recognized the need for providing integrated psycho-social care by the entire staff. Although some evidence-based guidelines (which should guide psychological interventions in infertility clinics) focusing on the themes and aims of psychological counselling have been provided in recent years, there is scarce evidence on the MHP's adherence to these manuals. Moreover, there is a dearth of research on how MHPs really conduct their interventions in countries where clinics are not compelled to include MHPs in their staff.
Study design, size, duration: This was a cross-sectional qualitative study of 14 experienced MHPs who have been working in public and private infertility clinics in different regions of Italy. All professionals were individually interviewed during a five-month period from June to October 2019. Semi-structured interviews were held in Italian via Skype or phone and lasted between 60 and 80 minutes. Each interview was transcribed verbatim.
Participants/materials, setting, methods: Eighteen invitations to participate in an interview-based study were sent to MHPs and 14 agreed to participate. The interview guide was devised based on themes identified in the literature review. Data were analyzed thematically using NVivo software. A coding framework was drafted by the Principal Investigator and reviewed by the team. The entire data set was then coded by two researchers, using the coding comparison function in NVivo, reporting fair to good agreement.
Main results and the role of chance: An all-encompassing thematic description of the data set was produced. The key themes were classified under the following thematic headings: providing implication counselling to couples attending infertility treatment or facing repeated failures; the couple as the unit of counselling intervention; strengthening couples' commitment to the course of treatment.

Almost all MHPs reported facing some challenges, when working with patients who had received donated gametes, such as addressing the need to build an affective parental bond beyond genetic heritage; MHPs reported a different stance from physicians when responding to a couple's requests for advice on managing the disclosure issue, often showing a tendency to hold back their personal inclinations; moreover, most MHPs experience difficulties in responding to physicians' expectations (i.e. to obtain a quick patient response and relief from anxiety and doubts/fears, or an early evaluation of psychiatric disorders to avoid possible legal proceedings in the future).

Overall, the results suggest that MHPs would like to have greater adherence to ESHRE psycho-social routine care guidelines, with a need for further integrated care by the entire staff.

However, MHPs seem to provide counselling with common strategies, pursuing the same aims, albeit with huge differences in treatment types and settings.
Limitations, reasons for caution: The auto-selection of participants may have resulted in a sample representing those with greater clinical experience and having seen a large number of patients. Moreover, the findings may underestimate the ways in which infertility counselling is delivered outside infertility Clinics.
Wider implications of the findings: This is the first study aiming to explore the characteristics of psychological counselling from the MHPs' perspective. Although some heterogeneity across clinical approaches to patients and settings exists, MHPs do deliver counselling in general attunement with couples' needs, with efforts to break the barriers of non-integrative care.
Trial registration number: Not applicable

P-460 Reproductive choices after oocyte vitrification for age-related reasons.

J. Nekkebroeck[1], L. Leunens[1], E. Buyse[1], H. Tournaye[1], M. De Vos[1]

[1]UZ Brussel, Centrum voor Reproductieve Geneeskunde, Jette- Brussels, Belgium

Study question: What is the relational status of women who returned to the fertility clinic after planned oocyte vitrification?
Summary answer: Of women who returned to the clinic after planned oocyte cryopreservation, 48% (59/122) had found the right partner to pursue childbearing.
What is known already: The profile of women seeking planned oocyte vitrification has been quite stable during the past decade. Most women are in their mid-and late thirties, are highly educated and have a career. These women attribute their childlessness to 'not having a suitable partner' rather than to 'prioritisation of career achievements'. Hence, the main driver for planned oocyte cryopreservation is to buy more time to find a suitable partner. The return rates of these women to the fertility centre and the utilisation rate of the cryopreserved oocytes are only 7-12%. Little is known about their reproductive choices.
Study design, size, duration: In a single centre, computerized clinical data were retrieved from women who underwent planned oocyte vitrification for age related reasons between January 2009 and December 2018 (n=668) and from those who returned (n=122) to the centre to discuss their reproductive options and/or to proceed with reproductive treatment.
Participants/materials, setting, methods: We collected data from computerised clinical charts of women who applied for reproductive treatment after planned oocyte vitrification. We evaluated whether women actually started treatment, assessed their relational status (single or in a relationship) and the utilisation rate of vitrified oocytes and treatment outcome.
Main results and the role of chance: 18.2% (122/668) women returned to the fertility centre. Four were beyond the age limit of IVF in Belgium and requested transport of their oocytes to a centre abroad. For four women the cryopreservation period of 10 years had expired. Upon return to the clinic, 55 women were single and 59 had found a partner. 28.8% (17/59) of women with a partner gained information but did not proceed with fertility treatment. No less than 42% (23/55) of single women refrained from fertility treatment after counselling by a gynaecologist and psychologist. For 60.9% (14/23) of those, a genetic reference for their child was utmost important whilst only 3/23 requested an anonymous sperm donor. 60.7% (74/122) women proceeded with reproductive treatment (artificial insemination, IVF or ICSI) of which 42 had a partner and 32 were single. The utilisation rate of vitrified oocytes in women who returned was 37% (45/122). Of these 45 women who used their vitrified oocytes, 17 had an ongoing pregnancy and 4 already delivered a baby.
Limitations, reasons for caution: Patients who did not return to the centre were not included. Hence, the reproductive pathway of only a subset of women who had their oocytes cryopreserved was analysed. Follow-up of reproductive outcomes in women who did not return is required for a comprehensive appraisal of planned oocyte vitrification.
Wider implications of the findings: Almost 50% of women who returned to the fertility centre with a desire for pregnancy had found a partner. After counselling, an important subset (42%) of single women decided not to pursue single motherhood.
Trial registration number: not applicable

P-461 Impact of pre-treatment optimism on emotional health during the waiting period and after treatment results

J. Boivin[1], H. Ockhuijsen[2], R. Morey[3], A. Van den Hoogen[4], A. Domar[5], N. Macklon[6]

[1]Cardiff University, School of Psychology Cardiff Fertility Studies Research Group, Cardiff- Wales, United Kingdom ;
[2]University Medical Center Utrecht, Women & Baby Unit, Utrecht, The Netherlands ;
[3]Cardiff University, School of Psychology, Cardiff- Wales, United Kingdom ;
[4]University Medical Centre Utrecht, Birth Center Neonatology, Utrecht, The Netherlands ;
[5]Harvard Medical School, Obstetrics- Gynecology- and Reproductive Biology, Boston, U.S.A. ;
[6]London's Women's Clinic, London's Women's Clinic, London, United Kingdom

Study question: What is the association between pre-IVF success expectations and wellbeing during and after treatment?
Summary answer: Patients were more optimistic than they perceived their doctors to be but this optimism was not harmful to wellbeing during or after the pregnancy test
What is known already: Many professionals worry that excessive patient optimism at the start of IVF will negatively impact emotional reactions during treatment and after a treatment cycle. Staff report managing expectations to be a major challenge in working with patients. Patients tend to over-estimate the chance of success with treatment, even among groups with characteristics that should reduce expectations of success (e.g., older age). The effect of high optimism on wellbeing during and after treatment results is not known.
Study design, size, duration: The study comprised a secondary analysis of data from the 20-month Positive Reappraisal Coping Intervention (PRCI) randomised controlled trial (Ockhuijsen 2014). Only data from the two control groups not receiving PRCI were used in analysis. Of 1445 invited, 230 were randomised to the control groups. Participants completed questionnaires prior to treatment (Time 1, T1), 10 days after embryo transfer during the waiting period (Time 2, T2), and six weeks after embryo transfer (Time 3 T3).
Participants/materials, setting, methods: Participants were recruited from a fertility clinic if being female gender and undergoing stimulated/cryopreserved IVF/ICSI cycle. Patient optimism was measured as a difference score between their ratings (0 to 100%) on: "What do you personally think is your chance of success with your treatment cycle?" and "What do you recall your doctor telling you was the chance of success with your treatment cycle?". At T1, T2, T3 women completed the Hospital Anxiety and Depression Scale.
Main results and the role of chance: Mean personal chance of success 42.70% (SD=22.76) was significantly higher than recalled doctor chance of pregnancy 30.42% (SD=16.52) (n=157, t(156)=6.57, p < .000). The difference between self and doctor estimates decreased as doctor estimates were reported to be more optimistic (F(3, 153)=4.58, p <.004). Regression was used to examine association between patient optimism and wellbeing (anxiety, depression) during and after treatment results (controlling for pre-treatment anxiety and depression). Overall regression showed that after controlling for pre-treatment values, patient optimism was not associated with anxiety (F(1, 130)=.497, p. = 482, B=-.049 [95% CI -.041 - .020]) or depression F(1, 130)=.481, p = .489, B=-.044 [95% CI -.031 - .015]) during the waiting period. Similarly, after controlling for pre-treatment and waiting period scores, pre-treatment patient optimism was not significantly associated with post-treatment anxiety (F(1, 116)=.000, p =.993, B=-.001 [95% CI -.008 - .993]) or depression (F(1, 116)=.202, p. = .654, B=-.031 [95% CI -.020 - .032]).
Limitations, reasons for caution: Participants were in the control arms of an RCT testing a psychological intervention. Optimism was measured only in reference to what patients believed the doctor said, and not what the doctor actually said. About 36.5% (n=89) of women reported not being told a chance of pregnancy with treatment.
Wider implications of the findings: Pre-treatment optimism may be a cognitive heuristic patients use to initiate treatment that does not markedly affect wellbeing in treatment. Future research should replicate findings using doctor reports and a wider range of wellbeing and psychological measures. Fertility staff should strive for accurate expectation management but not discourage optimism.
Trial registration number: not relevant

P-462 Parent's experiences of identity-release sperm donation as adult offspring obtain donor information

A. Widbom[1], S. Isaksson[2], G. Sydsjö[3], A. Skoog-Svanberg[4], C. Lampic[1]

[1]Karolinska Institutet, Women's and Children's Health- Division of Reproductive Health, Stockholm, Sweden ;
[2]Uppsala University, Department of Public Health and Caring Sciences, Uppsala, Sweden ;
[3]Linköping University, Division of Obstetrics and Gynaecology- Department of Clinical and Experimental Medicine, Linköping, Sweden ;
[4]Uppsala University, Department of Women's and Children's Health, Uppsala, Sweden

Study question: How do parents experience and handle their adult offspring's search for identifying information about their sperm donor?
Summary answer: As parent's experiences of 'fulfilling' conditions of parenthood vary, so does their willingness to integrate the donor in the parent-offspring-donor triad.
What is known already: In Sweden, offspring conceived with donor gametes are entitled to obtain identifying information about the donor when reaching mature age. Since this law was introduced in 1985, very few of the adult offspring who are eligible to obtain donor information have exercised this right. There is limited knowledge about the experiences of parents with adult offspring following identity-release donation.
Study design, size, duration: Based on a parallel multicenter study of adult offspring who had requested and received donor information at Swedish clinics, a purposive sample of their parents were approached during 2018-2019.
Participants/materials, setting, methods: Participants were 23 parents (15 women and 8 men) with varying educational and socioeconomic background and from urban and rural areas throughout Sweden. In these families, offspring's relation to the donor ranged from no further interest, considering future contact, occasional contact and regularly meeting with the donor. Individual semi-structured interviews with parents in heterosexual couples were conducted face-to-face or via telephone, transcribed verbatim and analyzed using thematic analysis.
Main results and the role of chance: Two overarching themes were constructed as (a) Fulfilling conditions of parenthood, and (b) Parents' handling of the parent-offspring-donor triad. Conditions of parenthood, e.g. the importance of parent-offspring resemblance or importance of achieving genetic parenthood, are set by parents and society, and are to varying extents fulfilled by the parents. The extent to which parenthood is experienced as 'fulfilled' appear to further influence how the parent handles the parent-offspring-donor triad. For some, the donor is included in the family, as a new father figure, or as an extension of the family. For others, the donor is kept at a distance from the family, perceiving his intentions as non-relational, or as a threat to parenthood. I.e., as parents to varying extents are confronted with conditions of parenthood, and to varying extents 'fulfill' those conditions, they develop their lines of action to the offspring's search for identifying information about his/her sperm donor on a continuum from excluding to including the donor in the family. In cases where the donor holds more ambiguous roles, or where there is disagreement in regards to the importance of the donor between the parent and the child, friction may arise within the parent-offspring-donor triad.
Limitations, reasons for caution: Concerning transferability to other populations, it should be considered that the study was performed, and parents' experiences were given, within the context of the Swedish legislation on identity-release donation.
Wider implications of the findings: The present findings highlight the complexity of providing adult offspring access to identifying information about the donor. Parents following identity-release gamete donation may benefit from counselling and support to manage family life with varying genetic linkage within and outside the family unit.
Trial registration number: not applicable

P-463 Let's talk about it: exploring attitudes towards engagement and open discussion of (in)fertility and reproductive heath on social media

S. Tothill[1], B. Grace[1], P. Zadeh[1], D. Patel[1]

[1]University College London, Institute for Women's Health, London, United Kingdom

Study question: What is the level of engagement of users on (in)fertility and reproductive health topics two popular social media platforms?
Summary answer: Level of engagement is high, especially where celebrities are involved.
What is known already: The media remains a powerful influence on health-related behaviour, warranting further critical examination. Social media platforms like Twitter, Facebook, and Instagram have rapidly redefined the process of communication between healthcare workers, patients and public, and extremely popular way of disseminating both health information and individuals' opinions and own health experiences. Yet little is documented about social media users' levels of engagement and discussion of the topic of (in)fertility, traditionally considered a taboo subject. As of January 2020, there are 1billion Instagram users and 363million twitter users globally. This study was conducted to explore engagement on fertility topics on these platforms.

Study design, size, duration: Data from both Instagram, a photo and video-sharing social networking service and Twitter, a microblogging and social networking service were analysed, to understand the engagement of users regarding the topic of (in)fertility.
Participants/materials, setting, methods: In order to find relevant posts, Google searches were initially conducted. The most popular posts were all celebrities', which were then searched on the 2 platforms over a 2 month period, ending in January 2020 and analysed. Legitimate accounts of public figures are confirmed via 'verified' badges on Instagram and Twitter. The number of followers, likes, the topics discussed and comments were all documented, analysed and categorised into themes.
Main results and the role of chance: In the past two years, many celebrities such as Amy Schumer, Anne Hathaway, Kim Kardashian-West and Chrissy Teigen, all millennials, have openly discussed their reproductive health; specifically their fertility issues and trouble conceiving. These women have over 211 million followers on Instagram and nearly a million on Twitter, showing the incredible reach their posts have. Their latest Instagram stories and posts regarding their fertility have been liked by over 16 million people, each having thousands of comments from users showing support, advice, their own personal experiences and heartache. Topics such as IVF, Infertility, endometriosis and TTC have been hashtagged over 5 million times, with other words such as #IVFJourney, #InfertilityWarrior and #InfertilitySucks, having hundreds of thousands of posts and comments. Celebrities opening up about such intimate issues has given social media users the confidence to open up about their personal fertility struggles and realise they are not alone in their journey. Attitudes are changing across generations, Michelle Obama, only recently publicly discussed her IVF experience which happened over 2 decades ago. As Gen-Z-ers start to embark on their fertility journey, social media usage for disseminating (in)fertility information will continue rise. However, so will the risk of spreading inaccurate information.
Limitations, reasons for caution: A key methodological limitations is that findings mostly reflect views of western social media users. As use of social media continues to rise in less developed countries, further studies can provide more geographic and global representations. As not all posts include hashtags, our findings may under-represent levels of engagement.
Wider implications of the findings: As attitudes towards discussions of fertility and reproductive health continue to evolve, social media and celebrity influence will continue to be influential tools. This should be considered in the context of improving fertility awareness and effective digital health interventions based on robust scientific evidence.
Trial registration number: Not applicable

P-464 Perceived threat of infertility and women's intention to anticipate childbearing: the mediating role of personally perceived barriers and facilitators

J. Pedro[1,2], T. Brandão[3], J. Fernandes[1], A. Barros[4,5], P. Xavier[5,6], L. Schmidt[7], M.E. Costa[1,2], M.V. Martins[1,2]

[1]University of Porto, Faculty of Psychology and Educational Sciences, Porto, Portugal ;
[2]Centre for Psychology at University of Porto-, University of Porto, Porto, Portugal ;
[3]Universidade Autónoma de Lisboa Luís de Camões, CIP- Departamento de Psicologia-, Lisboa, Portugal ;
[4]University of Porto, Department of Genetics- Faculty of Medicine, Porto, Portugal ;
[5]Centre for Reproductive Genetics A. Barros, Porto, Portugal ;
[6]University of Porto, São João Hospital, Porto, Portugal ;
[7]University of Copenhagen, Department of Public Health, Copenhagen, Denmark

Study question: What are the roles of the perceived threat of infertility (severity and susceptibility), barriers and facilitators on the intention to anticipate childbearing?
Summary answer: Perceived threat of infertility affects intention to anticipate childbearing via the perception of infertility as barrier and willingness to go through fertility treatments as facilitator.
What is known already: Previous studies showed that people of reproductive age do not have adequate fertility awareness. Infertility might be partly preventable (if people try to conceive earlier in their lives) and it has been supported that the postponement of childbearing can also be partly attributable to low fertility awareness. Some intervention studies have targeted fertility awareness to promote it, but very few considered barriers, facilitators or intentions regarding individuals' reproductive plans. Studies exploring the complex relationship between the perceived threat of infertility and undertaking fertility protective behaviours are needed.
Study design, size, duration: For this cross-sectional study, childless women were invited to participate, at private gynaecology clinics and through social networks between July 2016 and February 2018. The eligibility criteria were: being involved in a romantic heterosexual relationship (≥1 year); desiring to have children in the future; being between 20-45 years of age; not having knowledge of a fertility problem, and not being actively trying to conceive for ≥12 months (or 6 months, if women aged ≥ 35).
Participants/materials, setting, methods: The sample is composed of 240 childless women committed in a heterosexual relationship who desired to have children in the future. Women completed a self-reported questionnaire including measures about their reproductive project, barriers, and facilitators to achieving their reproductive goals, and infertility' susceptibility and severity. A mediation model using PROCESS was used to test whether the relationship of the perceived threat of infertility and intention to have children earlier is mediated by barriers and facilitators.
Main results and the role of chance: Women were on average 28 years old and were committed in their relationship for an average of 6 years. Participants desired to have 2.25 children, the first one at 30.5 years old and the last at 34.5. Only 25% reported high intention to try to have children earlier than planned. Being actively trying to conceive and the number of desired children were correlated with higher intention to anticipate childbearing. For this reason, these two variables were further introduced in the model as covariates. The mediation model revealed no significant direct effect after including mediators (effect=.02; 95%CI [-.013, .044]). Two indirect effects of perceived threat of infertility on intention to have children earlier were found, through perceiving infertility as a strong barrier [estimate for indirect effect: .01 (bias-corrected (BC) 95% confidence interval (CI) = .005; .027)], and through being willing to use fertility treatment as a facilitator [estimate for indirect effect: .01 (BC 95% CI= .001; .016)]. The analysis confirmed a full mediation model and it explained 20% of the variance of intention to have children earlier.
Limitations, reasons for caution: Due to the nature of our sample and recruitment in several settings, the results need to be interpreted with caution. The cross-sectional design does not allow drawing causal directions; further longitudinal studies exploring the role of these variables are needed.
Wider implications of the findings: Perceived threat of infertility seems to be associated with the intention to anticipate childbearing. Due to lack of fertility awareness, intervention initiatives might take into account these mediators, aiming to increase the knowledge on the risk of infertility and to clarify myths that can hinder people from seeking fertility treatments.
Trial registration number: NA

P-465 Incremental validity of the Psychological Inflexibility Scale – Infertility (PIS-I)

A. Galhardo[1], M. Cunha[1], B. Monteiro[2], J. Pinto-Gouveia[3]

[1]Instituto Superior Miguel Torga- Faculty of Psychology and Educational Sciences of the University of Coimbra, Psychology- Center for Research in Neuropsychology and Cognitive and Behavioral Intervention CINEICC, Coimbra, Portugal ;
[2]Instituto Superior Miguel Torga, Psychology, Coimbra, Portugal ;
[3]Faculty of Psychology and Educational Sciences of the University of Coimbra, Center for Research in Neuropsychology and Cognitive and Behavioral Intervention CINEICC, Coimbra, Portugal

Study question: Does an infertility-related self-report measure of psychological inflexibility, the Psychological Inflexibility Scale – Infertility (PIS-I) perform better than a generic measure of psychological inflexibility?
Summary answer: The PIS-I was found to add for the prediction of infertility-related mental health outcomes as well as more general mental health outcomes.
What is known already: Psychological inflexibility (PI) has been defined as a core transdiagnostic mechanism involved in the development and maintenance of a broad range of psychological difficulties. This led to the development of several context-related measures of PI (e.g., pain, tinnitus, diabetes), besides its general measure, the Acceptance and Action Questionnaire (AAQ-II). The PIS-I was developed to assess infertility-related PI. Previous studies have suggested

that people facing infertility showed higher scores in PI,when compared to fertile couples and couples pursuing adoption. Furthermore, PI showed a mediation role in the relationship of the impact of infertility on several life areas and depressive symptoms.

Study design, size, duration: The study had a longitudinal design. Participants were recruited through the Associação Portuguesa de Fertilidade (patients' association). Inclusion criteria were age (18 years or older) and an infertility medical diagnosis. Data were collected online through self-report instruments between June and December 2018. A sub-sample of 53 participants completed the PIS-I 6 weeks after the first administration.

Participants/materials, setting, methods: A sample encompassing 313 participants (287 women and 26 men) completed online the PIS-I, the AAQ-II, the Fertility Problem Inventory (FPI), the Infertility Self-efficacy Scale (ISE) and the Depression, Anxiety and Stress Scales – 21 (DASS-21). Partial correlations, controlling for the AAQ-II, were calculated to test the PIS-I incremental validity. Moreover, hierarchical regression models were computed to address the predictive power of the PIS-I regarding infertility-related mental health outcomes and more general mental health outcomes.

Main results and the role of chance: Partial correlations results were all significant, ranging from .16 to .45, suggesting that the PIS-I accounts for important variance in several measures after accounting for the related construct of general psychological inflexibility. Concerning infertility related mental health outcomes, in the first step the AAQ-II predicted infertility-related stress (FPI) and infertility self-efficacy (ISE) with R^2values of .40 and .20, respectively. In the second step the PIS-I significantly predicted these dependent variables above and beyond the AAQ-II with increases in R^2values of .12 and .04. Regarding general mental health outcomes, in the first step the AAQ-II acted as a significant predictor for each outcome with R^2values ranging from .24 to .40. In the second step, the PIS-I also significantly predicted the depression, anxiety and stress symptoms with increases in R^2values between .01 and .05.

Limitations, reasons for caution: The online recruitment tends to recruit more educated participants, with more access to online platforms. The study was disseminated through a patients' association, limiting the inclusion of people with infertility who do not seek medical treatment. The sample included more female participants when compared to male participants.

Wider implications of the findings: Context-specific measures have proved to be valuable, allowing to capture more specified features of psychological inflexibility. The PIS-I also showed to be a useful context-specific measure of PI for people facing infertility, adding to the prediction of other mental health outcomes.

Trial registration number: N/A.

P-466 How do men want to receive information about fertility? An evaluation of a fertility campaign targeting Danish men in Copenhagen

A.S.N. Berthelsen[1], A.L.N. Gamby[1], U. Christensen[2], L. Schmidt[2]

[1]University of Copenhagen, Department of Public Health, Copenhagen, Denmark ; [2]University of Copenhagen, Department of Public Health- Section of Social Medicine, Copenhagen, Denmark

Study question: What are young men's attitudes towards the fertility campaign "How's your sperm?", and how do they want to receive fertility information in the future?

Summary answer: The young men found the campaign relevant but it had limited impact on them. They preferred fertility information through web-based venues and during school.

What is known already: It is estimated that 16-26% of the Danish population who want children, at some point in their lives, will experience infertility. In Denmark, 40% of young healthy men have decreased sperm quality, and every fifth 50-year old man is childless. The fertility awareness is limited among men. There are few fertility awareness initiatives targeting men. In October 2018, the Municipality of Copenhagen launched the campaign 'How's your sperm?' as a tool to increase fertility knowledge among men. In order to identify potential barriers for the effect of fertility campaigns targeting men, evaluation of such campaigns is needed.

Study design, size, duration: Qualitative focus group interviews with 27 men distributed in six focus groups were carried out. Furthermore, three expert interviews of the main campaign developers were conducted to identify the logic model of the intervention. Data collection took place between April and October 2019.

Participants/materials, setting, methods: The interviewed men were single or cohabiting childless men and were all residents in the Capital Region of Copenhagen. The men were between 23 to 32 years old, and almost all were university students or had a university degree. The interviews were audiotaped, anonymized and transcribed in full. Data were analyzed using qualitative content analysis following the method by Graneheim and Lundman.

Main results and the role of chance: The overall theme regarding men's attitudes towards a fertility campaign and fertility awareness in general was: 'Fertility interventions targeting men'. The subthemes were: 'Campaign communication', 'Campaign exposure and relevance for the target group', 'The sender and aim of the campaign', 'Considerations of infertility', 'Attitudes towards future parenthood', 'Fertility knowledge' and 'Future initiatives'. Overall, the campaign had limited impact on the men because they believed the campaign was not relevant to their current life situation. Furthermore, the men were confused about the aim and message of the campaign, as they thought the campaign encouraged men to have their sperm quality tested. The men also criticized the campaign for making a link between sperm quality and masculinity. They recognized the importance of knowledge about reproductive health but they wanted more accurate information about fertility and risk factors for infertility. According to the men, future initiatives should prioritize accurate dissemination of fertility information in web-based venues. In addition, the men suggested that fertility information should be a mandatory part of the (sexual) education in upper-secondary schools and/or university level.

Limitations, reasons for caution: Most of the interviewed men had a university degree and wanted more facts instead of humor in the campaign, hence our results may not be directly transferred to a similar age group in the general population.

Wider implications of the findings: Our study contributes to the understanding of how to communicate future fertility awareness campaigns and initiatives. This may be useful in the process of increasing the fertility awareness in the population.

Trial registration number: N/A

P-467 Taking fertility for granted – A qualitative exploration of fertility awareness among young, childless men in Denmark and Sweden

G.M. Malling[1], L. Schmidt[1], T. Pitsillos[2], K. Hammarberg[3], T. Tydén[2], B. Friberg[4], I. Toftelund Jensen[1], S. Ziebe[5]

[1]University of Copenhagen, Department of Public Health, Copenhagen K, Denmark ; [2]University Hospital Uppsala, Department of Women's and Children's Health, Uppsala, Sweden ; [3]Monash University- Melbourne, Jean Hailes Research Unit- School of Public Health and Preventive Medicine, Melbourne, Australia ; [4]Lund University, Molecular Reproductive Medicine- Department of Translational Medicine, Malmö, Sweden ; [5]Copenhagen University Hospital- Rigshospitalet, The Fertility Clinic, Copenhagen, Denmark

Study question: How do young childless men in Denmark and Sweden reflect on their fertility, view fertility treatment, and how aware are they about infertility risk factors?

Summary answer: Most men had limited knowledge about factors that can impair fertility, presumed they were fertile, and were positive towards fertility treatment if they needed it.

What is known already: Almost all men in the Nordic countries want to become fathers and want at least two children. Previous qualitative interview studies with childless men aged 21-46 have shown that most men expect to become fathers when they want to. Further, recent reviews have concluded that men around the world have limited knowledge about fertility and factors that can diminish it. Most previous studies about fertility knowledge and attitudes among men have been based on quantitative methods using questionnaires with fixed-choice response options.

Study design, size, duration: This qualitative study assessed knowledge about fertility and attitudes towards fertility treatment among childless men in Denmark and Sweden in their last year of university education or vocational

training. In total, 17 Danish and 12 Swedish male students were interviewed. The interviews were conducted between February and September 2017 and ranged between 30 and 90 minutes, with an average length of one hour.

Participants/materials, setting, methods: Participants were recruited face-to-face, through postings on their educational institutions, and by snowball methods. Inclusion criteria were: being male, childless, aged 20-30 years and in the last year of education. The interview guide included questions probing participants' perceptions about their own fertility, fertility treatment, and fertility risk factors. The interviews were recorded and transcribed and the content analysed thematically.

Main results and the role of chance: Study participants were on average 25 years old (range 20-30). The analysis revealed the following themes: 1) Hope and Fear; 2) Parenthood and Involuntary Childlessness; 3) Fertility Treatment – A great Alternative; 4) Factors Meant to Influence Fertility; and 5) Uncertainty. Few participants had considered their own fertility but most were optimistic about their ability to become a parent in the future. Among those who that had thought about their fertility, hope and fear were the most prominent emotions. Most men were positive towards and would consider having fertility treatment if they experienced fertility problems. The young men had limited knowledge about factors that can potentially impair male and female fertility. On average each participant mentioned three different factors they believed influence male and female fertility either positively or negatively. However, their responses often entailed uncertainty, illustrated through words like 'uh', 'I think', 'maybe', and 'could be'. None of the men mentioned sexual transmitted infections (STIs) as a risk factor for infertility but most appeared aware of the effect of increasing age on fertility.

Limitations, reasons for caution: Participants' responses to the question about factors that affect fertility may not reflect all aspects of their knowledge on the topic. Further, men who do not want children may have been less likely to participate than men who want children.

Wider implications of the findings: This study highlights the need for educational strategies to improve young men's knowledge about fertility and the factors that influence it, particularly about the potential adverse effect of STIs on fertility. Men also need to be aware that there is no guarantee of success with fertility treatment.

Trial registration number: N/A

P-468 The infertility and fertility treatment experiences of Orthodox Jewish women in London

A. Vaz Mouyal[1], Z. Gurtin[1], J. Leach Scully[2], J. Harper[1]

[1]University College London, Institute For Women's Health, London, United Kingdom ;

[2]Innovation Institute UNSW, John Goodsell Building, Sidney, Australia

Study question: What are the infertility experiences of 26 British Orthodox Jewish women?

Summary answer: Infertility challenges the way Orthodox Jewish women understand their lives and identities. It further impacts their relationships with their Rabbis, partners, families, friends and communities.

What is known already: Procreation has a very important place within Orthodox Jewish communities, therefore infertility presents a particularly severe difficulty to Orthodox Jewish women. Jewish law tends to permit the use of assisted reproductive technologies (ART). Several studies on the use of ART in Israel have been carried out. Kahn's work shows the difficulties single Jewish women face when seeking solo motherhood in a society that honours motherhood and family life (Kahn, 2000), while Ivry (2010) describes the koshering of medical care in rabbinically mediated fertility treatment. The research presented here is the first in the field carried out in the UK.

Study design, size, duration: A total of 26 Orthodox Jewish women who had experienced infertility were interviewed. All interviews were conducted between 2017 and 2018. Women were recruited via adverts in local Jewish magazines, Facebook groups and via snowballing. The study design resulted from previous research carried out in Israel and the UK as part of PhD research.

Participants/materials, setting, methods: Semi-structured qualitative interviews were undertaken. The women were mostly interviewed in their houses. Interviews were conducted in English and lasted between an hour and an hour and half. All were transcribed verbatim and any identifiable information was changed to protect the women's identity. Qualitative descriptive methods alongside thematic analysis were used to express and discuss the data collected from the interviews.

Main results and the role of chance: Four main themes were identified: my destiny, my Rabbi, my relationships and my identity. ***My destiny*** focused on the view women had of God as "controller" and "giver" of their infertility. ***My Rabbi*** introduced the deep relationship that exists between some Orthodox Jewish women and their Rabbis, highlighting the way Rabbis are viewed as representatives and messengers of God. ***My relationships*** explored the effect of infertility on the women's relationships with their partners, families, friends and communities. ***My identity*** indicated the way women internalize their infertility due to their feelings of isolation, loneliness and estrangement from their familiar culture, community and beliefs. It became apparent that for some women, who did not feel fulfilled as women unless they were able to be a mother, all sense of self and identity slowly breaks down.

Limitations, reasons for caution: Due to the small sample size and limited geographical spread, the findings cannot claim to be representative of the Orthodox Jewish community of the UK. The lead author's own Jewish status could have influenced the participants' responses and/or the analysis, although involvement of other authors mitigated this.

Wider implications of the findings: This research gives useful insight into an underresearched population. Its findings offer guidance to medical professionals, counsellors, policy makers, and religious leaders. Other Orthodox Jewish women may be helped by knowing they are not alone. The findings suggest that other underresearched populations could experience distinctive difficulties with infertility and ART.

Trial registration number: n/a

P-469 Posttraumatic growth (PTG) in women with a long-standing experience of involuntary childlessness

G. Duraskova[1], B. Peterson[2]

[1]psychologist, Motol University Hospital, Prague, Czech Republic ;

[2]professor Crean College of Health and Behavioral Sciences, Chapman University, California, U.S.A.

Study question: What aspects of posttraumatic growth (PTG) are found in women with a long-standing experience of involuntary childlessness?

Summary answer: Women developed deeper self-recognition and greater humility, they reassessed their existing relationships, strengthened their partnerships, and experienced changes in their life philosophy.

What is known already: "The term posttraumatic growth refers to positive psychological change experienced as a result of the struggle with highly challenging life circumstances" (Calhoun & Tedeschi, 2004). For women experiencing infertility, research mainly focuses on the description of negative psychological factors with only few published reports mentioning positive personality development in conjunction with the infertility experience (Lee at al., 2009; Daniluk, 2001). The lack of studies on PTG in women diagnosed with infertility represents a gap in the literature which limits our knowledge about the potential positive implications that may result from efforts to cope with this stressful life challenge.

Study design, size, duration: The study used a qualitative design interviewing 24 women with a long-standing experience of primary infertility. In-depth semi-structured interviews were conducted in the Czech Republic during 2016 and lasted an average of 53 minutes. Interviews aimed to further understand the possible experiences of PTG in study participants. Participants shared both positive and negative aspects of the infertility experience. Data were analyzed using thematic analysis.

Participants/materials, setting, methods: Invitations to participate in the study were sent to 28 women who experienced involuntary childlessness (purposive selection). The final sample consisted of 24 women (4 declined to participate). The average age of participants was 37,3 years, and their average length of experience with infertility was 6,1 years. Women were asked how infertility affected/changed their partner relationships, sexual life, job, future plans, attitude to children/values/faith, and leisure time.

Main results and the role of chance: Five main themes of posttraumatic growth were identified: greater humility, deeper self-recognition, overall reassessment of relationships, changes in philosophy of life, and strengthening partnership. The experience of infertility taught these women to have more respect to life, reassess and find their personal value, recognize their inner strength, be more emphatic, develop their spiritual lives, and be responsible for their own

health. Women connected these changes with their experience of infertility. Without a control group of participants, we cannot exclude the possibility that women may have experienced these changes without experiencing infertility.
Limitations, reasons for caution: The study findings are limited by the qualitative study design, sampling procedure, and number of participants. Because of this, we cannot generalize our results for all women with long-term infertility experience. In addition, PTG is a subjective phenomenon and is limited by retrospective self-report and reflection.
Wider implications of the findings: The findings of our qualitative study show what aspects of PTG are experienced by women experiencing infertility. Medical and mental health providers can use our findings to facilitate the PTG process in patients. Because the study only sampled women, it is unknown if/how PTG is experienced by men.
Trial registration number: not applicable

P-470 The importance of the "family clock": Women's experience of fertility decision-making 6 years after attending the Fertility Assessment and Counselling clinic

E. Koert[1], R. Sylvest[1], I. Vittrup[2], H.W. Hvidman[2], K. Birch Petersen[3], J. Boivin[4], A. Nyboe Andersen[2], L. Schmidt[1]

[1]University of Copenhagen, Section of Social Medicine- Department of Public Health, Copenhagen, Denmark ;
[2]Copenhagen University Hospital - Rigshospitalet, Fertility Clinic, Copenhagen, Denmark ;
[3]The Fertility Partnership, Fertility Clinic, Copenhagen, Denmark ;
[4]University of Cardiff, School of Psychology, Cardiff, United Kingdom

Study question: What is women's lived experience of making fertility decisions in the six years after receiving personalized fertility education, assessment and counselling?
Summary answer: Women's "family clock" (preferred start time, number and spacing of children) was an important aspect of their lived experience of fertility decision-making.
What is known already: Research demonstrates that fertility education is needed to support informed and satisfying fertility decision-making. The Fertility Assessment and Counselling (FAC) clinic in Copenhagen, Denmark (opened in 2011) is a personalized fertility education, assessment and counselling intervention aimed at increasing knowledge through provision of general fertility information and a clinical examination and evaluation of personal risk factors (Hvidman et al., 2015). A one-year follow up study of women attending the FAC clinic found that the intervention impacted women's fertility decisions and was a catalyst for change in their lives. Additional long-term follow-up is needed to explore women's experiences in detail.
Study design, size, duration: A qualitative 6-year follow-up study with 24 women who attended the FAC clinic between January and June 2012. Women were interviewed in person between February and March 2018 at Rigshospitalet, Copenhagen, Denmark. Interviews ranged between 60 to 94 minutes (average 73 minutes) and were conducted in English.
Participants/materials, setting, methods: Invitations were sent to 141 women who attended the FAC clinic in 2012. Ninety-five women opened the invitation, 35 were interested in participating, 25 interviews were booked and 24 interviews held. Interviews were semi-structured and examined the women's perceptions and experience of the intervention six years after attending. This abstract focuses on data specific to the women's lived experience of making fertility decisions after attending the FAC clinic. Data was analyzed using thematic analysis.
Main results and the role of chance: At the time of the follow-up interview, women were on average 39.5 years old (range 31-45). Ten were single and 14 were partnered. The majority (21 women, 88%) became parents in the six years after attending the FAC clinic, with almost half (9 women) starting to try to become pregnant in the first year.

The women's "family clock" played an important role in their fertility decisions – beliefs regarding when to start trying to become pregnant, their preferred number of children and spacing between them. All who tried to become pregnant had given birth to at least one child. However, all of the women with one child regretted that they had "run out of time" and not achieved their desired family size (two or three children), commonly attributed to their age, age-related fertility decline, and/or single parenthood.

Women described feeling empowered to make informed decisions about their fertility after attending the FAC clinic. However, when considering a second pregnancy several years later, women experienced the pressure of time and their age and uncertainty about their fertility. They wished for repeated counselling and advice to aid decision-making after a first pregnancy, or if several years had passed since attending the FAC clinic.
Limitations, reasons for caution: There may be a selection bias given that participants were self-selected from women who attended the FAC clinic with 25% expressing an interest in the study after receiving an invitation. That said, the data from 24 women presented a broad spectrum of fertility decision-making experiences and trajectories.
Wider implications of the findings: When providing education and guidance to women regarding future fertility plans, consideration of their "family clock" should be included so women can make informed fertility decisions about timing of pregnancy and achieve all their family goals. Additional counselling and advice after pregnancy or several years have passed may be warranted.
Trial registration number: Not applicable

P-471 What guidelines should be followed for subfertile patients to achieve spontaneuos pregnanycy? A randomized controlled trial of couples trying to conceive

M. Martins, M.Sc.- Ph.D.[1,2], J. Fernandes[2], J. Pedro[1,2], P. Xavier[3,4], A. Barros[4,5], E. Costa[1,2], L. Schmidt[6]

[1]University of Porto, Faculty of Psychology, Porto, Portugal ;
[2]University of Porto, Centre for Psychology at University of Porto, Porto, Portugal ;
[3]Porto Clínica, Reproductive Endocrinology, Porto, Portugal ;
[4]University of Porto, Faculty of Medicine, Porto, Portugal ;
[5]Centre for Reproductive Genetics A. Barros, Reproductive Endocrinology, Porto, Portugal ;
[6]University of Copenhagen, Public Health, Copenhagen, Denmark

Study question: Do educational interventions on timing intercourse improve psychosocial adjustment and pregnancy rates in unselected subfertile individuals over the course of 12 months?
Summary answer: No significant psychosocial adjustment differences were found between groups over one year. However, the 'fertile window' monitoring group achieved a higher pregnancy rate than CG.
What is known already: It is well-know that general knowledge on fertility and fecundity is low. Recent evidence also suggests that both patients and professionals lack confidence in natural conception or expectant management and that education is needed. There is solid evidence that that time to pregnancy can be significantly shortened by targeting the fertile period with cervical mucus monitoring or the use of ovulation predictor kits. However, reproductive care guidelines recommend instead the practice of intercourse every other day for being less stressful to the couple. At present, there are no studies comparing the recommendation of these two strategies against a control group.
Study design, size, duration: We conducted a prospective, double-blind, three-arm parallel RCT, recruiting between July 2016 and June 2018. Subjects (n=414, 263 women) were randomly allocated into 'fertile window monitoring' (FWM, n = 137), 'every other day' (EOD, n = 124), and control group (CG, n = 153), and were assessed before (T0), 4-weeks (T1), 6-months (T2), and 12-months (T3) after the intervention. Interventions consisted of short animated videos addressing fecundity knowledge and the correspondent trying-to-conceive (TTC) strategy.
Participants/materials, setting, methods: Subjects were recruited via social media advertising and brochures with an accompanying link to the survey, or via gynecology and fertility clinics, where patients received tablet PCs with headsets. Individuals trying to conceive and in a marital relationship for > 1 year were enrolled in the RCT, and completed self-report questionnaires measuring psychosocial adjustment besides a specific questionnaire. Mixed models ANOVA tested effects on psychosocial variables, and OR and RR were estimated for pregnancy rates.
Main results and the role of chance: Participants were in their thirties (33.12±4.46), in a relationship for around eight years (8.81±5.19) and were TTC for around two years (2.23±2.53). One participant gave-up TTC at T1, and 331 were lost to follow-up. Eighty-three subjects completed all four moments and were included in the longitudinal analysis having psychosocial adjustment as DVs. Baseline characteristics were well balanced between groups. No significant

interaction or main effects of the interventions were found for stress (PSS), depression, anxiety (HADS), and sexual functioning (FSFI/IIEF). Results remained non-significant after controlling for pregnancy (P > .05). Amongst the 263 women, 55 reported not being pregnant at follow-ups and 46 reported a pregnancy. Of these, fourteen had a positive pregnancy test after IVF/ICSI and were excluded from analysis. The final sample for pregnancy rate analysis included 101 women. Individuals in the FWM group had significantly higher pregnancy rates than those in the CG (60.7 vs 35.9%, P = .038); OR 2.8 (95% CI 1.058-7.415). There were no differences in pregnancy rates between the EOD and CG subjects, nor between EOD and FWM.

Limitations, reasons for caution: This study is prone to bias as both undiagnosed and individuals in fertility treatment were included. The analyses did not include the monitoring of the use of the TTC strategy and did not use clinical pregnancy as an outcome.

Wider implications of the findings: Results show that the EOD strategy does not lead to better adjustment nor less stress, and hence guidelines need to be reviewed. Further studies should use large samples of untreated couples TTC<12 months to confirm the potential of FWM education as a tool to empower the self-management of reproductive health.

Trial registration number: Study partially funded by the Portuguese Foundation for Science and Technology [FCT PhD grant SFRH/BD/103234/2014]

P-472 Sleep - an underrated fertility booster? A questionnaire survey on the pattern of sleep among IVF patients and their reproductive outcome

R. CHELLADURAI[1], G. Pm[1], G.D. Ss[1], H. Vaidyanathan[1]

[1]SIMS Hospital, OBG and IVF, Chennai, India

Study question: Evaluating the impact of quality and quantity of sleep on fertilisation rate and clinical pregnancy rate in patients undergoing IVF in SIMS hospital,Chennai,India

Summary answer: Fertilization rates and clinical pregnancy rates were significantly higher among patients with PQLI (Pittsburg sleep quality index) score of less than 9 (no/mild sleep difficulties)

What is known already: High levels of psychological stress, anxiety, insomnia and depression have been reported in IVF patients.Sleep disturbance is a frequent but underrated symptom in IVF patients and aggravate the existing psychological problems .Secretion of Melatonin ,the hormone responsible for improving quality of oocytes by acting as an antioxidant, is increased during sleep. Also,sleep promotes pulsatility of gonadotrophins and the sleeP-wake cycle maintains the normal hormonal balance. However in most places, sleep disturbance is disregarded and ignored even during routine psychological counselling sessions. It remains an under-investigated modifiable target that may provide a non-pharmacological ,cost-effective method to improve IVF outcome.

Study design, size, duration: A questionnaire survey conducted at SIMS hospital Chennai between Jan 2017-Dec 2019. A total of 196 women undergoing IVF were given the Pittsburg sleep quality index questionnaire on the day of stimulation to evaluate their sleeping patterns in the previous month by measuring hours of sleep , latency, having bad dreams disturbing sleep, snoring, sleep disturbances like somnambulism ,whether requiring medications to induce sleep and job related sleep disturbances like shift-work or part-time.

Participants/materials, setting, methods: Patients were divided into three categories on the basis of PQLI: (A)a total score of "5" or less indicated no sleep difficulties; '(B)'6-8" indicated mild difficulties; '(C) '9" or more indicated severe difficulties. Fertilisation rates and clinical pregnancy rates were compared between the 3 groups.

Normal responders undergoing stimulation using Antagonist protocol were included.

Exclusion criteria included poor and hyper responders, male factor, female partner age >35 years, endometriosis, PID, using Donor gametes.

Main results and the role of chance: Based on the collected responses to the above questions, a statistical comparison of ART outcomes, in three PSQI categories, was performed by Mann-Whitney U test and chi-square test. Logistic regression analysis was subsequently conducted to assess the association of the conditions in the questions with ART outcomes, as represented by fertilization rates and clinical pregnancy rates.

Clinical pregnancy was determined by observation of a gestational sac with fetal heart beat by transvaginal ultrasound at 6 weeks of pregnancy. Fertilization rate (FR) was percentage of transformation of micro injected oocytes into two pronuclei.

The number of patients in each group were A(127/196) B(39/196) and C(30/196)

The average hours of sleep in the 3 groups were 7.9 hours,7.3 hours and 6.3 hours

Fertilization rates in the Groups A,B and C were 68%,62% and 46% , and clinical pregnancy rates 44%,39% and 23% respectively with a significant p value of <0.001.

Also it was found that the prevalence of co-existent psychological issues like anxiety, depression and OCD were higher among the C group with severe sleep difficulties. 6 of them required psychotherapy . All members in group C were advised to attend our classes on YOGA and meditation.

Limitations, reasons for caution: Though the prevalence of Insomnia and sleep disturbances are common, no major studies have been done on their impact on reproductive outcome in ART. Studies using larger population and multicentric trials is necessary .

Although the outcomes were adjusted for confounding factors, some unknown confounders may affect the outcomes.

Wider implications of the findings: The importance of sleep on reproductive outcome must be reiterated and insomnia ,if detected must be treated aggressively. Simple methods such as yoga,meditation and psychological support from family and peers would go a long way in helping these women cope with the stress of anxiety and insomnia during IVF treatment.

Trial registration number: not applicable

P-473 Responses to and communication about infertility among couples treated at fertility clinic: Implications for depressive symptoms

T. Matitashvili[1], K. Slauson-Blevins[2], A. Greil[3], S. Bocca[1]

[1]Jones Institute for Reproductive Medicine- Eastern Virginia Medical School, Reproductive Endocrinology and Infertility, Norfolk, U.S.A. ;
[2]Old Dominion University, Department of Sociology and Criminal Justice, Norfolk, U.S.A. ;
[3]Alfred University, Division of Social Sciences, Norfolk, U.S.A.

Study question: Do couple's responses to infertility depend on the source of the infertility and how do responses to infertility affect one's own and partner's depressive symptoms?

Summary answer: Generally couples responses to infertility are not influenced by the source of the problem. One's own responses are typically associated with one's own depressive symptoms.

What is known already: Most studies about psychological responses to infertility have used the individual rather than the couple as the unit of analysis. Several studies have reported on the coping strategies employed by each partner in an infertile couple. Less, however, is known about the associations between difference in perceptions of the experience of infertility and communication and each partner's well-being. In addition, a number of studies have examined whether there is difference in the experience of infertility depending on which partner is being diagnosed with infertility, but, so far, no clear conclusion can be drawn.

Study design, size, duration: This was a cross-sectional study administered by paper questionnaire. Both partners of infertile couples attending a fertility clinic filled out identical questionnaires. The questionnaires included background information, reproductive history, measures of life satisfaction and depressive symptoms, and scales measuring perceptions of various aspects of the infertility experience. Information about medical diagnosis was obtained from medical records. The study involved 156 men and women, including 58 couples, who are the main focus of this paper.

Participants/materials, setting, methods: Study received IRB approval from Eastern Virginia Medical School and Old Dominion University. Patients who attended the fertility clinic from December 2013 to April 2015 were asked to fill out a questionnaire containing 161 questions. Validated scales were constructed measuring importance of children, communication about fertility, perceived fertility-specific relationship power and fertility-specific sexual satisfaction. Results were analyzed via paired-samples t-tests, one-way ANOVAs, mixed ANOVAs, and OLS regression. $P < 0.05$ was regarded as statistically significant.

Main results and the role of chance: Women reported higher levels of importance of children and fertility-related sexual problems than their partners. Men reported higher general relationship satisfaction, fertility-specific relationship satisfaction, and perceived fertility-specific relationship power than their partners. With one exception, scale scores were not associated with which partner had a fertility problem. Women scored higher than their partners on the importance of children scale except among couples with infertility of unknown cause. For women, higher scores on importance of children, satisfaction with fertility–related communication and fertility-related sexual problems were associated with higher levels of one's own depressive symptoms. For men, higher scores on satisfaction with fertility–related communication, perceived fertility-related power, fertility-related relationship satisfaction, general relationship satisfaction and fertility-related sexual problems were associated with higher levels of one's own depressive symptoms. For women, fertility-related sexual problems was associated with higher levels of partner's depressive symptoms. For men, higher scores on importance of children was associated with higher levels of partner's depressive symptoms. The higher women score on the importance of children compared to their partners, the higher their level of depressive symptoms. The higher men score on fertility-related sexual problems and satisfaction with fertility-related communication, the higher their level of depressive symptoms (all $P < 0.05$).

Limitations, reasons for caution: Because study was cross-sectional, it is impossible to make causal inferences. The findings of this study are limited in generalizability as all patients were recruited from a single site and small sample size prevented us from including more variables in each analysis.

Wider implications of the findings: These findings have important implications for counseling infertile couples. It is especially important to note that relationship satisfaction and satisfaction with communication does not always have a positive effect on well-being. Fertility-related sexual problems appear to have implications for well-being among both men and women.

Trial registration number: n/a

P-474 Luteal granulosa cells from women undergoing a stress management program during ICSI cycles exhibit lower mitochondrial DNA levels: a randomized clinical trial

G. Raad[1], J. Tanios[2], N. El Salibi[3], S. Kerbaj[4], F. Shamas[5], J. Azouri[6], Y. Mourad[7], C. Fakih[8]

[5]Al Hadi Laboratory and Medical Center, Molecular Biology, Beirut, Lebanon ;
[6]Mount-Lebanon Hospital Lebanon, Azoury IVF clinic, Hazmieh, Lebanon ;
[7]Al Hadi Laboratory and Medical Center, Medical Laboratory, Beirut, Lebanon ;
[8]Al Hadi Labratory and Medical Center, Ivf, Beirut, Lebanon

Study question: What impact does stress management have during intracytoplasmic sperm injection (ICSI) cycles on mitochondrial DNA (mtDNA) levels in luteal granulosa cells?

Summary answer: Women undergoing stress management during ICSI cycles had lower mitochondrial DNA levels in their luteal granulosa cells compared to the control group.

What is known already: ICSI cycles were demonstrated to be psychologically stressful for most couples. In parallel, growing evidence supports the implication of mitochondria in the stress response. Furthermore, mitochondria are considered as potential regulators of oocyte- granulosa cells cross-talk. However, the effect of psychological stress during ICSI cycles on mtDNA levels in luteal granulosa cells and subsequent oocyte competence was never fully investigated nor well understood.

Study design, size, duration: A randomized controlled trial, with pre-test-posttest experimental design was conducted on 60 couples undergoing ICSI cycles, between May 2018 and May 2019, at Mount-Lebanon hospital. On the first day of ovarian stimulation, the couples were randomized using sealed opaque envelopes into control group (n=30) and stress management group (n=30). The physicians and embryologists were blinded to the allocation. The researchers provided stress management consisting of educational sessions about the treatment and relaxation techniques.

Participants/materials, setting, methods: Literate couples with a female partner < 38 years old, using their fresh gametes, and without psychiatric disorders were included. Stress levels were assessed on the first day of ovarian stimulation and on the day of embryo transfer using the Perceived Stress Scale (PSS 10). Luteal granulosa cells were collected on the day of oocytes pick-up. Granulosa vitality and morphology were evaluated and mtDNA levels were quantified using Ion Torrent next generation sequencing technology.

Main results and the role of chance: During the first day of ovarian stimulation, statistically significant higher scores of PSS (PSS initial) were detected in women of the study group (23.1 ± 5.1) compared to the control group (19.3 ± 7.01) ($p < 0.05$). However, ΔPSS (PSS initial – PSS on the day of transfer) showed significant reduction in perceived stress in women of the study group compared to the control group ($p < 0.01$). At the ovarian level, trypan blue staining indicated that the percentage of viable granulosa was significantly higher in the study group compared to the control group ($p < 0.05$). In addition, a statistically significant higher percentage of granulosa cells with normal morphology were detected in women of the stress management group compared to the control group ($p < 0.05$). Furthermore, mtDNA levels were significantly higher in luteal granulosa cells of control group compared to the study group ($p < 0.05$).

Limitations, reasons for caution: The study excluded subjects with severe infertility factors. Consequently, the efficiency of this stress management program should be also tested in these subjects before automatically generalizing it to all infertility cases.

Wider implications of the findings: This stress management program seems to be able to reduce psychological stress among IVF patients thus improving their mental health. It also influences the ovarian physiology through the granulosa cells. Hence, further investigations are needed to evaluate whether applying this program in clinical settings could affect other ICSI related outcomes.

Trial registration number: LBCTR2019101289

P-475 Seeking pregnancy through assisted reproduction technology treatments (ART): A comparison between couples receiving donated gametes and couples using their own gametes

F. Andrei[1], P. Salvatori[1], L. Cipriani[2], G. Damiano[2], N.C. Rossi[1], E. Porcu[2]

[1]University of Bologna, Department of Psychology, Bologna, Italy ;
[2]Infertility and IVF Unit, University of Bologna-Sant'Orsola Hospital, Bologna, Italy

Study question: What are the psychological differences between couples waiting for gametes donation and those using their own gametes, considering previous ART attempts and cause of infertility?

Summary answer: Differences in infertility self-efficacy were found between the two groups, while no significant differences with regards to psychological symptoms and quality of life emerged.

What is known already: Involuntary childlessness often produces overwhelming feelings of anger, shame, grief, and guilt. For those couples who decide to undergo ART, such emotional reactions may persist, if not worsen, throughout the different phases of the treatment. Higher levels of psychological distress and lower levels of quality of life seem to affect especially couples who experienced repeated failures. Additionally, the only published study comparing couples by the severity of infertility shows that couples who use their own gametes seem to have higher depression, anxiety, infertility stress, and infertility-related sexual concerns than couples awaiting for gametes donation.

Study design, size, duration: Data were collected cross-sectionally from October 2018 to October 2019. One hundred seven couples seeking treatments to conceive took part to the study.

Participants/materials, setting, methods: Data were collected from 107 couples at their first access to the Infertility and IVF Unit of the Sant'Orsola Hospital, University of Bologna (Italy). During a first consult, clinical information were recorded and the Infertility Self-Efficacy Scale, Fertility Quality of Life, and Symptom Check-List were given to participants. During a second consult, couples were placed on a waiting list for either gametes donation (n=42) or IVF with their own gametes (n=65), and questionnaires were returned.

Main results and the role of chance: Univariate ANOVAs showed a significant interaction between previous ART attempts (yes/no) and awaited treatment (IVF with gametes donation/IVF with the couple's own gametes) with regards to infertility self-efficacy. Couples who used their own gametes showed higher levels of self-efficacy if they were at their first ART attempt compared to those who already tried to conceive through ART without succeeding. Gametes receiving couples showed an opposite pattern ($F = 6.54$, $P < .01$). With regards to quality of life, we found a main effect of the variable previous ART attempts, showing that couples who already underwent ART treatments had overall lower levels of quality of life ($F = 2.68$, $P < .01$). No differences were found with regards to levels of anxiety, depression and anger/hostility (all $Ps > .05$).

Limitations, reasons for caution: The sample size and the cross-sectional design allowed us to draw conclusions only about the associations between study variables. We could not include additional relevant variables, such as time from infertility diagnosis and parity, which may have affected our results.

Wider implications of the findings: The differences between gametes receiving couples and couples who used their own gametes in self-efficacy may be determined by both the difficulties each couple face during ART treatment and the infertility history. Shifting to gametes donation may give new hope to those couples who experienced repeated failures with ART.

Trial registration number: CE: 273/2018/Sper/AOUBO

P-476 Factors associated with decision regret following oocyte cryopreservation for diminished ovarian reserve and/or age-related fertility decline

T.A. Boza[1], A.P. Çil[1], L.S. Karakis[2], R. Abalı[2], M. Ceyhan[1], E.G. Aksakal[1], M. Bahçeci[2], B. Urman[1]

[1]American Hospital, Womens' Health Unit, Istanbul, Turkey ; [2]Bahceci Health Group, IVF Centre, Istanbul, Turkey

Study question: What are the factors associated with decision regret following oocyte cryopreservation (OC) in women with diminished ovarian reserve (DOR) and/or age-related fertility decline?

Summary answer: The perception of inadequate emotional support during the procedure and low expectations regarding its efficacy were associated with increased decision regret.

What is known already: Recently we published our data on cycle characteristics and reproductive outcomes of women with DOR undergoing OC. Since cycle cancellation rates are high and reproductive outcomes are poor in such patients, we aimed to counsel these patients about their expectations of OC and determine factors which may be associated with future decision regret. Decision regret is considered as an overall indicator of quality of health decisions. Although there are a few studies on decision regret following elective OC in women with normal ovarian reserve, no studies to date have addressed factors associated with decision regret in women with DOR.

Study design, size, duration: A cross sectional survey study was conducted involving 552 women with DOR and/or age-related fertility decline who underwent OC in two private ART centers (American Hospital and Bahceci IVF Centre) from 2015 to 2019. Following IRB approval, women were contacted by phone and asked whether they would be willing to participate in a standardized online questionnaire to evaluate decision regret, their current relationship status, satisfaction level with the procedure, and their attitude towards future childbearing.

Participants/materials, setting, methods: Of the 552 women who were contacted, 468 accepted the invitation, and 162 (34.6%) responded to the survey. The primary outcome of the study was decision regret measured using the validated Decision Regret Scale (DRS). The associations between decision regret and level of patient satisfaction, reproductive expectations and desire for parenthood were assessed. DRS was interpreted as follows: 0: no regret; 1-25: mild regret, and 25-100: moderate to severe regret.

Main results and the role of chance: Mean age at the time of OC and survey submission was 37.8±4.6 and 40 ±1.0, respectively. The total number of oocytes cryopreserved was <10 in 70% of women. The average follow-up time interval from OC to survey submission was 2.5 years. Five patients reported pregnancy after OC; 4 spontaneous and one using cryopreserved oocytes. The median and mean DRS scores were 10 (interquartile range: 25) and 13.4 (range 0-70), respectively, indicating a low prevalence of regret. Eighty-five (52.5%) women reported mild regret and 26 (16%) moderate to severe regret. Increased decision regret was associated with perception of inadequate emotional support during OC ($p=0.045$) and low expectations about the efficacy of the procedure($p=<0.001$). Decision regret was not associated with age, number of frozen eggs, perceived adequacy of information prior to OC, patient-estimated probability of achieving a live birth and use of banked eggs, attitude towards alternative child bearing methods, current relationship status or time elapsed since OC. One hundred sixty-seven women (88%) reported increased sense of control over future reproductive planning following OC. One hundred eighty-three women (89%) indicated they would be satisfied with their decision, even if they never used their frozen eggs.

Limitations, reasons for caution: One of the main limitations of our study is that these results reflect the attitudes of highly educated Turkish women with DOR towards OC, which should be extrapolated to other populations with caution. The other limitation is the relatively short and variable follow-up duration of the study.

Wider implications of the findings: Findings of this study indicate that the prevalence of regret among patients with DOR undergoing OC is low. Hence, the number of patients who return to use their oocytes is low, this restricts our ability to assess the impact of reproductive failure. Long-term studies including patients with failure are necessary.

Trial registration number: None

P-477 Assessment of the psycho-affective repercussions of male infertility

F. Hammami[1], A. Zouari[2], S. Ellouze[2], G. Rim[2], M. Chibani[3], R. Rachdi[3], S. Jellad[1]

[1]Military hospital of Tunis, Laboratory of Reproductive Biology- Unit of Assisted Medical Procreation, Tunis, Tunisia ; [2]Razi hospital, Department of Psychiatry B, Mannouba, Tunisia ; [3]Military hospital of Tunis, Unit of Assisted Medical Procreation Military Hospital of Tunis, Tunis, Tunisia

Study question: This study aims to evaluate the prevalence of anxiety and depressive disorders in men after diagnosis of their infertility.

Summary answer: Diagnosis of infertility is associated with important prevalence of anxiety and depressive disorders in men. Severity of these disorders increases with age and infertility's duration.

What is known already: Studies comparing women and men found that women react more strongly overall to infertility. The impact of psychological wellness in infertile women has been widely studied unlike the consequences of male psychological disorders that are not well explored. Similar to their female counter parts, men seeking fertility treatments have also an increased prevalence of anxiety and depression.

Study design, size, duration: A cross sectional study was conducted between June and September 2019 in the laboratory of reproductive Biology and Unit of assisted medical procreation of Military Hospital of Tunis.

Participants/materials, setting, methods: Data of 108 men consulting for couple's infertility exploration was included. All patients were interviewed on sociodemographic characteristics, medical and surgical history. We specified also the type and the duration of the infertility and we analyzed different semen parameters for each patient. Sperm abnormalities were classified as normal, moderate, severe, extreme and azoospermia. We used Hospital Anxiety and Depression Scale (HADS) to assess anxiety and depression.

Main results and the role of chance: The mean age of participants was 36,8 years. Eleven patients had a history of varicocele and six of them suffered from associated erectile dysfunction. Infertility was primary in most of patients (77,8%) with an average duration of 3,32 years. About 25% of the patients had at least one previous failed assisted reproductive attempt. Spermogram abnormalities were found in 78,7% of patients. 8,33% of them suffered from azoospermia. Depression was diagnosed in 29,7% of patients and anxious state in 34,2% of them. The severity of depression was correlated to anxiety ($P < 0,001$), older age of patients ($P=0,034$), and high infertility duration ($P=0,037$). However, the severity of sperm abnormalities was not correlated to anxiety or depression. No associations were found between psychological distress and erectile dysfunction or previous failed assisted reproductive technique attempt.

Limitations, reasons for caution: Diagnosis was established according to a self-reported scale without psychiatric consultation. Most of the couples had a feminine infertility factor, which might have generated a sample bias.
Wider implications of the findings: Anxiety and depression should be diagnosed and treated in men seeking for fertility treatment, especially that it can lead to accelerated cellular aging, poor quality gametes, and other complications. Systematic screening for these psychiatric disorders in infertile men population is therefore essential, in order to ensure multidisciplinary and adequate care.
Trial registration number: Not applicable

P-478 Transgender and Fertility preservation: how to assist young adults and adolescents transgender pathway

N. Mendes[1,2], A. Condat[2], J. Chambry[3], B. Bennanni Smires[1], S. Sarandi[1], L. Chobe Christian[1], L. Martinerie[4], F. Eustache[1]

[1]Service de Biologie de la Reproduction- CECOS- Hôpital Jean-Verdier- Avenue du 14 Juillet- 93140 Bondy- France, Fertility center, Bondy, France ;
[2]Service de Psychiatrie de l'Enfant et de l'Adolescent- Hôpital Pitié-Salpêtrière- 47-83 boulevard de l'Hôpital- 75013 Paris- France, Psychiatry, Paris, France ;
[3]Centre interhospitalier d'accueil permanent pour adolescents Paris rive droit- Hôpital Maison Blanche- Paris- 75018- France, Psychiatry, Paris, France ;
[4]Service d'Endocrinologie et de Diabétologie Pédiatrique- Hôpital Robert Debré & Université de Paris- Paris- 75019- France., Endocrinoly, Paris, France

Study question: Do our national counseling protocol and social insurance system improve access of fertility preservation (FP) prior hormonal therapy or sex reassignment surgery for transgender adolescents in comparison to international experience?
Summary answer: Two-thirds of the cases from our fertility center desire to FP. The obstacle in France seems to be the impossibility of using preserved gametes.
What is known already: International guidelines recommend that healthcare personnel should discuss FP with transgender individuals before starting gender affirmation therapy in adults and adolescents. Unfortunately, low access rates to FP center are reported. Many factors can affect the decision to undergo a FP, as laws, financial status, social climate and attitude of medical professionals ... Several studies indicate the risk of regret after a potential irreversible treatment. The nation social insurance system improve access to fertility preservation in France. It is important that transgender adolescents and adults be advised in the light of their vulnerability.
Study design, size, duration: From january 2018 to january 2020, 67 trans people (adults and adolescents), AMAB (assigned male at birth) (n=38) and AFAB (assigned female at birth) (n=29), were seen at our ART center.
Participants/materials, setting, methods: All trans people were seen first by a medical biologist and a psychologist to discuss and explain FP processes and the French law. In line with the psychiatrists and endocrinologists, a reflection period was proposed, then FP was performed whenever the person was willing to and organized in accordance with their choice. Comparison between adults and adolescents wish for fertility preservation and the method chosen were analyzed using student t test.
Main results and the role of chance: Mean age was 20.7 +/-6.7 years. Of all trans people, 75% were willing to undergo FP but only 42% actually went through the process. Almost 20% remained undecided. Among AMAB, 82% wished to undergo FP (mean age 23.4 +/-7.7), in comparison to 66% of AFAB (mean age 17 +/-1.8). No difference was found in the desire for FP between adults and adolescents (p=0.503). However, adults were more likely to actually go through the process of FP than adolescents (p<0.01). Qualitative data collected from psychological and biological evaluations suggested this result what related to the difficulty, consistent with the French Law, to reuse the preserved gametes after change of civil gender status.
Limitations, reasons for caution: These first results will need to be confirmed on a larger cohort.
Wider implications of the findings: Psychological counseling is in need of more data to assist trans people in the pathway decision. If financial aspect is not an argument to understand the difference between adults and adolescents fertility decision, is important to investigate further tracks.
Trial registration number: not applicable

P-479 Answer patterns by recurrent pregnancy loss patients on depression and stress scales

A. Slot[1], M.C. Krog[2], S. Bliddal[3], L.R. Olsen[4], H.S. Nielsen[5], A.M. Kolte[6]

[1]Copenhagen University Hospital- Rigshospitalet, The Recurrent Pregnancy Loss Unit- The Fertility Clinic, Copenhagen, Denmark ;
[2]Copenhagen University Hospital- Rigshospitalet, The Recurrent Pregnancy Loss Unit- The fertility Clinic and Department of Clinical Immunology, Copenhagen, Denmark ;
[3]Copenhagen University Hospital, Departments of Medical Endocrinology, Copenhagen, Denmark ;
[4]Mental Health Services in the Capital Region of Denmark, Child and Adolescent Mental Health Center, Copenhagen, Denmark ;
[5]University of Copenhagen- Rigshospitalet and Amager-Hvidovre Hospital, The Recurrent Pregnancy Loss Unit and Department of Gynaecology and obstetrics, Copenhagen, Denmark ;
[6]Copenhagen University Hospital, Recurrent Pregnancy Loss Unit- The Fertility Clinic, Copenhagen, Denmark

Study question: Are there specific patterns in how women with recurrent pregnancy loss (RPL) answered the Major Depression Inventory (MDI) and the Perceived stress scale (PSS)?
Summary answer: Women with RPL often feel guilt, angered and lack self-confidence. Women with primary RPL are a particularly sensitive group.
What is known already: RPL affects between 1-3% of all couples trying to conceive a child and the grief of experiencing pregnancy losses are to some women comparable to the grief of experiencing a neonatal death. Women with RPL more often suffer from psychological comorbidities such as anxiety, stress, and depression compared with other women trying to have a child. Recently, a qualitative study underlined the need for all involved health care professionals to be sensitive to the couples' history of pregnancy losses and to acknowledge their grief.
Study design, size, duration: This is a secondary analysis of a cohort study including women referred to the RPL Unit at the Fertility Clinic at Rigshospitalet in Denmark June 2010 -June 2013. In total, 302 women completed the MDI and the PSS. The prevalence of psychological stress and depression as summarized scores was published by our research group in 2015. Here we investigated if there were patterns in responses to the individual items on the MDI and the PSS.
Participants/materials, setting, methods: RPL was defined as ≥3 consecutive pregnancy losses, and 162 women had primary RPL (experienced RPL without having a child), 136 had secondary RPL (having a child prior to experiencing RPL), and four had tertiary RPL. The women's answers were reviewed and the cut-off for a "confirmative" answer was "slightly less than half the time" or more often on the MDI and "sometimes" or more often on the PSS.
Main results and the role of chance: The most frequent answers to the MDI were the three core symptoms of depression (42% lack of energy, 35% feeling sad, 35% loss of interest,) along with feeling less self-confident (28%) and guilty (26%). The cohort included 26 women who fulfilled the criteria for moderate to severe depression, 19 had primary RPL and 7 had secondary RPL. Of the 276 women who did not fulfill the criteria for moderate/severe depression, 9 women (3%) "felt that life wasn't worth living". The most frequent answers in PSS evaluation were being "angered because of things outside their control" (76%) and not feeling "things were going your way" (71%). Women with primary RPL answered that they felt less self-confident (32% vs 18%, p=0.007), restless (17% vs. 9% p=0.033), had concentration problems (25% vs. 10%, p=0,001) and that life wasn't worth living (13% vs. 3%, p=0.002) significantly more often compared with women with secondary RPL. In the PSS evaluation women with primary RPL more often reported "being unable to control important things" (69% vs 55%, p=0.018) and "unable to handle personal problems" (38% vs. 25%, p=0.020) compared with the women experiencing secondary RPL. There were no significant differences between the groups regarding the remaining items.
Limitations, reasons for caution: The questionnaires were constructed to result in a combined score or as a clinical tool for diagnosing, and not to analyse each item individually. Confirmatory answers on the MDI in the study presented here does not equal clinical depression but reflect prevalent feelings among women with RPL.
Wider implications of the findings: Women with RPL commonly experience guilt, lack of self-confidence, and being angered. Women with primary RPL

may be a particularly sensitive group. Treating clinicians need to understand the psychological impact of RPL and could try to encourage behavior to empower the women.

Trial registration number: Not Applicable

P-480 Understanding parents' intention to share information about the donor-conception with their offspring by application of the Theory of Planned Behavior

C. Lampic[1], A. Skoog Svanberg[2], K. Sorjonen[3], G. Sydsjö[4]

[1]Karolinska Institutet, Women's and Children's Health, Stockholm, Sweden ;
[2]Uppsala University, Women's and Children's Health, Uppsala, Sweden ;
[3]Karolinska Institutet, Clinical Neurosciences, Stockholm, Sweden ;
[4]Linköping University, Clinical and Experimental Medicine, Linköping, Sweden

Study question: Does the Theory of Planned Behavior contribute to understanding parents' intentions to share information about genetic origin with their child?

Summary answer: Parents' intention to start disclosure was influenced by beliefs that disclosure would have desired consequences and a desire to act in accordance to societal norms.

What is known already: There is growing consensus on donor-conceived persons' right to information about their genetic origin. As a result, there an increased use of identity-release donation and parents are encouraged to share information about the donor conception with their child from an early age. Nevertheless, disclosure to the child remains a challenge for many parents, particularly heterosexual couples, who are concerned about disrupted relationships and uncertain about when and how to talk with the child. The Theory of Planned Behavior (TPB) has been shown to explain various health-related behaviors and may be applied to increase the understanding of parents' decision-making regarding disclosure.

Study design, size, duration: The present study is part of the prospective longitudinal 'Swedish Study on Gamete Donation' (SSGD) including all fertility clinics performing gamete donation in Sweden. Consecutive groups of recipient couples were recruited 2005-2008 and followed with individual questionnaires before and after treatment with oocyte and sperm from identity-release donors. The present study includes data from the follow-up assessment of the SSGD when participants' offspring had reached age 7.

Participants/materials, setting, methods: Eligible were heterosexual recipients with 7-year old children following identity-release oocyte donation (OD, n=147) and sperm donation (SD, n=174). A total of 83 OD-parents (56% response) and 113 SD-parents (65% response) responded to a postal survey. They individually completed the study-specific TPB-Disclosure Questionnaire assessing behavioral, normative and control beliefs and the intention to talk with child about the donor conception during the upcoming year. Data were analyzed with Path analysis.

Main results and the role of chance: More than half of participants had already started talking with their 7-year old child about his/her donor conception (OD 61%, SD 58%). All components of the Theory of Planned Behavior significantly influenced parents' intention to talk with their child about his/her donor conception during the upcoming year. Among parents who had not yet started the disclosure process, their intention to talk with their child was influenced by beliefs that disclosure would have desired consequences and a desire to act in accordance to perceived positive attitudes towards disclosure in society. Interestingly, a higher level of control beliefs, i.e. feeling confident and in control over the disclosure process, was not significantly related to a stronger intention to talk with the child during the upcoming year. Type of treatment (OD/SD) and the existence/absence of a genetic link to the child did not directly influence parents' intention to talk with the child about the donor conception.

Limitations, reasons for caution: The study was performed with heterosexual couples within the context of the Swedish legislation that mandates identity-release donation, which limits the generalizability to other populations. Also, attrition may have introduced selection bias to the study findings.

Wider implications of the findings: The present results indicate that the Theory of Planned Behavior may contribute to understanding disclosure decisions among heterosexual couples building a family with donor gametes. Parents may benefit from opportunities to discuss perceived consequences of disclosure in order to support family life following donor conception.

Trial registration number: not applicable

P-481 Social aspects of infertility in Europe: a patient survey

M. Lopez-Teijon[1], M. Benigna[2], A. Garcia-Faura[1], B. Marques[1], S. Novo[1], F. Garcia[1], C. Carolina[1]

[1]Institut Marques, Reproductive Medicine Service, Barcelona, Spain ;
[2]Institut Marques, Reproductive Medicine Service, Roma, Italy

Study question: Do european patients have a feeling of social rejection to infertility? Has it changed during the last years?

Summary answer: 63,34% of patients believe that fertility treatments aren't accepted by the society in which they live, and their feeling of rejection by society is increasing.

What is known already: Each country offers a different cultural context in which to view infertility, and legislation controlling fertility treatments also forms opinion. In Europe the law differs very widely between countries, with some countries being extremely restrictive (such as Germany) and others, such as Great Britain or Spain, where infertility treatments are far more visible in society.

Study design, size, duration: Between June-December 2019 questionnaires were filled in by 1733 patients undergoing fertility treatment, from 10 different countries. We asked 3 questions:

Do you think that in your country fertility treatments are taboo?

Have you told the people in your immediate environment that you are undergoing fertility treatment?

Would you agree to be interviewed in the media in order to help other people?

We compared the results to those obtained from the same questionnaire in 2013.

Participants/materials, setting, methods: The questionnaire was completed by patients currently in treatment at our clinics in Spain, Italy and Ireland. They were completed by female patients (either single, with a male partner or with a female partner). We performed a descriptive analysis of the results.

Main results and the role of chance: For 63,3% of patients fertility treatment is a taboo subject. In 2013, this percentage was 52,3%, indicating that infertility as a taboo subject increased in nearly all countries.

However, the social perception of infertility within Europe was very variable. The greatest feeling of rejection was found in Italy (74%) and Germany (74%). Ireland (56%), Switzerland (55%), France (54%), Spain (52%), Sweden(50%) and UK(47%) were in the middle. Belgium was the most tolerant (36%).

It is interesting to note that the most tolerant countries in 2013 no longer are so; Spain increased by 17% and the UK by 11%.

87% of patients did share their experience of infertility with their closest family and friends but without giving any details of the treatment. This was 12% more than in 2013. The family continues to provide a point of refuge but now 37% more patients inform everyone in their immediate environment of their treatment.

With regard to being willing to discuss their infertility with the media, 68% would now agree to do so (in 2013 55% agreed). Maintaining their anonymity is still an indispensable factor for the majority of patients.

There is very little variability in reponses between patients from different countries for the last two questions.

Limitations, reasons for caution: The nature of the questions and the inclusion of personal values regarding the concept of a 'taboo' issue could give rise to ambiguity and therefore limit the validity of some replies to the questionnaire.

Wider implications of the findings: The results allow us to better define the psychological needs of infertile patients, and to see how the context of their country of origin may affect them.

It's surprising that the increasing success of techniques in reproductive medicine isn't accompanied by a similar increase in social acceptance of the treatments.

Trial registration number: Not applicable

P-482 Characteristics and intentions of heterosexual couples comprised of a transgender man and his cisgender woman awaiting sperm donation to conceive a child.

S. Bonan Benchetrit[1], N. Mendes[2], E. Chapel-Lardic[1], O. Rosenblum[2], C. Dudckiewicz-Sibony[1], J.P. Wolf[1], A. Condat[2], C. Chalas[1], C. Patrat[1], V. Drouineaud[1]

[1]Assistance Publique – Hôpitaux de Paris AP- HP Centre- Université de Paris-, Service de Biologie de la Reproduction - CECOS-, Paris, France ;

[2]Assistance Publique-Hôpitaux de Paris AP-HP- Groupe Hospitalier de La Pitié-Salpétrière-, Service de Psychiatrie de l'enfant et de l'adolescent-, Paris, France

Study question: What are the main characteristics and intentions of couples comprised of a transgender man and his cisgender woman awaiting sperm donation?
Summary answer: The couples often met before the man's transition, shared a common life of several years, intend to inform their child of sperm donation and transidentity.
What is known already: It has been reported that more than half of transgender men (female-to-male transgender persons) desired to have children. Since 1994, Assisted Reproductive Technologies (ART) are strictly offered to heterosexual couples in France. Indeed, in order for a transgender man to have access to ART to conceive a child, he must be in a relationship with a woman and have changed his legal sexual identity from female to male. Very little data have been previously reported about the characteristics and intentions of heterosexual couples in which the man is transgender and awaiting sperm donation to conceive.
Study design, size, duration: A retrospective analysis of unit records of 43 heterosexual couples comprised of a transgender man with his cisgender female partner, who apply for ART with donor sperm to conceive a child, was performed. Couples were recruited at the Centre de Conservation des Oeufs et du Sperme (CECOS) (APHP, Cochin, Paris) between October 2010 and December 2019. Couples were asked questions of qualitative and quantitative nature.
Participants/materials, setting, methods: The study was set in the CECOS of (APHP, Cochin, Paris). Our study reported here sought to analyze: socio-demographic characteristics of the couples, personal history of the transgender man, sex transition, meeting and life of the couple, intentions regarding disclosure of sperm donation and father's transidentity to the child.
Main results and the role of chance: Men and women were 32±6.6 and 29.7±4.6 years old, respectively. 37% of transgender men had a higher level than the bachelor degree. Most men (65%) and women (67%) were employees. Transgender men often reported first manifestations during early childhood (54%), difficult experience of breast development (70%) and menstruations (79%). 40% of men reported difficulties during the school and an unstable professional career. Sex transition process was often triggered by a television program (28%) or following web/social networks use (28%). Importantly, in 77% of the cases, the couple met before the man's transition. Most women were heterosexual (60.5%), some identified as lesbian (2.3%) [CP1] or bisexual (14%). 81% of women were comprehensive at the announcement of transidentity. The couples were often stable with a good socio-professional integration and a common life of at least 3 years in 80% of the cases. 4.6% of men and 11.6% of women previously have had a child with another partner. 7% of couples had already a child conceived by sperm donation and 54% had a child project for less than 2 years and 41% for 3 to 5 years. Almost all couples intended to inform their child of sperm donation (95%) and father's transidentity (90%).
Limitations, reasons for caution: The profile of our couples probably does not reflect that of all couples consisting in a transgender man and a cisgender woman. The study spends a long period and couples' characteristics could probably change over the time. The French legislation is still restrictive and influences the profile of those couples
Wider implications of the findings: The future Bioethics law should allow the access to ART for single women and lesbian couples and will probably allow the profile of couples composed of a transgender person to be diversified.
Trial registration number: NA

POSTER VIEWING SESSION

REPRODUCTIVE (EPI)GENETICS

P-483 Embryo selection after PGT-A. Day 5 embryos should be preferred to day 6, even if worst by morphology and time-lapse.

V. Nagornyy[1]

[1]Clinic of Reproductive Medicine 'NADIYA', Embryology department, Kiev, Ukraine

Study question: Should a good morphology day 6 embryo be chosen over day 5 poor morphology in a limited options scenario of PGT-A embryo transfer?
Summary answer: Day 6 PGT-A embryos produced less pregnancies in our settings even when compared to the day 5 "BB grade only" embryo transfers.
What is known already: To date, many studies have shown that day 6 embryos seem to have a reduced potential for achieving pregnancy when compared to day 5 embryos. However, most of those included data of non-PGT-A embryos, while day 5 embryos are well known for having higher euploidy rates. If PGT-A embryos were compared, authors usually were unable to conclude any differences in pregnancy rates between euploid day 5 and day 6 embryos. So, during the laboratory routine there is no obvious choice if only good morphology day 6 and impaired morphology day 5 embryo are available for PGT-A transfer.
Study design, size, duration: This was the retrospective analysis of 1331 PGT-A single embryo transfers in regard to embyo culture day, morhphological score and pregnancy outcome. When available the time-lapse analysis data were included in the comparison.
Participants/materials, setting, methods: PGT-A analysis was performed by aCGH method in
Main results and the role of chance: From 1331 PGT-A single embryo transfers the day 6 embryos were used in 342 cases (25.7%), day 5 "BB grade only" in 101 cases (7.6%). Surprisingly, corresponding clinical pregnancy rates were 45.0% and 54.5%.

When morphology of embryos transferred after biopsy at day 6 was analysed, we observed that 41.6% of those had AA grade, 31.1% were AB or BA and only 28.3% were BB scored. Thus, this group had obviously better scores than day 5 "BB grade only" cohort and difference was not caused by poor morphology.

After we compared the distribution of embryo transfer orders for day 6 AA and day 5 "BB grade only" transfer, we can conclude that in most cases the reason for day 6 embryo selection was not the fact that all day 5 euploid embryos were already transferred in the previous attempts. In fact, the day 5 "BB grade only" transfers occurred after several unsuccessful transfers more often.Time-lapse data indicates that day 6 embryos had slower development starting at 6 cell stage with increasing lag onward, otherwise performing similar.

This data leads us to conclusion that day 6 embryos produce less pregnancies due to their intrinsic values other than morphology and chromosomal constitution.
Limitations, reasons for caution: This is a retrospective analysis and thus it may be subject of bias.
Wider implications of the findings: Our data seem to suggest that it may be better to avoid culture of embryos until day 6 if biopsy is possible at day 5 .
Trial registration number: Not applicable

P-484 FMR1 and AKT/mTOR signaling in human granulosa cells: functional interaction and impact on ovarian response

J. Rehnitz[1], E. Capp[2], B. Messmer[1], A. Germeyer[3], J.E. Dietrich[3], T. Strowitzki[3], P.H. Vogt[1]

[1]University Women´s Hospital, Gynecological Endocrinology and Fertily Disorders - Division of Reproductive Genetics, Heidelberg, Germany ;
[2]Universidade Federal do Rio Grande do Sul, Department of Obstetrics and Gynecology- Medicine School, Porto Alegre, Brazil ;
[3]University Women´s Hospital, Gynecological Endocrinology and Fertily Disorders, Heidelberg, Germany

Study question: Does *FMR1* impact AKT/mTOR-signaling-pathway in human granulosa cells (GC) and is this relevant for ovarian response?
Summary answer: *FMR1*-expression significantly correlates with *AKT-, TSC2-, mTOR-* and *S6K*-expression in GC of women with different ovarian-response indicating a functional effect of *FMR1*/FMRP on AKT/mTOR-regulated follicular-maturation.
What is known already: *FMR1* controls folliculogenesis and human oocyte-maturation. Its transcript and protein (FMRP) is highly expressed in women´s GC. Increased *FMR1* expression levels lead to reduced FMRP production (i.e. negative feed-back loop) causing premature ovarian insufficiency/failure (POI/POF) in 20% of cases.
FMRP is supposed to control translation of *Tsc2* and *mTor*, both members of the AKT/mTOR signaling-pathway, via RISC-(RNA-induced-silencing-complex)-formation.

AKT/mTOR-signaling controls primordial follicle activation and therewith ovarian-reserve. *FMR1*/FMRP expression and mTOR/AKT-signaling are putatively linked in human GCs as their expression was altered in cell culture after FSH-stimulation or inhibition of AKT with MK-2206-2HCl or mTOR with rapamycin, respectively.

Study design, size, duration: 297 fertile women undergoing controlled ovarian stimulation for IVF/ICSI-treatment were recruited from 2013 to 2019 in our outpatient clinic in Heidelberg. They were divided according to their ovarian response into either NOR: normal (n: 217) or POR: poor responders (n: 80) (according to ESHRE guidelines).This study was approved by the local ethical committee and conducted according to the principles of the Declaration of Helsinki.

Participants/materials, setting, methods: All patients provided written informed consent and completed a clinical questionnaire.

mRNA was extracted from GCs after follicular aspiration and oocyte separation; quantitative expression analyses of *FMR1, AKT, TSC2, mTOR, S6K, FOXO3, FOXO1* genes were performed with specific TaqMan-Assays.

Statistical analyses with SPSS; significance set $p<0.05$.

Main results and the role of chance: Rate of *FMR1* expression significantly correlates with *AKT-, TSC2-, mTOR-, S6K*-expression levels ($p< 0.001$ for all; correlation coefficients (cc): 0.515 for *AKT*, 0.458 for *TSC2*, 0.542 for *mTOR* and 0.465 for *S6K*) suggesting a functional linkage. In patients with POR those effects were even more prominent with the biggest increase for *mTOR* and *S6K* (cc: 0.763 for *mTOR*; 0.656 for *S6K;* all $p<0.001$).

Functional interaction between FMRP and transcripts of these members of the AKT/mTOR signal pathway seem therefore to be required for follicular oocyte maturation.

Interestingly, corresponding expression analyses of some downstream members of this signal pathway, *FOXO3* and *FOXO1*, in NOR and POR samples did not display association with *FMR1* expression levels. But they demonstrated higher expression of *FOXO1* in NOR and lower in POR, associated each with inverse *AKT*-levels. This suggests a negative feedback mechanism for these genes also with a putative impact on women´s ovarian reserve.

Limitations, reasons for caution: Control of human folliculogenesis and oocyte maturation by AKT/mTOR-signal-pathway is well known. To prove proposed functional interactions to the molecular control of *FMR1*/FMRP-expression in GC significant numbers of NOR- and POR-samples in different age groups have to be collected to exclude age dependent expression variabilities of these genes.

Wider implications of the findings: Results confirm our earlier expression analyses performed in granulosa cell cultures (COV434) pointing already to a linkage of *FMR1*/FMRP expression with the mTOR/AKT-signaling pathway.

Results will also help to improve POR-diagnostic in women before controlled stimulation for subsequent IVF/ICSI-procedures to raise their chances for sufficient mature follicles.

Trial registration number: not applicable

P-485 Noninvasive preimplantation genetic test for aneuploidy (NIPGT-A) has a lower false positive rate than that of the invasive PGT-A

L. Vagnini[1], C.G. Petersen[1,2], A. Renzi[1], J.B.A. Oliveira[1,2], A.H. Oliani[3], R. Nakano[4], C.G. Almodin[5], C. Marcondes[6], A. Ceschin[7], A. Amaral[8], E. Borges Jr[9], A. Castelo Branco[10], J.B. Soares[11], J. Lopes[12], J.G. Franco Jr.[1,2]

[12]*CENAFERT, Research, Salvador, Brazil*

Study question: Does NIPGT-A have lower false positive rates (FPR) than invasive PGT-A?

Summary answer: When DNA sequencing from whole embryo cells was used as the gold-standard, the FPR of NIPGT-A was 3.32-times smaller than that obtained with invasive PGT-A.

What is known already: After many years of using PGT-A, there are still many concerns, such as risks of invasive action and difficulties in the correct interpretation of mosaicism, which could lead to errors in the interpretation of false positive and negative results. Recently, a new technology (NIPGT-A) has arisen using cell-free DNA present in the spent culture media of human blastocysts. Unlike invasive PGT-A that uses only trophoblastic cells, NIPGT-A reflects the ploidy status of trophoblastic cells and inner cell mass, suggesting that this new technology could be less prone to errors, being more reliable than invasive test.

Study design, size, duration: This cohort study included a total of 37 blastocysts vitrified on day 5 that were previously biopsied for invasive PGT-A and presented a diagnosis of aneuploidy. The embryos were donated under informed consent by patients following the Human Medical Authority regulations. Blastocysts were thawed and cultured in 15µl drops of culture medium under oil. After their expansion (4-8hours), the blastocysts were transferred to NGS tubes and their corresponding spent media were collected for analysis.

Participants/materials, setting, methods: The DNA of all samples (spent culture medium and whole embryo) was amplified by the MALBAC® technology (Yikon Genomics). The samples were subjected to next-generation sequencing (NGS) using Illumina MiSeq® System. The ploidy status results obtained from ChromGo™ software (Yikon Genomics) for culture medium and whole embryo were compared to determine the accuracy of NIPGT-A for screening chromosomal abnormalities in each embryo.

Main results and the role of chance: DNA from all 37 spent media samples and whole embryos were successfully amplified. Comparing the results of NIPGT-A and whole embryos sequencing, the positive predictive value (PPV) was 93.5% and the FPR was 6.5%. On the other hand, comparing the whole embryo and invasive PGT-A results, the PPV was 78.4%, and the FPR was 21.6% (Table 1). Both NIPGT-A and invasive PGT-A had a negative predictive value (NPV) of 100% and a false negative rate (FNR) of 0%. In the eight cases of disagreement the results are presented in the Table 2.

Table 1. NIPGT-A and Invasive PGT-A results

NIPGT-A	Whole Embryo		Invasive PGT-A	Whole Embryo	
	Aneuploidy	Normal		Aneuploidy	Normal
Aneuploidy	29	2	Aneuploidy	29	8
Normal	0	6	Normal	–	–

PPV: 93.5% FPR: 6.5%
PPV: 78.4% FPR: 21.6%

Table 2. Disagreement results of whole embryo, NIPGT-A and invasive PGT-A

Whole embryo	NIPGT-A	Invasive PGT-A
46,XY	46,XY	XY,+1q(x3);+3q(x3)
46,XY	46,XY	XY,-2(x1)
46,XY	XY,-1(x1);-9q(x1)	XY,+9q(x3)
46,XX	46,XX	XX,+9q(x3)
46,XX	46,XX	XX,-4(x1)
46,XY	46,XY	X0, multiple abnormalities
46,XX	46,XX	XX,+13(x3)
46,XY	XY,-1(x1);-9(x1),-19(x1);-21(x1)	XY,-9(x1)

Limitations, reasons for caution: The sample size was relatively small, however comparative analysis between the results of invasive and noninvasive PGT-A with whole embryo are rare. All donated embryos were classified as aneuploidy by invasive PGT-A. Additionally, the cut-off for aneuploidy in cases of invasive PGT-A could be variable (multicenter study).
Wider implications of the findings: NIPGT-A has a lower FPR than invasive PGT-A and does not require micromanipulation skills, avoiding trophectoderm biopsies trauma and seems to provide more accurate results corresponding to the ploidy status of the whole embryo. Thereby NIPGT-A should be considered as the test of choice for genetic evaluation of the embryo.
Trial registration number: Not Applicable

P-486 Does day of PGT-A biopsy predict mosaicism rates?

B. McGuinness[1], B. Abittan[2], A. Pratt[3], W. Shan[4], S. Brownridge[2], R. Goldman[2], M. Christine[2]

[1]NYU Winthrop Hospital, Obstetrics and Gynecology, Mineola, U.S.A. ;
[2]Northwell Health Fertility, Reproductive Endocrinology and Infertility, Manhasset, U.S.A. ;
[3]Sanford H. Calhoun High School, General, Merrick, U.S.A. ;
[4]The Feinstein Institute for Medical Research, Biostats Unit, Manhasset, U.S.A.

Study question: Does the rate of mosaicism differ between blastocysts biopsied on day 5 (D5) versus day 6 (D6) using NGS (Next-Generation Sequencing) technology for PGT-A (Preimplantation Genetic Testing for Aneuploidies)?
Summary answer: Although rate of aneuploidy is higher with embryos biopsied on D6 versus D5, rate of detected mosaicism does not vary based on blastocyst biopsy day.
What is known already: Advancing technologies in the field of assisted reproductive technology has sensitized our methodologies with the utilization of NGS in identifying trophectoderm (TE) mosaicism (≥ 2 distinct cell lines within a TE biopsy). The timing of post-fertilization mitotic errors affects the percentage of abnormal cells present within a mosaic embryo, but it is not known if the rate of mosaicism is related to the day of TE biopsy.
Study design, size, duration: This is a retrospective cohort study of patients who underwent IVF/PGT-A using NGS technique from January 2018 to July 2019. A total of 663 patients underwent 797 IVF/PGT-A cycles. 50 cycles were excluded due to incomplete data for analysis.
Participants/materials, setting, methods: The numbers of euploid, aneuploid, low and high-level mosaic embryos were collected. Of the included cycles, 257 cycles (34.4%) had embryos biopsied on both day 5 (D5) and day 6 (D6). These cycles were analyzed using paired non-parametric testing to compare the D5 and D6 rates of mosaicism. The Wilcoxon rank-sum was used to analyze rates of euploidy, aneuploidy, total mosaicism, low-level mosaicism, and high-level mosaicism. Significance was defined by $p < 0.05$.
Main results and the role of chance: The rates of total mosaicism (15.7% vs. 14.2%; p=0.19), low-level mosaicism (61.5% vs. 58.9%; p=0.14), and high-level mosaicism (38.5% vs. 41.1%; p=0.09) did not differ significantly between D5 and D6 biopsies respectively. Embryos biopsied on D5 were less likely to be aneuploid and more likely to be euploid than those biopsied on D6 (Aneuploid: 33.3% vs. 44.2%; p=<0.001. Euploid: 48.8% vs. 38.8%; p=<0.001). Comparison of matched samples determined that D5 and D6 blastocytes have the same distribution of mosaicism and do not have the same distribution of aneuploidy or euploidy.
Limitations, reasons for caution: This study is limited by small sample size. 797 IVF/PGT-A cycles occurred but only 257 cycles had embryos biopsied on both D5 and D6 and complete data for analysis. Further research is needed to better understand the in vitro development of mosaic embryos and the underlying mechanisms of blastocyst formation.
Wider implications of the findings: Although studies have examined the detection of blastocyst stage mosaicism with use of PGT, no study has used paired non-parametric testing to compare D5 and D6 rates of mosaicism as was done here. This study supports the argument that timing of PGT biopsy does not affect rate of detected mosaicism.
Trial registration number: not applicable

P-487 The polymorphism Ala307Thr of the Follicle Stimulating Hormone Receptor (FSHR) gene is associated with different doses of recombinant FSH received during IVF/ICSI treatment.

F. Dieamant[1,2], C.G. Petersen[1,2], L.D. Vagnini[2], A. Renzi[2], M. Canas[2], B. Petersen[1,2], A.L. Mauri[1,2], M. Mattila[1], J. Ricci[1], A. Nicoletti[1], C. Zamara[1], A.H. Oliani[3], J.B.A. Oliveira[1,2], J.G. Franco Jr.[1,2]

[1]Centre for Human Reproduction Prof Franco Jr, Research, Ribeirao Preto, Brazil ;
[2]Paulista Center for Diagnosis- Research and Training, Research, Ribeirao Preto, Brazil ;
[3]Sao Jose do Rio Preto School of Medicine FAMERP, Research, Sao Jose do Rio Preto, Brazil

Study question: Is there an association between FSHR gene Ala307Thr polymorphism (rs6165) and ovarian reserve, ovarian response or clinical results in IVF/ICSI treatment?
Summary answer: Ala/Ala genotype was associated with the use of higher doses of recombinant FSH(r-FSH), suggesting that homozygosis of this allelic variant(Ala) provides lower sensitivity to r-FSH.
What is known already: Follicle-stimulating hormone (FSH) is essential for folliculogenesis and acts through the FSHR that is present on the membrane of granulosa cells. Polymorphisms in the FSHR gene may lead to an altered pattern of receptor expression on the cell surface or to changes in affinity for FSH. The Ala307Thr polymorphism is located in the extracellular domain within the hormone binding region, which can influence the response to endogenous and exogenous FSH stimulation. However, the influence of the FSHR Ala307Thr polymorphism on ovarian function is still controversial.
Study design, size, duration: This prospective cohort study included 450 women who underwent IVF/ICSI cycles. The enrolled individuals met the following inclusion criteria: age of ≤37 years; normal karyotype; presence of two ovaries as observed by ultrasound examination; and no history of ovarian surgery, endometriosis, hydrosalpinx, infection, or endocrine disorders.
Participants/materials, setting, methods: DNA was extracted from peripheral blood, and the Ala307Thr FSHR polymorphism (rs6165) was genotyped using TaqMan SNP genotyping assay. The results were associated with age, anti-Müllerian hormone (AMH) levels, antral follicle counts (AFC), total dose of r-FSH, follicle size, number of retrieved oocytes, and clinical outcome of IVF/ICSI cycles. The statistical analyses were performed using Fisher's exact test and Kruskal-Wallis test.
Main results and the role of chance: An association between the genotypes of the FSHR (Ala307Thr) polymorphism and different doses of r-FSH was observed. Patients with the Ala/Ala genotype received a higher r-FSH dose than patients with the Ala/Thr (P=0.0002) and Thr/Thr (P=0.02) genotypes. No other correlation was observed. Table 1 summarizes the results.
Limitations, reasons for caution: Possible limitation is the cross-sectional nature of the data. Differences in the genetic backgrounds of various ethnic populations might also be considered.
Wider implications of the findings: The results suggest that FSHR Ala307Thr (rs6165) gene polymorphism is related to ovarian response but not to ovarian reserve. This SNP can be used as an additional tool in the individualization of ovarian stimulation protocols.
Trial registration number: Not Aplicable

P-488 The live birth rate and the position of breakpoints in patients with recurrent miscarriage caused by reciprocal translocation

T. Sato[1], F. Ozawa[1], C. Saito[1], H. Yosihara[1], C. Banno[1], Y. Sawada[1], Y. Matsumoto[1], M. Sugiura-Ogasawara[1]

[1]Nagoya City University Graduate School of Medical Sciences, Department of Obstetrics and Gynecology, Nagoya, Japan

Study question: Can we estimate the frequency of alternate segregation from the position of breakpoints in patients with recurrent miscarriage (RM) caused by reciprocal translocation?
Summary answer: We could find no association between the frequency of alternate segregation and the position of breakpoints.

Table 1. Results

	FSHR (rs6165) genotypes			
	Thr/Thr	Thr/Ala	Ala/Ala	P
n (%)	141 (31.3%)	213 (47.4%)	96 (21.3%)	
Age	35.0±3.8	34.5±4.1	34.5±4.7	0.57
BMI (kg/m^2)	24.3±4.0	24.3±4.0	24.4±4.7	0.81
AMH (ng/ml)	1.7±2.3	1.9±2.1	1.6±2.1	0.26
AFC (n)	12.6±8.7	13.4±7.4	12.3±9.0	0.11
Total dose FSH (UI)	2085±922[a]	1946±955[b]	2364±1060[a,b]	[a]0.02; [b]0.0002
Time of stimulation (days)	10.3±2.5	10.1±2.4	10.5±2.2	0.17
Follicles (n): Total	11.4±6.6	12.0±7.4	11.6±7.4	0.86
Follicles (n): ≥18 mm	3.8±2.2	5.7±2.0	3.6±2.5	0.64
Retrieved oocytes: Total (n)	8.2±5.4	8.1±5.1	8.2±5.4	0.98
Retrieved oocytes Metaphase II (n)	6.1±4.3	5.9±4.1	6.1±4.8	0.92
Fertilization rate	64.5±26.4%	64.6±26.5%	64.4±29.9%	0.96
Implantation rate	23.9%	26.1%	25.7%	0.82
Pregnancy rate/transfer	34.6%	39.9%	39.8%	0.65
Pregnancy rate/patient	31.2%	35.2%	34.4%	0.79

What is known already: Preimplantation genetic testing for structural rearrangements (PGT-SR) is performed to prevent miscarriage worldwide, but it cannot improve the live birth rate in patients with RM. In carriers of reciprocal translocations, it has been reported that the proportion of each meiotic segregation mode depends on certain characteristics, including the gender of the carrier, the position of the breakpoints and the involvement of acrocentric chromosomes. However, there is no method for using the karyotype to estimate the frequency of alternate segregation ending in a live birth.
Study design, size, duration: This is a retrospective study to evaluate the proportion of meiotic segregation modes in PGT-SR performed at our hospital between 2007 and 2019. A total of 469 day 3 or day 5 embryos from 67 cycles of PGT-SR for 20 couples with RM caused by reciprocal translocation were examined by fluorescence in situ hybridization (FISH) or array comparative genomic hybridization (aCGH).
Participants/materials, setting, methods: For PGT-SR, FISH or aCGH was performed on biopsied samples of day 3 or day 5 embryos. According to the results, the meiotic segregation mode was classified, and the effects of the gender and age of the carriers, the size of the translocated segments, the ratio of the translocated segment to the size of the arm with the breakpoint and the form of the tetravalent chromosome structure in meiosis were evaluated.
Main results and the role of chance: Overall, 26% of 391 embryos with results were diagnosed with alternate segregation, 18% with adjacent-1 segregation, 8% with adjacent-2 segregation, 37% with 3:1 segregation, 2% with 4:0 segregation and 9% remained undiagnosed. There was no significant difference in the alternate segregation frequencies between 10 patients with more than 10 embryos with the meiotic segregation mode results. The frequency of alternate segregation was identical between male and female translocation carriers (26.1 vs 26.1%), while the incidence of the 3:1 segregation was significantly higher in female carriers than in male carriers (33.7 vs 19.1%, $p<0.05$). The age of the carrier did not affect the proportion of the meiotic segregation mode.No correlation was observed between the size of the translocated segments or its ratio to the size of the arm with the breakpoint and the frequency of alternate segregation.The frequency of adjacent-1 segregation was significantly higher in patients in which the sizes of both translocated segments were less than 50% of the size of each arm with the breakpoint compared with others (27.1 vs 12.1%, $p<0.01$).The form of the tetravalent chromosome structure in meiosis did not correlate with the frequency of alternate segregation.
Limitations, reasons for caution: The findings of the present study were limited by the relatively small sample size. In particular, more samples will be needed to evaluate the relationship between the form of the tetravalent chromosome structure in meiosis and the frequency of alternate segregation.
Wider implications of the findings: It might be possible to estimate the miscarriage rate because the frequency of adjacent-1 segregation which tends to end in miscarriage could be speculated from the position of the breakpoints. This information may be useful in the genetic counseling of couples who are reciprocal translocation carriers before performing PGT-SR.
Trial registration number: Not applicable

P-489 Is there a role for mitochondrial DNA quantification as a biomarker to select euploid blastocysts with high implantation potential?

V.C. Moreno[1], R.C.S. Figueira[1], S. Verza Jr[1], S.C. Esteves[2]

[1]Androfert – Andrology and Human Reproduction Clinic, Laboratory, Campinas/SP, Brazil ;
[2]Androfert – Andrology and Human Reproduction Clinic, Clinical Board, Campinas/SP, Brazil

Study question: Is mitochondrial DNA (mtDNA) quantification in trophectoderm cells a useful biomarker to select euploid blastocysts with a high implantation potential?
Summary answer: Although low mtDNA levels are associated with higher implantation rates, blastocyst morphology is more informative than mtDNA quantification to identify euploid embryos that implant.
What is known already: Transfer of euploid blastocysts does not invariably result in ongoing pregnancies, thus indicating that other factors impact embryonic implantation potential. Factors such as metabolic rates and adenosine triphosphate content have been shown to vary significantly in oocytes and embryos and could affect embryo viability. On this basis, embryo function, indirectly measured by mtDNA copy number, emerged as a potential quantitative biomarker for embryonic selection prior to transfer. Initial data have shown that euploid blastocysts with elevated mtDNA copy numbers rarely result in successful pregnancies. However, subsequent research could not confirm these observations and the literature remains equivocal.

Study design, size, duration: A prospective observational study was performed between September 2017 and September 2019 to analyze the contribution of mtDNA levels for embryo implantation in 160 euploid blastocysts obtained from 123 infertile couples undergoing preimplantation genetic testing for aneuploidy (PGT-A). Implantation outcomes were assessed based on mtDNA levels and blastocyst morphology criteria to determine the usefulness of these biomarkers to predict successful implantation in a single euploid blastocyst transfer program.
Participants/materials, setting, methods: Trophectoderm biopsies were subjected to whole genome amplification followed by comprehensive chromosome analysis via next-generation sequencing (NGS). mtDNA quantification was also performed using NGS. A mitochondrial score (Low - High) using the mitochondrial-to-nuclear DNA ratio (mt/gDNA) was applied. Statistical analyses included comparative analyses, correlation coefficients, and generalized linear models. Areas under the ROC curve (AUC) were estimated to assess the ability of the mt/gDNA and blastocyst morphology to predict implantation outcomes.
Main results and the role of chance: Implantation rates were significantly higher in Low-score (n=140) than High-score (n=20) euploid blastocysts selected for transfer (48.6% vs. 25.0%, p=0.048). Correlational analysis showed a significant but weakly positive correlation between mt/gDNA and successful implantation (Spearman's correlation, r=0.157, p=0.04). By contrast, a strong negative correlation was observed between blastocyst morphology and implantation occurrence (Spearman's correlation, r=-0.283, p < 0.0001). The logistic regression analyses showed no association between mt/gDNA and implantation, whereas blastocyst morphology had a positive influence on the likelihood of euploid blastocyst implantation (OR=5.103, 95% IC: 1.027-25.357, p=0.04). ROC analyses suggested that blastocyst morphology alone was able to better rank the embryos with positive implantation outcomes than mt/gDNA alone (AUC = 0.72635, p=0.05). The combination of both parameters conferred a small increase in the implantation predictive ability (AUC= 0.74725, p=0.04).
Limitations, reasons for caution: Our findings are based on a relatively small dataset. Another limitation is the lack of randomization as embryo morphology was the primary criterion for selecting euploid blastocysts for single embryo transfer. Thus, there was a difference in the number of embryos among the mt/gDNA score groups.
Wider implications of the findings: Although an association exists between mtDNA levels and implantation rates, mtDNA cannot be used as an independent biomarker to identify euploid blastocysts that result in successful implantation. Our findings suggest that at present blastocyst morphology should be prioritized in the clinical settings to rank euploid blastocysts with high implantation potential.
Trial registration number: None

P-490 The mean euploidy rate per cohort of biopsied blastocysts is independent of couples' previous reproductive history: an analysis of 2676 cycles with preimplantation-genetic-testing-for-aneuploidies.

D. Cimadomo[1], A. Capalbo[2], A. Vaiarelli[1], S. Colamaria[1], R. Maggiulli[1], L. Albricci[1], L. Dovere[1], M. Stoppa[1], L. Tacconi[1], F. Sanges[1], D. Soscia[1], A. Giancani[1], E. Scepi[1], F.M. Ubaldi[1], L. Rienzi[1]

[1]Clinica Valle Giulia, G.EN.E.R.A. centers for reproductive medicine, Roma, Italy ; [2]Igenomix, Igenomix Italy, Marostica, Italy

Study question: Is the mean euploidy rate per cohort of biopsied blastocysts (m-ER) associated with the previous reproductive history of the couples undergoing preimplantation-genetic-testing-for-aneuploidies (PGT-A)?
Summary answer: If adjusted for maternal age, couples' previous reproductive history has no effect on the m-ER after PGT-A.
What is known already: Several studies investigated the association between the euploidy rates after PGT-A and i) patients' characteristics (e.g. maternal/paternal age, sperm factor), ii) ovarian stimulation strategy (e.g. protocol, dose of gonadotrophins, trigger of ovulation), iii) IVF cycle characteristics (e.g. incubator, culture strategy), iv) blastocysts' features (e.g. morphological quality, developmental rate). Conversely, the expected m-ER after PGT-A due to couples' previous reproductive history (previous cycles, miscarriages, live births and lack of euploid blastocysts identified during prior cycles) still needs to be outlined. Yet, this information is critical to counsel the patients towards a first PGT-A cycle, or after former adverse outcomes.
Study design, size, duration: Observational study including all trophectoderm biopsy-based PGT-A cycles (n=2236 couples;2676 treatments;8151 embryos) conducted via comprehensive-chromosome-testing techniques (CCT: qPCR or NGS;Igenomix) between 2013 and 2019 at a private Italian clinic (Genera Rome). The m-ER was investigated according to couples' previous reproductive history (previous live birth(s):no/yes; previous failed IVF cycle(s):-none/1/2/>2; previous miscarriage(s):none/1/>1). For PGT-A cycles following previous attempts (n=440/2676,16.4%), the m-ER was also investigated according to the former results (absence/presence of euploid blastocyst(s) in the previous cohort(s)).
Participants/materials, setting, methods: The m-ER followed a distribution different from a Gaussian (Kolgomorov-Smirnov and Shapiro-Wilk tests<0.01). Therefore non-parametric tests were adopted for the investigation (i.e. Mann-Whitney U or Kruskal-Wallis tests). Generalized-linear-models were adopted to adjust for confounders. Maternal age (mean:39.3±3.3yr) was the only variable significantly associated with the m-ER (partial-eta-squared:0.19,p<0.01 and power>0.99) and all the analyses were thus conducted among ranges of maternal age (<35yr,n=208 m-ER:66%±31%; 35-37yr,n=533 m-ER:58%±33%; 38-40yr,n=909 m-ER:43%±35%; 41-42yr,n=574 m-ER:28%±34%; >42yr,n=452 m-ER:17%±31%).
Main results and the role of chance: The m-ER was independent from previous live births (<35yr:no, n=195 67%±31%/yes, n=13 54%±36% p=0.2; 35-37yr:no, n=500 58%±32%/yes, n=33 58%±38% p=0.8; 38-40yr:no, n=795 43%±35%/yes, n=114 41%±33% p=0.6; 41-42yr:no, n=510 28%±34%/yes, n=64 29%±35% p=0.5; >42yr:no, n=387 17%±30%/yes=65 21%±36% p=0.6), as well as from the number of previous failed IVF cycles (<35yr:none, n=119 65%±31%/1, n=53 67%±30%/2, n=21 78%±23%/>2, n=15 54%±39% p=0.3; 35-37yr:none, n=301 59%±32%/1, n=102 59%±32%/2, n=62 57%±33%/>2, n=68 51%±35% p=0.4; 38-40yr:none, n=466 44%±35%/1, n=187 42%±34%/2, n=122 41%±34%/>2, n=134 40%±35% p=0.5; 41-42yr:none, n=277 27%±34%/1, n=138 27%±34%/2, n=76 35%±38%/>2, n=83 27%±29% p=0.4; >42yr:none, n=235 15%±28%/1, n=107 15%±28%/2, n=54 28%±39%/>2, n=56 23%±34% p=0.1) and/or miscarriages (<35yr:none, n=171 66%±31%/1, n=25 69%±27%/>1, n=12 63%±40% p=0.9; 35-37yr:none, n=416 58%±33%/1, n=75 56%±30%/>1, n=42 60%±36% p=0.6; 38-40yr:none, n=674 42%±35%/1, n=158 44%±34%/>1, n=77 44%±35% p=0.9; 41-42yr:none, n=404 29%±35%/1, n=99 29%±33%/>1, n=71 20%±27% p=0.3; >42yr:none n=324 18%±31%/1, n=79 17%±33%/>1, n=49 14%±25% p=0.8). Lastly, for the 440 cycles performed after former completed PGT-A cycles, the absence/presence of euploid blastocysts in the previous cohort(s) did not associate with the m-ER (<35yr:absence, n=5 69%±19%/presence, n=203 66%±31% p=0.3; 35-37yr:absence, n=23 40%±33%/presence n=510 59%±32% p=0.1 ; 38-40yr:absence, n=84 38%±33%/presence, n=825 43%±35% p=0.25; 41-42yr:absence, n=75 29%±35%/presence, n=499 28%±34% p=0.4; >42yr:absence, n=78 20%±31%/presence, n=374 17%±30% p=0.7).
Limitations, reasons for caution: Segmental and allegedly-mosaic aneuploidies were not reported. The sample size among the treatments following a former completed PGT-A cycle should be increased. The data should be confirmed from a multicenter perspective. For couples who experienced former IVF failures and/or miscarriages, the implantation rate after euploid blastocyst transfer should be investigated.
Wider implications of the findings: These data are critical to counsel infertile couples before and after PGT-A cycles. Apparently, their previous reproductive history does not affect the m-ER beyond the maternal-age-effect. For idiopathic repeated-IVF-failures and recurrent-pregnancy-losses, the causes might be related to endometrial receptivity issues. Yet, transferring only euploid blastocysts minimizes embryo-derived adverse reproductive outcomes.
Trial registration number: None

P-491 Cleavage biopsy, same results as trophectoderm biopsy but without mosaicism

C. Encinas[1], S. Novo[1], A. Brualla[2], Á. García-Faura[1], B. Marquès[1], F. García[1], C. Castelló[1], M. López-Teijón[1]

[1]Institut Marquès, Reproductive Medicine Service, Barcelona, Spain ; [2]Institut Marquès Ireland, Reproductive Medicine Service, Clane, Ireland

Study question: Analysing the evolution of PGT-A, does the biopsy at blastocyst stage bring great advantages?

Summary answer: Both cleavage and blastocyst stage biopsy provide optimal and equivalent clinical results.
What is known already: Recently, trophectoderm biopsy has been considered the gold standard for Preimplantational Genetic Testing (PGT). The main reason is that the higher number of analysed cells, the better representation of embryo's chromosomal constitution should be achieved. However, this technique has also made the mosaic embryo diagnostic group appear, a result that can be considered as ambiguous. The possibility of getting a confusing result is being used by some groups as an argument to challenge the usefulness of blastocyst biopsy and PGT-A. This study aims to assess the differences in clinical outcomes between treatments were cleavage or trophectoderm biopsies have been performed.
Study design, size, duration: This is a retrospective study containing data from 681 single blastocysts transfer PGT-A cycles between 2017 and 2019 using Next Generation Sequencing (NGS). On one hand, D3-group: 229 cycles with cleavage stage embryos biopsied at day 3 of culture, cultured up to blastocyst stage and fresh transferred. On the other hand, D5/6-group: 452 cycles, with embryos cultured to blastocyst stage, biopsied and vitrified.
Participants/materials, setting, methods: In both groups, embryos were cultured using single step media in time-lapse incubators up to blastocyst stage. Patient characteristics and demographic data were homogenous and similar between both groups. The number of embryos biopsied, blastocyst rate, results of *NGS* analysis and pregnancy and miscarriage rates were compared between both groups. The Chi-square test was used for statistics.
Main results and the role of chance: D3-group had significantly more biopsied embryos (n=1097/1287; 85.2%) than D5/6-group (n=1715/3233; 53%; p<0.05). However, the good quality blastocyst rate was equivalent between groups (D3=50.2%; D5/6=53%; p=0.086), demonstrating that cleavage stage embryo biopsy did not compromise embryonic development.

To compare NGS results between groups, all biopsied embryos were included in D5/6 group, while in D3-group only the biopsied embryos with good quality in day 5/6 were considered (≥3BB Gardner score). Aneuploidy rates proved to be similar (D3:48%; D5/6:46.8%; p=0.262) as well as the non diagnostic result (D3=5.1%; D5/6=1.2%; p=0.091). Nevertheless, there were statistically significant differences between euploidy rates, being higher in D3-group (46.9%) than in grouP-D5/6 (34.5%; p<0.05). After genetic counselling, and considering some mosaic embryos as transferable, a total of 45.3% of embryos could be considered for transfer matching the values obtained in D3-group.

In both groups, a single blastocyst was transferred. There were 144 embryo transfers in D3-group and 262 in D5/6 group. Pregnancy rates (D3=68.8%; D5/6=72.5%; p=0.152), ongoing pregnancy rates (D3:=52.8%; D5/6=52.3%; p=0.411), and miscarriage rates (D3=8.1%; D5/6=8.4%; p=0.356), were equivalent between groups.
Limitations, reasons for caution: Although the considerable data set provided, live birth rates should be analysed. Every D3-group embryo was transferred in the fresh cycle, but all D5/6-group embryos were transferred in a cycle were no ovarian stimulation was performed. This could be a source of bias.
Wider implications of the findings: Considering that pregnancy and miscarriage rates were similar, both strategies can coexist and it is not mandatory to biopsy at blastocyst stage. As it is done in our clinic, each case should be evaluated to decide which is the best strategy for the patient.
Trial registration number: doesn't apply

P-492 Mitoscore in a euploid embryo- can it be a game changer ?

S.S. Garimella[1], K. Mantravadi[1], D.R. Gedela[1]

[1]oasis fertility, reproductive medicine, hyderabad, India

Study question: Does mitoscore value predict implantation potential of an embryo and have an impact on antenatal outcomes and neonatal birth weight?
Summary answer: Mitoscore has no role in predicting implantation potential of an embryo, but high mitoscore was associated with hypertensive disorders in pregnancy and lower birth weight.
What is known already: Mitoscore is a mitochondrial biomarker which is an indicator of energy status of embryo. Some studies indicate that increase in the mitochondrial DNA (mtDNA) in the embryo is indicative of insufficient level of energy and a low implantation potential. But recently there is a debate about the usefulness of mitoscore as a predictor of successful implantation .Therefore, more research is needed to further our understanding of the clinical usefulness of mitoscore as a biomarker for embryo viability
Study design, size, duration: This is a retrospective study involving analysis of 132 term babies born from transfer of a single euploid blastocyst from February 2018 to march 2019 at our center
Participants/materials, setting, methods: We performed preimplantation genetic testing for aneuploidy (PGT A) for patients with advanced maternal age, recurrent pregnancy losses and recurrent implantation failure.Trophectoderm biopsy was done and the samples were analysed by comprehensive chromosomal screening. Based on mitoscore value two groups were formed, group A (< 25) group B (> 25). Clinical pregnancy rates(CPR), live birth rates (LBR), hypertensive disorders in the antenatal period, birth weights and anomaly rates in the two groups were compared.
Main results and the role of chance: There was no difference in baseline characters between the two groups. Out of 132 euploid blastocysts 64 (48.4%) of the blasts had a mitoscore< 25 and 68 (51.6%) had a mitoscore of > 25. There was no statistically significant difference in CPR (68.7 % vs 66.1%) and LBR (57.8% vs 55.8%).Hypertensive disorders in the antenatal period were significantly higher in the group with mitoscore > 25 (37.6% in group B vs 12.2% in group A). %). Birth weights of babies in the group with mitoscore more than 25 (2.54 +/- 0.46) was significantly lower when compared to the group with mitoscore less than 25 (2.19 +/- 0.36) (p=0.025). There was no difference in anomaly rates in both the groups
Limitations, reasons for caution: This is a retrospective data and sample size was small and indications of PGT A are still debatable. Further research is necessary.
Wider implications of the findings: This study provides evidence that mitoscore has no role in predicting the implantation potential of an embryo. Higher mitoscore embryos were associated with hypertensive disorders in pregnancy and lower birth weights. Therefore further research is required to understand the implications of mitoscore and its effect on reproductive outcomes
Trial registration number: not applicable

P-493 Prospective analysis of multiplatform preimplantation genetic testing for aneuploidy (PGT-A) confirmation of trophectoderm re-biopsy from aneuploid embryos and corresponding whole embryos

M. Abae[1], N. Arrach[2], Y. Ying[3], X. Zhang[4], A. Goodman[5], K. Abae[6]

[1]Fertility & Genetics, Reproductive Endocrinology, Plantation- FL, U.S.A. ;
[2]Progenesis, Progenesis, San Diego, U.S.A. ;
[3]Univeristy of Soujht Florida, Obstetrics & Gynecology, Tampa, U.S.A. ;
[4]Fertility & Genetics, Embryology, Plantation, U.S.A. ;
[5]NXGENMDX, Pgt, Grand Rapids, U.S.A. ;
[6]Fertility & Genetics, Fertiility & Genetics, Plantation, U.S.A.

Study question: How do results of PGT-A compare between different contemporary testing platforms, next generation sequencing (NGS) and single nucleotide polymorphism (SNP) from trophectoderm (TE) re-biopsy samples and corresponding whole embryos (EM)
Summary answer: SNP had moderate correlation with NGS. Discrepancy between TE and whole EM results was not associated with platforms, but to sample variability and potentially mosaicism.
What is known already: PGT-A improves successful pregnancy outcomes following elective single embryo transfer. However, significant clinical uncertainty remains about the accuracy of mosaicism in embryos undergoing PGT-A testing. Furthermore, re-biopsy of abnormal embryos have occasionally led to euploid results adding new challenges to the PGT-A management and patient expectation.
Study design, size, duration: Thirty pre-tested aneuploid embryos that were donated by couples who had a previously confirmed viable pregnancy after transfer of single euploid embryo following PGT-A. Discarded genetically abnormal embryos that were consented for donation for research were analyzed in this exempt IRB approved blinded study. The inclusion criteria did not consider factors such as cause of infertility, age, race, or ethnicity. This study excluded any untested or genetically normal embryos.
Participants/materials, setting, methods: Thirty pre-tested aneuploidy embryos with SNP that were donated for this study were re-biopsied. TE and the corresponding EM were loaded separately. Sixty blinded samples were

subject to whole genome amplification followed by NGS. Each DNA sample was tested with two sequencing platforms: VeriSeq-PGS and Reproseq.

Main results and the role of chance: Of 30 embryos, 23 were successfully amplified/sequenced in both TE and EM. The two NGS platforms had 100% correlation when same source DNA is used. Each sequencing platform showed 96% correlation between TE and EM. SNP and NGS had 79% correlation at TE level and 84% at EM. Discrepancy between TE and whole EM results was not associated with the platforms, but to sample variability, potentially due to mosaicism. There was 17.4% (4 out of 23) of re-biopsied TE and whole EM found to be euploid by the two NGS platforms compared to SNP. This discrepancy could be related to the technology used, biopsy quality or to embryonic mosaicism.

Limitations, reasons for caution: The two NGS platforms were performed on the same DNA, while SNP array was performed with separate biopsy. Difference in biopsy quality and/or potential mosaicism can lead to a discrepancy between NGS and SNP.

Wider implications of the findings: PGT-A has shown to improve pregnancy outcomes with a single embryo transfer. However, the choice of PGT-A technology platform presents a challenge from genetic counselling perspective. The impact of potential mosaicism, PGT-A technological limitation, and variability across biopsies should be taken into account when counseling patients with PGT-A.

Trial registration number: Not Applicable

P-494 Clinical exome sequencing from peripheral blood reveals novel gene variants to prevent ovarian failure

Study question: Could the identification of specific sequence variants in DNA stratify individuals with ovarian failure?

Summary answer: This prospective study has discovered 66 DNA variants associated with ovarian failure.

What is known already: Around 1% of women under the age of 40 develop premature ovarian insufficiency (POI), which includes accelerated attrition of the ovarian follicle reserve and amenorrhea. An unknown percentage of women suffer occult ovarian failure, a less severe form of ovarian insufficiency that increases infertility due to a diminished ovarian reserve. In most cases, the genetic cause or origin of this heterogeneous and complex disorder is unknown. Interestingly, whole exome sequencing based studies have started identifying new POI-associated sequence variants even though most of those studies suffer from lack of control or small sample size.

Study design, size, duration: A 150 case-control study was conducted between 2017 and 2019: 118 cases diagnosed with primary ovarian insufficiency (n=35) or occult ovarian failure (n=83) and 32 controls based on AMH levels and/or antral follicle counts. Next, whole-exome sequencing of DNA from 150 peripheral blood samples was performed using SureSelect Clinical Research Exome V2 (Agilent Technologies) and Illumina sequencing. The study was approved by the institutional review board of Instituto Valenciano de Infertilidad (1709-PAM-090-PR).

Participants/materials, setting, methods: In order to identify variants more likely associated with ovarian failure, we excluded variants with a population frequency higher than 5% - considering the negative impact of variants associated with ovarian failure during natural selection. In addition, only variants in genomic positions with >100x were considered. Furthermore, variants were filtered according to their absence/presence in IGSR, to identify new variants and only non-synonymous variants with consequence at protein level were considered for case-control comparison.

Main results and the role of chance: Genes previously associated with ovarian failure accumulated less gene variants than any selection from the total of the exome (t test, p value =2.2e-16). Analysis of the clinical exome (18311 genes) revealed more than 47,000 variants were patient specific, therefore associated with individual genetic variation. We highlighted 66 novel variants that were at least shared by 10 % of cases and absent in controls, as a criterion to be related to ovarian failure. This profile of 66 variants altogether identified the 100% of cases stratifying into two main types of ovarian failure, finding inside one of them two clear subtypes. With two variants, DNAH6, a gene related to microtubule activity, was the major contributor to the stratification. Furthermore, 6 of these 66 variants were presented in at least 20 cases, one particularly affecting 31 cases of ovarian failure including both primary ovarian insufficiency and occult ovarian failure. Genes and biological processes affected by these new variants included: MUC6 for cytoprotection of epithelial surfaces; BRPF3, involved in chromatin organization; AP5M1,which could play a role in apoptosis; CRISPLD2, that promotes extracellular matrix assembly; GALNS, participates in degradation of glycosaminoglycans; and MCM5, a component of the complex needed for DNA replication initiation.

Limitations, reasons for caution: To prove the preventive value of this variant profile, an independent clinical validation should be performed. A higher sample size would help in the patient stratification of subtypes of ovarian failure due to the genetic heterogeneity of this disorder; however, we have detected a common variant in 31 cases.

Wider implications of the findings: This study elucidates the underlying genetic cause of idiopathic ovarian failure, identifying new variants by blood sequencing that could become a preventive biomarker and create a new taxonomy for this disorder. Additionally, our results highlighted that studies based only on disease associated genes could overshadow discovery of new variants.

P-495 Correlation between blastocyst morphology, euploidy and implantation in a PGT-A program of 1312 screened blastocysts. Is it worth biopsing a grade C embryo?

C. Escriba[1], M. Alaves[1], M. Benavent[1], C. Miret[1], A. Garcia[1], N. Costa-Borges[2], G. Calderon[2], J. Crespo[1], J. Teruel[1]

[1]Juana Crespo, IVF Laboratory, Valencia, Spain ;
[2]Embryotools, Research and quality, Barcelona, Spain

Study question: What is the reproductive potential of grade C blastocysts? Are we really helping the patients by biopsing them?

Summary answer: Grade C blastocysts have significantly poorer reproductive potential than grade A and B blastocysts regarding aneuploidy and implantation rates but still result in ongoing pregnancies.

What is known already: Several studies show the benefit of trophectoderm biopsy combined with chromosomal screening, a good vitrification program and subsequent transfer of euploid embryos. However, the indications as to when to biopsy poor quality embryos and their clinical contribution to patients is still unclear or controversial.

Some studies suggest that grade C embryos have a higher aneuploidy rate, but euploid ones have a similar implantation rate to better quality embryos. However, this contradicts the establish fact that embryo quality is predictive of implantation.

Study design, size, duration: This is a retrospective observational study performed in a private centre between May 2017 and September 2019. The study includes the data analysis of 1312 blastocysts undergoing PGT-A (mean maternal age, 39.4 ± 3.76 years) obtained from 270 patients following 339 PGS cycles. 232 euploid blastocysts were transferred in 178 frozen embryo transfers. Of this, it was possible to track the implantation outcome of 226 of them.

Participants/materials, setting, methods: PGT-A was offered to patients of advanced maternal age and/or with repeated IVF failures. Patients underwent

ICSI cycles with day 3 assisted hatching. Trophectoderm biopsies were performed on day 5 and/or day 6 embryos, with laser assistance.
Blastocyst morphology was scored in 3 groups: A: excellent (AA, AB, BA), B: good (BB), C: average and poor-quality embryos (BC, CB, CC). (Gardner-Schoolcraft classification)
Relationships between these groups regarding euploidy, implantation and miscarriage rates were assessed.
Main results and the role of chance: The euploidy rate was 38.2 (n=157), 29.7(n=853) and 26.8% (n=302) in the A, B and C blastocyst morphology groups, respectively, showing that in group A there were significantly more euploid embryos than in groups B and C. There are no differences between the mean age of the 3 groups. (38.16, 38.26 and 38.46 years, respectively).

The mosaicism rate does not differ between groups. (14, 15 and 13.6% in A, B and C groups, respectively).

Chi-square tests were used to assess the relationship between blastocyst morphology and euploidy rates and between blastocyst morphology and implantation/miscarriage rates of euploid blastocysts.

The implantation rate of euploid blastocysts was 80 (n=45),61.15 (n=139) and 35% (n=42) in the A, B and C blastocyst morphology groups, respectively, showing high significant differences among the three groups.

Focusing only on poor-quality (CC) blastocysts within the grade C embryos population we observe that the implantation rate drops to 25% (n=24) from the 35% of overall implantation rate of the group (BC, CB, CC), highlighting the importance of embryo quality as a predictor of the implantation potential even if euploid.

Miscarriage rates were inversely correlated to quality (8 (n=36), 13 (n=85) and 26% (n=15)) but did not achieve statistical significance.
Limitations, reasons for caution: The study is limited by its retrospective nature and the low number of grade C blastocysts transferred as they are the last option for transfer. Additionally, it is common to transfer more than one grade C embryo to increase the chances of pregnancy, losing implantation track of some of them.
Wider implications of the findings: It is uncontested that grade C embryos have a lower reproductive potential, but we managed to quantify this potential, providing clinicians with useful information to manage the cycle and inform patients accordingly.
Trial registration number: Not applicable

P-496 The Structural Rearrangement-specific Characteristics Have Limited Effect on Ploidy Status in Young Couples Undergoing Preimplantation Genetic Testing for Structural Rearrangements (PGT-SR) by aCGH/NGS

M. Gultomruk[1], F.K. Boynukalin[2], C. Rubio[3], L. Rodrigo[3], E. Turgut[2], Z. Yarkiner[4], S. Ecemis[5], G. Karlikaya[2], N. Findikli[1], M. Bahceci[2]

[1]Bahceci Fulya IVF Centre, IVF Laboratory, Istanbul, Turkey ;
[2]Bahceci Fulya IVF Centre, Infertility Clinic, Istanbul, Turkey ;
[3]Ignomix S.L, Reproductive Genetics, Valencia, Spain ;
[4]Cyprus Science University, Biostatistics, Kyrenia, Cyprus ;
[5]Bahceci Ankara IVF Centre, Infertility Clinic, Ankara, Turkey

Study question: What are the possible effects of carrier and rearrangement-specific characteristics on the ploidy status of embryos and presence of interchromosomal effect(ICE) in cases undergoing PGT-SR?
Summary answer: Euploidy and ICE rates are similar in Robertsonian and reciprocal translocations. Euploidy rates are independent from carrier and structural rearrangement-specific characteristics, except female age.
What is known already: Structural chromosome rearrangements such as reciprocal translocations (RecT), Robertsonian translocations (RobT) and inversions are associated with increased risk of fertility problems, recurrent miscarriages and progeny congenital abnormalities due to the production of unbalanced gametes during meiosis. It has long been suggested that chromosomes with structural rearrangements can also impair the segregation of other chromosomes which is known as ICE. ICE has previously been evaluated in several studies, but the results are conflicting. The limited number of chromosomes analyzed in fluorescence in situ hybridization(FISH) technique and blastomere biopsy could be the main drawbacks of most of the published studies evaluating ICE.
Study design, size, duration: This retrospective study includes 95 RecT (124 cycles) and 36 RobT (49 cycles) carriers undergoing PGT-SR between March 2016-July 2019. Array Comparative Genomic Hybridization (aCGH) or Next Generation Sequencing (NGS) were the techniques used coupled with trophectoderm biopsy (TB). Only cases with female age under 37 were included. A total of 532 blastocyst embryos (female RecT;200, male RecT;176, female RobT;78 and male RobT;78) were evaluated.
Participants/materials, setting, methods: One hundred and seventy-three PGT-SR cycles with 532 blastocyst-stage embryos were evaluated according to the gender of the carrier partner, the type of rearrangement, chromosomes involved in the translocations as well as the position of breakpoints on the incidence of balanced/unbalanced embryos and ICE. Multi-level generalized linear mixed model was used to for statistical comparisons of the probability of achieving a euploid embryo.
Main results and the role of chance: The median female and male ages, retrieved oocytes, matured oocytes, number of fertilized oocytes and number of biopsied embryos were similar among the female RecT and RobT, and male RecT and RobT carriers. The euploidy rate was also similar in RobT compared with RecT carriers [57/156(36.5%) vs 112/376(29.8%), p=0.127]. Pure ICE (aneuploid balanced) rate was significantly higher in RobT [48/156(30.8%) vs 53/376(14.1%), p<0.001]. In contrast, combined ICE (aneuploid unbalanced) was significantly higher in RecT [72/376(19.1%) vs 16/156(10.3%), p=0.011]. No significant differences were observed in the total percentage of pure ICE plus combined ICE between RobT and RecT [64/156(41%) vs 125/376(33.2%), p=0.088]. A gender-based subgroup analysis also shown no differences in euploidy rate between male RecT and female RecT carriers [58/176(33%) vs 54/200(27%), p=0.207] and male RobT and female RobT carriers [28/78(35.9%) vs 29/78(37.2%), p=0.86]. No significant differences were observed in euploidy rates, pure ICE and combined ICE according to the length of the translocated fragment, the chromosome group, and the position of the breakpoints in RecT cases. Multi-level generalized linear mixed model using binomial distribution revealed that and female age was the factor related to the incidence of euploid embryo.
Limitations, reasons for caution: The size number, the retrospective nature of the study and the absence of age-matched controls are the main limitations.
Wider implications of the findings: Limited studies evaluated PGT-SR based on TB and 24 chromosomes analysis. Reported studies included limited embryo yield; female age, which caused bias, is not restricted. Our data provide a deeper insight about the effect of the translocation type, carrier-gender, chromosomes involved in rearrangement and position of breakpoints on PGT-SR results.
Trial registration number: None

P-497 Genetic and Clinical Outcomes of Preimplantation Genetic Testing for Aneuploidy (PGT-A) by Using Next Generation Sequencing (NGS) in Young Couples With Idiopathic Recurrent Miscarriage

F.K. Boynukalin[1], M. Gultomruk[2], E. Turgut[3], S. Ecemis[4], Z. Yarkiner[5], R. Abali[3], G. Karlikaya[3], N. Findikli[6], M. Bahceci[7]

Study question: Are clinical outcomes of preimplantation genetic test for aneuploidy(PGT-A) satisfactory in idiopathic recurrent miscarriage(iRM) and is there a characteristic distribution for aneuploidy screening data?
Summary answer: Although ~50% live-birth per embryo transfer(ET) is acquired, high miscarriage rate(MR) is observed in iRM with PGT-A. Aneuploidy type differs compared to product of conception.

What is known already: Aneuploidy account for 42% of miscarriages in RM. The theoretical goal of PGT-A was to identify and transfer euploid embryos and decrease the rate of miscarriage. There is paucity of data regarding the role of PGT-A in RM. Although, several retrospective analysis performed on RM patients demonstrated a trend toward decreased MR and increased live birth rate(LBR), such results are usually blurred and biased by the presence of an additive aneuploidy risk as advanced maternal age. In addition, these studies used chromosomes analyzed in fluorescence in situ hybridization(FISH) technique and blastomer biopsy which are the main drawback of the studies.

Study design, size, duration: This is a retrospective single center study to analyze the PGT-A results, using trophectoderm biopsy and NGS, of iRM cases in which female age is <35. Data of 133 patients undergoing PGT-A with their 423 blastocyst embryos between February 2016-January 2019 were evaluated. Patients were sub-grouped according to the number of previous miscarriages as; 2, 3, and >3. The effect of patient and embryo characteristics on ploidy status, LBR and MR were assesed.

Participants/materials, setting, methods: Multi-level generalized linear mixed model was used to analyze the effect of previous live birth, previous number of miscarriages, body mass index, female age, male age and cycle characteristics on probability of achieving a euploid embryo. Binary Logistic Regression was used to analyze affect of factors on abortion compared to live birth. The distribution of monosomies, trisomies and partial aneuploidies affecting each chromosome were detected in embryo yield.

Main results and the role of chance: The overall incidence of euploid embryo was found to be 62.4%(264/423). The distribution of aneuploidy type was as; monosomy 27%(43/159), trisomy 22%(35/159), segmental 17%(27/159), double aneuploidy 15.7%(25/159), complex aneuploidy 11.9%(19/159) and chaotic 6.3%(10/159). The most frequently involved chromosomes in aneuploidies were 16(14%), 21(10.1%) and 22(9.4%). The euploidy rate of embryos was not statistically different between 2, 3 and >3 number of miscarriages (64.7%(124/207), 59.4%(82/138), 61.5%(48/78); respectively, p=0.598). Multi-level generalized linear mixed model revealed that female age was the only significant factor that effects the probability of euploidy (OR:0.87, 95%CI:0.78-0.98, p=0.009). Clinical pregnancy rate (CPR), LBR and MR for patients per ET was 64.3%(83/129), 48.8%(63/129) and 24.1%(20/83) respectively. Although there is a trend toward increased MR with increasing number of previous miscarriage, CPR, LBR and MR were not significantly different in subgroups regarding 2, 3, >3 (CPR: 62.3%(43/69), 75.7%(28/37), 52.2%(12/23), p=0.16; LBR: 52.2%(36/69), 51.4%(19/37), 34.8%(8/23), p=0.33; MR: 16.3%(7/43), 32.1%(9/28), 33.3%(4/12), p=0.23 respectively). MR is higher than reported studies for infertile patients in the PGT-A and lower than expected MR for RM patients with natural conception. Binary logistic regression analysis showed that BMI (p=0.004, OR:1.22, 95%CI[1.06-1.4]), embryo quality (poor quality, p=0.082, OR:4.6, 95%CI[1.2-17.1]) were significantly correlated with miscarriage.

Limitations, reasons for caution: The retrospective nature of the study is the main limitation. In addition, the study did not contain a control group.

Wider implications of the findings: Until now, there is paucity of data to recommend PGT-A as part of routine use for RM. However the data are compelling that this technology can enhance outcome by reducing the risk of clinical miscarriages and ongoing aneuploidy pregnancies. Well-designed studies is needed to analyze efficacy and safety of treatment.

Trial registration number: not applicable

P-498 Relationship between both euploidy and thawing survival rates and embryo quality, day of biopsy or hatching status in Preimplantation Genetic Testing cycles

M. Florensa Bargalló[1], A. Cladellas Artola[1], M. Bellés Fernandez[1], M. Jimenez Blasco[1], J. Herreros Cuesta[1], H. Huete Ferriz[1], N. Garrido Puchalt[2], M. Esbert Algam[1]

[1]IVI Barcelona, IVF laboratory, Barcelona, Spain ;
[2]IVI Foundation, Research administration, Valencia, Spain

Study question: In blastocyst biopsy cycles, is there any association between embryo quality, biopsy day and embryo hatching status and both embryo ploidy or post-thawing survival rates?

Summary answer: Good embryo quality is related to euploidy while day-6 biopsied embryos and hatched blastocysts have fewer chances to survive after freezing.

What is known already: In Preimplantation Genetic Testing (PGT) cycles, blastocyst formation has long been related to euploidy and some authors have detected differences in the ploidy depending on the embryo quality or whether the biopsy has been performed on day-5, day-6, or day-7 of development. However, very little has been published about differences in the survival rate related to the quality of the Inner Cell Mass (ICM) and the trophectoderm (TE), the day of biopsy or the hatching status of the embryo.

Study design, size, duration: Retrospective study including 2538 biopsied blastocysts from 856 PGT cycles performed in the same center between February 2018 and October 2019. Biopsied embryos were divided according to ICM and TE quality Gardner's evaluation (Best AA; Good AB, BA, BB; Poor AC, CA, BC, CB, CC) and the day of biopsy (day-5 or day-6). Completely hatched blastocysts (HB) were analyzed separately. The independent relationship between each group and both euploidy and survival rate was assessed.

Participants/materials, setting, methods: For each cycle, serial biopsies were performed depending on the herniation status of each embryo on day-5 or on day-6 of development. TE biopsy was immediately followed by vitrification of all biopsied embryos. Comprehensive chromosome screening PGT was performed using high resolution next generation sequencing (NGS) methodology. Embryos were thawed and replaced in case of both normalcy and survival evidence following an endometrial preparation cycle. Statistical report was performed under R version 3.6.1. (2019-07-05).

Main results and the role of chance: A total of 2534 embryos resulted informative after genetic analysis (99.84%). Embryo ploidy showed a relationship with embryo quality as significant differences were found among the percentage of euploid embryos of the three quality groups (Best 61.56% n=294; Good 44.52% n= 1642; Poor 31.09% n= 595) (p<0.001). Euploidy did not correlate with the biopsy day (hence, the day of herniation) independently of the embryo quality or with the hatching status of the embryo. Thus, no differences were found between the euploidy rate of day-5 (44.15%; n=1838) and day-6 (40.72%; n=679) (odds ratio [OR]=0.87; p=0.1191) or between the chromosomal status of the hatched (47.19%; n=310) versus non-hatched embryos (42.79%; n=2228) (OR 0.84; p=0.1375). Regarding survival rate, results showed no relationship with embryo quality even if a trend was detected against Poor embryo quality group compared to Best (OR=0.38; p=0.1670) and Good (OR=0.36; p=0.0779). On the other hand, non-hatched day-6 biopsied embryos had lower survival rates (82.19%) than non-hatched day-5 embryos (91.46%) (OR=0.12; p=0.0111) independently of the embryo quality. Concerning the hatching status of the embryo, HB had fewer chances to survive (69.01%) than non-hatched blastocysts (91.27%) (OR=4.69; p<0.001).

Limitations, reasons for caution: This study is limited by its retrospective nature. Even if embryologists do pass routine evaluation controls, qualitative blastocyst morphology grading is always confined by its subjectivity.

Wider implications of the findings: Knowing that embryo quality correlates to euploidy can help improving the counselling to PGT and non-PGT patients. Furthermore, finding that day-6 non-hatched blastocysts and HB have fewer chances to survive can lead to a more continuous evaluation of the embryos on day-5 in case of blastocyst biopsy.

Trial registration number: not applicable

P-499 Polar body analysis in preimplantation genetic testing for monogenic diseases (PGT-M) – a genome wide approach for haplotype phasing and assessment of ploidy

P. Forsblom[1], J. Pricelius[1], M. Stecher[1], C. Bayerl[1], D. Gutknecht[2], B. Poost[3], Y. Charron[4], C. Meyer[5], A. Jantke[4], D. Noss[3], M. Bals-Pratsch[2], C. Nevinny-Stickel-Hinzpeter[1]

[1]SYNLAB Human Genetics Munich, Preimplantation diagnostics and chromosomal microarrays, Munich, Germany ;
[2]Profertilita Centre for Reproductive Medicine, IVF clinic, Regensburg, Germany ;
[3]Centre for Reproductive Medicine, IVF clinic, Munich, Germany ;

[4]Centre for Assisted Fertility Treatment and Fertility Preservation, IVF clinic, Berlin, Germany ;
[5]Cryos International, Denmark ApS, Aarhus, Denmark

Study question: Can single nucleotide polymorphism (SNP) arrays be successfully utilized on polar bodies for simultaneous PGT-M and assessment of the chromosomal status of the oocyte?
Summary answer: Genome-wide SNP array provide a nearly universal tool for PGT-M on polar bodies. The oocyte ploidy can be assessed in the same analytical procedure.
What is known already: Polar bodies can be sourced as an alternative sample material for PGT-M when the analysis of blastomeres or trophectoderm cells is not possible due to ethical, medical, religious or legal reasons. Traditionally, the analysis has been based on short tandem repeats (STRs) and linkage analysis which is time consuming and costly as the assay has to be developed for each family separately. As only the disease locus is assessed in the STR-based linkage analysis the chromosomal status of the oocyte remains unclear. Thus, there is room for improvement in the current methodology.
Study design, size, duration: Retrospective study in a setting of a commercial diagnostic laboratory. The phenotypes segregating in the families were inherited as autosomal dominant (inherited breast and ovarian cancer, spinocerebellar ataxia type 3), autosomal recessive (puryvatkinase deficiency) and X chromosomal (ornithine transcarbamylase deficiency, Renpenning syndrome) traits. Altogether five patients were included in the study. The work was conducted between February 2018 and December 2019.
Participants/materials, setting, methods: Sequentially biopsied polar bodies from oocytes fertilized with ICSI were subjected to whole genome amplification (Repli-g Single Cell Kit; Qiagen). Genome-wide genotyping of the amplified samples as well as DNA samples of the mother and at least one reference individual was carried out (Human KaryomaP-12 SNP array; Vitrolife). A direct analysis of the disease-causing variant was included in the assay when applicable. BlueFuseMulti software (Illumina) with modified settings was utilized for the data analysis.
Main results and the role of chance: Here we report the successful use of genome-wide genotyping on polar bodies allowing the simultaneous assessment of the maternally inherited disease and the oocyte ploidy. Polar body sets of 19 zygotes were analysed: eleven zygotes were non-affected, seven affected and one couldn't be interpreted because the second polar body delivered no data. The genome-wide analysis showed aneuploidy in four of the non-affected zygotes. Three patients had one zygote suitable for culture and transfer whereas two patients had two suitable zygotes. One double-embryo transfer and two single embryo transfers ensued resulting in one clinical pregnancy and birth of a healthy baby. Two non-affected zygotes didn't survive warming. One patient with one suitable zygote is awaiting for warming and transfer.

The set-backs in polar body analysis are considerable. When the disease is inherited in autosomal recessive or X-chromosomal manner the sole use of polar body analysis results in wasting of a significant number of zygotes as paternally inherited alleles and the sex of the embryo cannot be determined. In comparison to trophectoderm cells the analysis of polar bodies inherently contains a higher fall out rate, although in this patient series only two polar bodies failed the amplification or analysis.
Limitations, reasons for caution: This is a retrospective study with a small sample size. Thus, further studies are needed to establish the clinical and diagnostic utility of the procedure. Only maternally inherited diseases can be analysed and both polar bodies are needed for reliable diagnostics.
Wider implications of the findings: In situations where PGT-M on embryonal cells isn't allowed or desired polar body analysis is a worthy alternative. In these cases SNP arrays allow the testing of a wide range of genetic diseases with the simultaneous detection of oocyte ploidy, particularly of interest for patients of advanced maternal age.
Trial registration number: Not applicable

P-500 Novel compound heterozygous mutations in WEE2 gene is associated with fertilization failure: a case report about an infertile woman

Y. Tian[1], B. Xiaohong[2]

[1]Tianjin Medical University General Hospital, Department of Gynecology and Obstetrics-, Tianjin, China ;
[2]Tianjin Medical University General Hospital, Department of Gynecology and Obstetrics, Tianjin, China

Study question: To identify the genetic cause of repeated fertilization failure even after ICSI combined with artificial oocyte activation (ICSI-AOA) in a non-consanguineous family.
Summary answer: With whole-exome sequencing, a novel compound heterozygous mutation in *WEE2* gene was identified in an infertile female who experienced with fertilization failure after ICSI-AOA
What is known already: The genetic factors play an important role in oocyte activation defect and likely result in repeated human fertilization failure even after ICSI-AOA. In mouse oocyte at metaphase II stage, Wee2 inhibited phosphorylation of Cdc2, which was required for metaphase II exit. Down regulation of Wee2 during egg activation leads to failure of pronucleus formation. Recently, mutations in *WEE2* were identified to result in failure of pronuclei formation and human fertilization in infertile women.
Study design, size, duration: We have characterized a patient with 2-year history of primary unexplained infertility belonging to a non-consanguineous family from China. During 3 assisted reproduction attempts (IVF+ rescue ICSI, ICSI and ICSI-AOA), the woman presented a repeated fertilization failure for MII oocyte retrieval after controlled ovarian hyperstimulation. We performed whole-exome sequencing and sanger sequencing in the patient and her family members.
Participants/materials, setting, methods: Genomic DNA samples of the patient and her family's members were extracted from peripheral blood. Whole-exome capture and sequencing were performed following the standard protocols provided by BGI Genomics (BGI-Shenzhen). The sequencing depth of WES was 100× . The pathogenicity of variants was assessed by four software: SIFT, PolyPhen2, Mutation Taster and Human Splicing Finder. The structure prediction of wide type and mutant type WEE2 were performed by PyMol software.
Main results and the role of chance: Three ART cycles were conducted for this couple and even ICSI-AOA did not rescue fertilization failure phenotype. Aneuploidy or pathogenic microdeletion/microduplication (>100Kb) were not found in the couple. We identified a novel compound heterozygous mutation c.1535+3A>G and c.946C>T (p. Leu316Phe) in the *WEE2* gene in female proband who experienced fertilization failure. The allele frequencies of variation c.1535+3A>G and c.946C>T were not found in the 1000genome database or ExAC database. Trios analysis revealed that the detected variations follow an autosomal recessive pattern. Variation c.1535+3A>G in *WEE2* was predicted to break WT donor site and probably affects splicing. With SIFT, PolyPhen-2 and Mutation Taster software, it is predicted that the missense mutation c.946C>T (p. Leu316Phe) of *WEE2* is pathogenic. Prediction with PyMOL software indicated that the mutation could change the structure of WEE2 protein.
Limitations, reasons for caution: The functional analysis of oocytes is not performed yet to detect the local expression of this variant. A causal relationship between the mutation and the fertilization failure need to be established.
Wider implications of the findings: This case report expanded the spectrum of *WEE2* gene mutations responsible for human fertilization failure and provided genetic evidence for fertilization failure.
Trial registration number: None

P-501 Model based on maternal age to determine the optimal number of blastocysts required to retrieve at least one euploid embryo

M. Ferrández Rives[1], M. Enciso[1], L. Ortega[2], Y. Galiana[2], B. Rodriguez-Estrada[1], I. Jurado[1], M. Berruezo[1], A.B. Climent[3], J. Sarasa[1], J. Aizpurua[4]

[1]iGLS, Genetic Laboratory, Alicante, Spain ;
[2]IVF Spain, Embryology department, Alicante, Spain ;
[3]IVF Spain, Statistics department, Alicante, Spain ;
[4]IVF Spain, Gynecology, Alicante, Spain

Study question: Is it possible to anticipate the number of blastocysts and/or cycles needed to retrieve at least one euploid embryo based on maternal age?

Summary answer: The probability of finding at least one euploid embryo can be estimated based on age and the number of blastocysts available.

What is known already: Aneuploidy in human preimplantation embryos plays an important role in assisted reproduction treatments, being one of the main reasons for implantation failures and miscarriages. The impact of female age on euploidy rate is well-known, as with advancing maternal age, the risk of chromosomal abnormalities in embryos increases. Although patients undergo preimplantation genetic testing because of the clinical significance of aneuploidy, unfortunately the retrieval of euploid embryos is not guaranteed and limited information about the probability of obtaining euploid embryos is available. The estimation of the probability of euploid embryo retrieval would enable effective treatment plans and accurate counselling of patients.

Study design, size, duration: This is a retrospective study including data from a total of 1048 cycles (476 own-oocyte cycles and 572 donor-oocyte cycles) undergoing PGT-A (Preimplantation Genetic Testing for Aneuploidy) at blastocyst stage between January 2017 and January 2020. A total of 3940 embryos were studied. Relationship between maternal age, total number of blastocysts biopsied and embryo euploidy was assessed.

Participants/materials, setting, methods: Patients referred for PGT-A analysis for a variety of reasons including advanced maternal age, recurrent implantation failure, recurrent miscarriage and male factor infertility (aged 24-54 years) were included in the study. All embryos were cultured to blastocyst stage, biopsied and PGT-A-tested for all 24 chromosomes using Next Generation Sequencing (Illumina, VeriSeq protocol). Outcome measures were: number of blastocysts (BT), euploidy rate (ER) and the probability of finding at least one euploid embryo for transfer (POE).

Main results and the role of chance: Our results show a negative influence of female age on euploidy rate and the number of blastocysts per cycle ($p<0.001$). Moreover, the probability of finding at least one transferable euploid embryo (POE) is strongly associated to age and the number of blastocysts available. POE is highest in egg-donation cycles (96%) and it reached 100% in cohorts of >3 blastocysts. Nevertheless, POE decreases with age (approximated by the following quadratic function: $y = -0.003x^2 + 0.1785x - 1.6825$, $R^2=0.91$) and this decline is very sharp after 40 years old.

In women <35 years old, the mean number of blastocysts per cycle (4.3) guarantees one euploid embryo in 96% of cases. Meanwhile, women aged 35-40 and over 40 produce 3 and 2.2 blastocysts per cycle, respectively. In these groups, the availability of at least one euploid embryo is guaranteed in 65% and 28% of cycles, respectively. POE decline with age can be mitigated by the banking of embryos from various cycles. This embryo banking strategy significantly increases the likelihood of euploid embryo transfer in advanced maternal age groups. The presence of one euploid embryo in the group of patients over 40 studied can be guaranteed in cohorts of >7 blastocysts (~3-4 cycles).

Limitations, reasons for caution: This model can serve as a valuable tool to improve assisted reproduction treatment results, however, other variables such as the number of oocytes retrieved, sperm quality parameters or AMH levels may also need to be considered as potential factors with influence in the model.

Wider implications of the findings: Our results confirm the well-known negative effect of female age on embryo euploidy. We have identified a model based on maternal age able to predict the likelihood of euploid embryo transfer. This model can help doctors to plan their treatments and counsel patients about their options of success.

Study question: What is the impact on clinical outcome of putative low-grade mosaicism diagnosis?

Summary answer: Blastocysts diagnosed with putative low-grade mosaicism produce comparable clinical outcomes to uniform euploid blastocysts in terms of sustained implantation and miscarriage rates.

What is known already: Highly sensitive NGS-based technologies allow precise discrimination of subtle chromosomal copy number variations (CNVs) in multicellular biopsies.These alterations are often interpreted as evidence of an embryo's chromosomal mosaicism. Because of the unknown clinical impact of mosaicism, uniformly euploid embryos are prioritized for transfer, whilst putative mosaic ones are given low priority or even discarded. Presently, transfer outcomes of putative mosaic embryos have only been compared retrospectively in selected subpopulations of patients that failed to get pregnant with previous euploid embryos. This prospective non-selection study was designed to avoid/minimize confounding factors and provide robust evidence on putative mosaicism clinical predictive values.

Study design, size, duration: This is an interim analysis of a multicenter prospective non-selection study of consecutive cases performed at five IVF clinics between Sept2018 and July2019. Trophectoderm biopsies showing intermediate chromosome CNVs consistent with low mosaicism (20-50%) were blindly reported as euploid. The presence of low-grade alterations did not influence the embryo selection process, thus allowing an unbiased comparison of clinical outcomes between fully euploid and putative mosaic embryos. Ethical committee approvals were obtained at each site.

Participants/materials, setting, methods: Consecutive patients (female age 35-44) undergoing homologous IVF cycles with blastocyst-stage PGT-A and single frozen euploid embryo transfer (SEET) were enrolled. Main exclusion condition was blastocyst of the worst morphological class. Sustained implantation rate (>20weeks) was the primary outcome measure. A sample size of 878 SEET was planned (beta=0.80; alfa=0.05) assuming 47% sustained implantation rate in the control group and 12% variation. This sample-size is also powered to detect meaningful differences in the miscarriage rate.

Main results and the role of chance: This study evaluates transfer outcomes of 368 SEET: 197 from uniform euploid embryo group (group A), 94 from putative very-low mosaic (20-30%, group B) and 77 from the putative low mosaic group (30-50%; group C). Positive pregnancy test rate was 58.4% (95%CI=51.2%-65.3%), 60.6% (95%CI=50.0%-70.6%) and 58.4% (95%CI=46.6%-69.6%) for group A, B and C, respectively (P=NS). Biochemical pregnancy loss rate was 9.6% (95%CI=4.9%-16.5%),10.5% (95%CI=4.0%-21.5%) and 13.3% (95%CI=5.0%-26.8%) for A, B and C respectively (P=NS). Miscarriage rate was also not significantly different across groups: 12.5% (95%CI=6.8%-20.4%), 13.7% (95%CI=5.7%-26.3%) and 12.8% (95%CI=4.3%-27.4%) for A, B and C, respectively (P=NS). Sustained implantation rate was also similar: 46.2% (95%CI=39.1%-53.4%), 48,8% (95%CI=36.4%-57.4%) and 44.2% (95%CI=32.8%-55.9%), for A, B and C respectively (P=NS). Multivariate logistic regression analysis including main and potentially relevant patient and cycle factors showed slower embryo development (embryo developed to blastocysts on day 7) as the only covariate associated with sustained implantation outcome (R=0.19; 95%CI=0.05-0.7). In the multivariate analysis, after adjusting for confounding factors, the presence of a PGT-A analysis consistent with mosaicism was not significantly associated with either primary or secondary outcome measures (OR=1.001; 95%CI=0.61-1.06). When groups B and C were combined, the lack of association persisted.

Limitations, reasons for caution: Although current interim data are sufficiently powered to exclude clinically relevant differences between study groups, the planned sample size isn't yet fully met. Study's main limitation consists in the lack of cytogenetic analysis follow-up of putative mosaic embryos pregnancies. However, indication for invasive prenatal testing couldn't be justified by evidence.

Wider implications of the findings: This is the largest prospective non-selection study evaluating the outcome of putative mosaic embryo transfers. If confirmed, these results demonstrate that intermediate CNVs consistent with low-grade mosaicism don't provide any clinically useful diagnostic criteria for defining embryonic reproductive competence. Re-assessment of aneuploidy categorization and embryo selection schemes will be required.

Trial registration number: NCT03673592

P-503 Assessing egg utilization efficiency from the outcome of Preimplantation Genetic Testing cycles

W. Wu[1], X. Yang[2]

[1]First Affiliated Hospital of Nanjing Medical University, Reproductive Medical Center, Nanjing, China ;
[2]Nanjing Medical Univesity, First Clinical Medical College, Nanjing, China

Study question: In patients using preimplantation genetic testing (PGT), the average number of eggs needed to obtain 1, 2, and ≥3 euploid/balanced embryos was calculated for populations with different characteristics.
Summary answer: Couples with one or both reciprocal translocation carriers need more eggs to obtain the same number of euploid/balanced embryos,especially those with general balanced translocation carriers.
What is known already: Chromosome rearrangement can significantly affect fertility and increase the risk of miscarriage. Although there are theoretical models for the probability of normal gamete formation among balanced translocation carriers, more clinical data are needed to support the average number of eggs required to obtain the expected number of euploid/balanced embryos during ovarian stimulation process.
Study design, size, duration: From June 2011 to July 2019, 1,659 PGT retrieval cycles were collected.There were 368 cycles in PGT for aneuploidies(PGT-A group), 105 cycles in PGT for monogenetic(PGT-M group) and 1186 cycles in PGT for structural rearrangements which including 829 cycles of general translocation group and 357 cycles of Robertson translocations group.
Participants/materials, setting, methods: All patients were treated with appropriate ovarian stimulation protocol.When the diameter of the dominant follicles reached about 18mm, human chorionic gonadotropin (HCG) was injected and ovum extraction was conducted under the guidance of transvaginal ultrasound 36 hours later.

Embryo testing: blastocyst or blastomere biopsies are performed using array-based comparative genomic hybridization (aCGH) or next-generation sequencing (NGS).
Main results and the role of chance: The average number of eggs needed to obtain1, 2 and ≥3 euploid/balanced embryos in the PGT-A group was 7.65, 10.38, and 12.95, respectively; the average age of the woman was 33.83 ± 4.62, and the average age of the man was 35.40 ± 5.67. The average number of eggs needed to obtain1, 2 and ≥3 euploid/balanced embryos in the PGT-M group was 7.4, 10.77, and 14.33, respectively; the average age of the woman was 31.45 ± 4.04, and the average age of the man was 32.53 ± 4.87. The average number of eggs needed to obtain 1, 2 and ≥3 euploid/balanced embryos in the PGT-SR general translocation group was 11.1, 13.32, and 15.59, respectively; the average age of the woman was 28.97 ± 3.86, and the average age of the man was 30.32 ± 4.95. The average number of eggs needed to obtain 1, 2 and ≥3 euploid/balanced embryos in the Robertson translocations group was 10.01, 12.49, and 15.32, respectively; the average age of the woman was 29.30 ± 4.04, and the average age of the man was 30.84 ± 4.81.
Limitations, reasons for caution: Patients using PGT-M are first tested for a single gene of the relevant disease.Aneuploidy screening will not be continued if they carried the pathogenic gene,which causing the average number of eggs needed to obtain euploid/balanced embryos increased.The number of patients included in the PGT-M group was relatively small.
Wider implications of the findings: The study provides clinical data on the expected number of eggs required to obtain euploid/balanced embryos in different patient populations with different characteristics, and provides a reference for clinicians to determine the optimal ovarian stimulation protocol for patients.
Trial registration number: without

P-504 Increased Body Mass Index and Its Impact on Blastocyst Ploidy Status

A. El-Damen[1], I. Elkhatib[1], A. Bayram[1], A. Arnanz[1], A. Abdala[1], N. Nobrega[1], S. Samir[2], L. Melado[3], B. Lawrenz[3], N. De Munck[1], H. Fatemi[3]

[1]IVI Middle East Fertility Clinic, IVF Laboratory, Abu Dhabi, United Arab Emirates ;
[2]IVI Middle East Fertility Clinic, Administration, Abu Dhabi, United Arab Emirates ;
[3]IVI Middle East Fertility Clinic, Clinical Department, Abu Dhabi, United Arab Emirates

Study question: Does increased Body Mass Index (BMI) affect blastocyst ploidy and cycle outcomes in IVF/ICSI patients with Preimplantation Genetic Testing for Aneuploidy (PGT-A)?
Summary answer: Increased BMI has no correlation with blastocyst ploidy; but decreases the number of mature oocytes per large follicles and per total doses of stimulation drugs.
What is known already: World Health Organization (WHO) identified obesity as a global epidemic as its prevalence has tripled since 1975. It is a major risk factor for many diseases including infertility, with a prevalence of 71% of the female Middle Eastern population being affected. Obesity has a detrimental effect on female fertility by causing hypothalamic-pituitary dysfunction which may lead to anovulation and impaired follicular development. Increased BMI has a negative prognosis factor for cycle cancellation, the number of oocytes collected, the number of embryos available, clinical pregnancy rate and abortion rate which may be due to both impaired oocyte quality and uterine function.
Study design, size, duration: A retrospective cohort study including 1115 fresh IVF/ICSI cycles from 807 patient was conducted in a single private fertility clinic in Abu Dhabi, UAE between March 2017 and December 2018. According to WHO, patients were stratified as: underweight, normal, pre-obese, obese I, obese II and obese III when they have a BMI of: <18.50, 18.50–24.99, 25.00–29.99, 30.00–34.99, 35.00-39.9 and ≥40 kg/m^2, respectively. ANOVA test was used to compare means of different parameters.
Participants/materials, setting, methods: Females were ≥18 years old who underwent fresh IVF/ICSI treatment with PGT-A. Routine work included ovarian stimulation using different types of protocols. Fresh oocytes were inseminated either by IVF or ICSI and the resulted fertilized oocytes were cultured till blastocysts were biopsied on day 5, 6 and 7 of development and tested for PGT-A using NGS. blastocysts were vitrified and euploid ones were warmed and transferred in a subsequent natural or hormonal replaced cycle.
Main results and the role of chance: We stratified our population regarding BMI into the following groups: Normal, underweight, preobese, obese I, obese II and obese III with the following percentages: 35.8%, 1.8%, 37.9%, 18.8%, 5% and 0.7% (n= 400, 20, 422, 209, 56 and 8) respectively. Our study demonstrated no significant difference between the groups regarding number of stimulation days (p=0.074), oocytes retrieved (p=0.66), mature oocytes (p=0.93), fertilized oocytes (p=0.72), biopsied (p=0.21) and euploid blastocysts (p=0.22). The same non-significant difference was also reported regarding fertilization and euploidy rates (p=0.26 and p=0.19). Interestingly, negative correlations were found between BMI and (i) the number of mature oocytes per follicles >11mm (p= 0.044), (ii) aspirated oocytes per total stimulation doses (p= 0.020) and (iii) mature oocytes per total stimulation doses (p= 0.029). Correcting for BMI as a confounder and applying multivariate regression and Poisson models resulted in a negative correlation between euploidy rate and age and a positive correlation between euploidy rate and the number of mature oocytes (both p<0.001).

Applying a multivariate regression model and correcting for age and number of mature oocytes collected revealed that increased BMI did not have any impact on implantation (51.2% vs 50.8%p=0.079) or clinical pregnancy rates(47.4% vs 46.7%, p= 0.092) respectively.
Limitations, reasons for caution: Our results were based on retrospective data from a single fertility clinic, which does not permit to control for various factors leading to the selection of a stimulation protocol by a physician for each patient.
Wider implications of the findings: Although increased BMI doesn't affect euploidy rate or cycle outcomes of patients undergoing IVF/ICSI with PGT-A, obese patients need to be administered more stimulation doses for them to have the same number of mature oocytes as the normal weight patients, which decreases the cost-effectiveness of their treatment cycles.
Trial registration number: NA

P-505 BCORL1, USP9x and POF1B copy number variation in premature ovarian failure: A Preliminary study

C. Furtado[1], F. Gennaro[2], G. Kogure[3], R. Ferriani[4], R. Reis[3]

[1]Federal University of Ceara, Drug Research and Development Center-Postgraduate Program in Medical and Surgical Sciences, Fortaleza, Brazil ;
[2]Ribeirao Preto Medical School- University of Sao Paulo, Obstetrics and Gynaecology, Ribeirão Preto, Brazil ;
[3]Ribeirao Preto Medical School- University of Sao Paulo, Obstetrics and Gynaecology, Ribeirao Preto, Brazil ;

[4]Ribeirao Preto Medical School- University of Sao Paulo-, Obstetrics and Gynaecology, Ribeirao Preto, Brazil

Study question: Copy number variation (CNV) in X-chromosome linked genes are related to idiopathic premature ovarian insufficiency (POI)?
Summary answer: POI presented alteration in the number of copies for the X-linked genes *USP9X* and *POF1B*.
What is known already: X-linked genes are strongly associated with ovarian function and have several POI candidate genes. Both amplifications and deletions can alter the level of expression of clusters of genes associated with POI, including genes involved in pairing and segregation such as *POF1B* and *USP9X* and in response to apoptosis *BCORL1*. Consequently, those alterations may promote changes in the XCI pattern, such as nonrandom (skewed) X inactivation in female genome and maybe an important feature of POI.
Study design, size, duration: Cross-sectional study, in which 37 non-syndromic POI women were included.
Participants/materials, setting, methods: POI (FSH>40 IU/l) with 46,XX karyotype participated in this study. Age, body mass index (BMI) were analyzed. The CNVs in the *BCORL1*, *USP9X* and *POF1B* was measured by quantitative real time PCR and the reference genes were the *HPRT1* (x-linked) and the *MFN2* (autossomal). A control DNA (male and female) was used in the comparisons. XCI was based in the Human Androgen Receptor (HUMARA) and X-linked retinitis pigmentosa 2 (*RP2*) assays.
Main results and the role of chance: The mean age was 32.10 ± 6.81 and BMI was 25.41 ± 4.64. Most POI women presented number of copies (> 0.75) close to the female control (46, XX) for the *BCORL1* (97.2%), *USP9X* (55.6%) and *POF1B* (58.3%). Reduced number of copies similar to the male control (<0.75) was observed for the *USP9X* (44.4%) and *POF1B* (41.17%). Skewed XCI (≥75%) was observed in 24,32% (n=9) POI. From those POI with copy number alterations only 10% presented skewed XCI.
Limitations, reasons for caution: Limited number of cases of the study group. An increase of sample size is recommended to make the data more robust and confirm the results.
Wider implications of the findings: Alterations in X-linked genes and skewed XCI was observed in POI women, a genetic condition that is frequently observed in ovarian dysfunctions, suggesting a possible role in POI etiology.
Trial registration number: 13305/2012

P-506 Determining copy number variation in SMN1 using a highly multiplexed Next Generation Sequencing panel

A. Harris[1], G. Del Mistro[1], T. Fahland[1], H. Xie[1], J. Bishop[1], J. Veitch[2], V. Mozhayskiy[1]

[1]Thermo Fisher Scientific, Clinical Next Generation Sequencing, Carlsbad- CA, U.S.A. ; [2]Thermo Fisher Scientific, Clinical Next Generation Sequencing, South San Francisco- CA, U.S.A.

Study question: Can a Next Generation Sequencing (NGS) panel be used to accurately assess samples for copy number variation (CNV) in genes that have high homology such as SMN1 and SMN2?
Summary answer: We were able to characterize test samples for functional SMN1 copy number with 97.8% accuracy and SMN2 copy number with 95.6% accuracy (n=91).
What is known already: Loss of SMN1 activity is a cause of spinal muscular atrophy (SMA). SMN1 and SMN2 are highly homologous genes that are difficult to distinguish on NGS platforms due to relatively short read lengths. Typically the copy number determination of these genes is assessed with other technologies such as Multiplexed Ligation Probe Assays (MLPA) and microarray.
Study design, size, duration: We tested 91 gDNA samples from Coriell cell lines with functional SMN1/2 copy number status known from microarray. The samples were tested as part of a characterization of the NGS panel in development. Results needed to meet pre-defined quality control criteria to be included in the assessment.
Participants/materials, setting, methods: Samples were amplified using a two-pool primer panel comprised of approximately 14,000 PCR primer pairs targeting coding sequences and known intronic variants in 420 genes implicated in recessive autosomal and X-linked diseases. The resulting DNA barcoded libraries were sequenced in a multiplex of 16 per Ion 540™ Chip using the Ion S5™ Sequencing System.
Main results and the role of chance: We used an *in silico* baseline derived from amplicon representation from normal samples and a custom CNV calling pipeline to determine both i) the mean copy numbers from amplicons with 100% identity between homologous portions of the genes of interest and ii) the homolog-specific copy numbers for amplicons with distinguishing sequence variants between the primers or sequence variants under the primers which enriched amplification in one member of a gene pair. Using this information and orthogonal microarray results taken as "truth," we were able to obtain SMN1 carrier status with 100% sensitivity (n=4) and 98.9% specificity (n=87). Follow up will be needed from individual labs employing our test to determine reproducibility with their own samples of interest.
For Research Use Only. Not for use in diagnostic procedures.**Limitations, reasons for caution:** We tested our method on a limited set of gDNA samples isolated from cell lines. Factors that could compromise performance for other samples include amplification and sequencing variation not accommodated by our CNV baseline and SNPs falling under primers resulting in decreased amplification efficiency that mimics a copy number loss.
Wider implications of the findings: Our panel design and analysis methods enable the determination of SMN1/2 copy number as part of a much broader NGS assay of hundreds of genes responsible for inherited diseases, enabling the development of more convenient future tools.
Trial registration number: not applicable

P-507 DNA detection in the blastocoelic fluid (BF) from expanded blastocysts generated by conventional IVF cycles: clinical implications

C. Albanese[1], M.C. Magli[1], S. Azzena[1], M. Piiffanelli[1], B. Balicchia[1], C. Tabanelli[1], L. Gianaroli[1]

[1]S.I.S.Me.R., Reproductive Medicine Unit, Bologna, Italy

Study question: Does the presence or absence of DNA in the BF correlate with blastocyst viability?
Summary answer: After whole genome amplification (WGA) of BFs, failure to detect DNA correlates with significantly higher implantation rates when compared to blastocysts with positive DNA amplification.
What is known already: The presence of DNA in the BF could represent a strategy towards a euploid condition through the extrusion of aneuploid cells into the blastocoelic cavity. This event could not occur at a measurable level when the blastocyst is fully or prominently euploid, whereas positive BF DNA amplification could indicate a blastocyst with aneuploid cells trying to correct a defective chromosome condition. Especially in the case of low to moderate level of mosaicism, the capacity of extruding the majority of abnormal cells into the BF would preserve the blastocyst potential of further development after transfer.
Study design, size, duration: This prospective cohort study included 184 conventional IVF cycles performed from January 2016 to October 2019. In 91 cycles (Study-group), the BF was collected from expanded blastocysts before vitrification and stored at -80°C. The control-group included 93 cycles, whose blastocysts were vitrified without blastocentesis. Single blastocysts were transferred by selection according to morphology. BFs were later submitted to WGA by operators blinded to the clinical outcome. WGA results were then related to implantation.
Participants/materials, setting, methods: Maternal age and indications to IVF were comparable between the two groups. The same protocol of vitrification was applied and only cycles with expanded blastocysts of high grade were included in the study. Amplification after WGA was evaluated by loading an aliquot of the amplified product onto a 1.5% agarose gel. A clinical pregnancy rate was defined by the presence of fetal heart-beat. The ongoing pregnancy rate was a pregnancy ongoing after 12 week gestation.
Main results and the role of chance: The clinical outcome was comparable in the study-group and control-group with similar clinical pregnancy rates (51 and 55% respectively) and ongoing pregnancy rates (47 and 47% respectively) suggesting that the procedure of blastocentesis per se had no impact on blastocyst viability. When the study-group was subdivided according to WGA results, we had 55 cases where BF failed to amplify (sub-group with failed BF-WGA) and 36 with positive amplification (sub-group with positive BF-WGA). Maternal age was 36.4±3.2 and 35.5±3.5 years respectively. When looking at the transfer outcome in the two sub-groups, the clinical pregnancy rate was significantly higher in the sub-group with failed BF-WGA (75%) when compared to the

sub-group with positive BF-WGA (25%, P<0.001). The ongoing pregnancy rate showed the same trend and was 69% and 11% respectively (P<0.001).
Limitations, reasons for caution: The study is a prospective cohort study, but not prospectively randomized.
Wider implications of the findings: Failure to detect DNA after BF amplification could represent an additional criterion to select viable embryos for transfer in conventional IVF cycles. If confirmed in a prospective randomized study, this approach would improve the clinical outcome of vitrified blastocysts by using a simple, non-invasive and moderately expensive approach.
Trial registration number: Not applicable

P-508 A pilot study to identify Single Nucleotide Variants (SNVs) as predictors of oocyte/embryo quality in fertile women undergoing Preimplantation Genetic Testing for Monogenic Disorders (PGT-M)

G. Kakourou[1], T. Mamas[1], C. Vrettou[1], E. Tsorva[2], S. Zacharia[2], C. Oraiopoulou[3], E. Chatzi[4], E. Kourkouni[5], G. Kourlaba[5], D. Christopikou[2], M. Mastrominas[2], M. Moysidou[3], A. Chatziparasidou[3], I. Georgiou[4], J. Traeger-Synodinos[1]

[1]National & Kapodistrian University of Athens, Department of Medical Genetics, Athens, Greece ;
[2]Embryogenesis, Assisted Reproduction Unit, Athens, Greece ;
[3]Embryolab SA, IVF Unit, Thessaloniki, Greece ;
[4]Genetics and IVF Unit- Faculty of Medicine- University of Ioannina, Department of Obstetrics and Gynecology, Ioannina, Greece ;
[5]Center for Clinical Epidemiology and Outcomes Research, Cleo, Athens, Greece

Study question: Are SNVs in 26 selected genes potentially involved in preimplantation development, associated with oocyte and embryo quality in fertile women undergoing PGT-M?
Summary answer: SNVs in 10/26 studied genes revealed significant associations with oocyte number, fertilization rate and blastocyst formation in fertile women undergoing PGT-M.
What is known already: Genetic profiling of prospective parents has been one of the approaches for identifying biomarkers of IVF success. Specific genotypes have been associated with IVF failure, gamete/embryo quality etc., with most studies focusing on infertile populations. Recent studies identified SNVs (rs1801133, rs1801131 in *MTHFR*, and rs2305957 on chromosome 4 linked to *INTU, SLC25A31, HSPA4L, PLK4, MFSD8, LARP1B* and *PGRMC2*) associated with embryo quality or chromosomal status in infertile women. Additionally, preimplantation development may be influenced by pathways involved in follicle development, meiosis, mitosis and DNA repair, for which many other genes have been implicated in human and animal studies.
Study design, size, duration: DNA from fertile prospective mothers was genotyped using exonic NGS (Qiaseq™ Targeted Custom Panel, Miseq) for 18 genes (*AIRE-AMH-AURKA-AURKB-AURKC-FSHR-HSPA4L-HUWE1-INTU-KHDC3L-LARP1B-MFSD8-MTHFR-PGRMC2-PLK4-SENP7-SLC25A31-WBP1*) and 9 selected SNVs in a further 8 genes: rs175080(*MLH3*), rs1799963(*F2*), rs6025(*F5*), rs5918(*ITGB3*), rs5985(*F13A1*), rs1805087(*MTR*), rs1801394(*MTRR*), rs28756992(*MLH3*) and rs2305957(*HSPA4L*). The study (September 2017-2019), approved by the University of Athens Bioethics Committee and National Authority of Assisted Reproduction, involved PGT-M cycles performed between 2013-2019. Statistical analysis was performed by the Center for Clinical Epidemiology and Outcomes Research.
Participants/materials, setting, methods: The study was performed at the UoA Laboratory of Medical Genetics, and focused on fertile couples undergoing PGT-M. NGS was performed for 85 women undergoing 107 PGT-M-cycles. The following details were collected: maternal age, stimulation protocol, number of oocytes collected/fertilized, blastocyst formation. Maternal genotypes were analysed in association with number of oocytes collected (No.O), fertilization rate (FR), percentage of blastocysts developed per MII oocyte (BL/MII) and percentage of blastocysts per 2PN embryo (BL/2PN).
Main results and the role of chance: A 20x coverage was achieved in all exons and SNV regions investigated, identifying 121 variants. Using STATA SE, v.13, to test for normality and associations between continuous variables and different genotypes, significant associations (p<0.05) were detected for each of the studied parameters: 1) No.O: lower for minor allele (MA) of rs564533 (*KHDC3L*), higher for TT vs. CC/TT genotype of rs7616677 (*SENP7*) and lower for AA vs. GA/GG genotype of rs939443 (*SENP7*). 2) FR: lower for MAs of rs1059476 and rs2241909 of *AURKB* and higher for MAs of rs61736572 and rs61736575 of *AMH*, higher for MA of rs56043017 of *PLK4*. 3) BL/MII: higher for MA of rs1801133 of *MTHFR*, lower for MAs of rs7616677 and rs939443 of *SENP7* and higher for MA of rs2433031 of *SENP7*. 4) BL/2PN: lower for MA of rs35518193 of *HSPA4L*, higher for MA of rs2433031 of *SENP7*. No significant associations were revealed for rs1801131 and rs2305957. Where comparisons were possible, these findings remained significant independent of age and stimulation protocol. Additional associations were revealed for rs3746964, rs878081, rs1800521 (*AIRE*), rs10407022 (*AMH*) and rs175080 (*MLH3*) when stratifying for age and stimulation protocol.
Limitations, reasons for caution: The main limitations of the study include its retrospective nature, whereby IVF practices have changed considerably over the period of the study (2013-2019). The polymorphisms identified with likely significant impact, require prospective validation in other PGT-M cycles, as well as on embryo samples of variable quality.
Wider implications of the findings: Infertility is a complex condition. Identifying prognostic factors in ART patients is confounded by multiple variables (parental age, stimulation and fertilization protocols, embryo transfer stage/conditions etc.). PGT-M facilitates investigation of a fertile ART population, minimizing many confounding variables, and potentially facilitating the identification of genomic biomarkers predictive of gamete/embryo quality.
Trial registration number: This study was supported by a State Scholarships Foundation (IKY) for post-doctoral research and co-funded by national grants and the European union (ESPA 2014-2020). Trial registration number not applicable

P-509 Applied machine learning based on time-lapse technology and reproductive history data designed for pre-implantation embryo ploidy prediction.

S. Davies[1], D. Christopikou[1], N. Kallioras[2], P. Tsakalis[2], E. Tsorva[1], S. Zaxaria[1], K. Economou[1], R. Najdecki[3], E. Timotheou[3], P. Tatsi[3], T. Chartomatsidou[3], C. Papanikopoulos[1], N. Lagaros[2], M. Mastrominas[1], E. Papanikolaou[3]

[1]c/o Embryogenesis-Private Centre for Reproductive Studies, embryology, Maroussi- Athens, Greece ;

[3]Assisting Nature- Private IVF Unit, Ob/gyn, Thessaloniki, Greece

Study question: To determine whether Artificial Intelligence (AI) algorithms based on time-lapse (TLM) morphokinetic parameters and reproductive history can be used to predict embryo ploidy status.
Summary answer: Cleavage time intervals from 5-6-7-8-9-cell stage to time of morulation, along with maternal age and PGT indication enhances the prediction of blastocyst ploidy.
What is known already: Time-lapse technology allows continuous monitoring of embryo development and has assisted in progression towards automated and objective systems to assess the embryos and improve IVF treatment. Artificial intelligence technology, based on data and pattern exploitation, has been reported as a tool to identify embryo viability and predict IVF outcome. However, studies reporting an association between morphokinetic parameters and embryo ploidy status are controversial and do not support the predictive value of time-lapse analysis for preimplantation genetic testing of embryo ploidy thus far.
Study design, size, duration: Double blind, retrospective longitudinal cohort study. Embryo morphokinetic parameters of 383 blastocysts were collected from 193 patients undergoing preimplantation genetic testing for aneuploidy (PGT-A) and structural rearrangements (PGT-SR) between November 2017 and December 2019 from two independent IVF clinics.
Participants/materials, setting, methods: The morphokinetic parameters of blastocysts, subject to PGT-A/PGT-SR analysis with next generation sequencing (NGS), were used to validate and test for ploidy prediction through a set of machine learning classifier algorithms. Data augmentation and pre-processing methods were applied on the sample to ensure unbiased results and optimal feature selection. Validation and testing were performed through a stratified five-fold split. The efficacy of ploidy prediction was quantified using ROC curves, AUC and confusion matrices.

Main results and the role of chance: After exhaustive feature selection via methods like Pearson Correlation and Decision Tree algorithms the following morphokinetic and reproductive history features were shown to contribute the most to predicting euploidy: tPNf, t4, t7-tPNf, tM-t5, tM-t6, tM-t7, tM-t8, tM-t9, maternal age and indication of PGT (PGTSR vs PGTA for recurrent miscarriages, advanced maternal age or severe male factor). A model was then created based on those parameters which showed a significant AUC=0.70 from the ROC curve analysis. The mean accuracy throughout the 5 validation folds was measured at 0.68 and the mean precision at 0.73. Out of 383 samples (150 euploid/ 233 aneuploid) the classification results, obtained from confusion matrices were: 157 true positives (TP), 76 false positives (FP), 96 true negatives (TN), 54 false negatives (FN). The features used can be sorted according to their correlation strength (higher to lower) as follows: PGT indication, Maternal Age, tM-t9, tM-t7, tM-t8, tM-t6, tM-t5, t7-tPNf, tPNf and t4. It is observed that lower values of maternal age, tM-t9, tM-t7, tM-t8, tM-t6, tM-t5 and tPNf correspond to higher probability for euploidy while the opposite stands for t7-tPNf and t4.
Limitations, reasons for caution: The main limitation of the current study is the small sample size. Machine learning algorithms provide better results and generalize efficiently when sufficient data is provided.
Wider implications of the findings: Machine learning model depicts specific cleavage time intervals, maternal age and PGT indication as significant predictors of embryo ploidy. This model cannot substitute pre-implantation genetic testing for aneuploidy but can potentially be useful during the prioritization of embryos for transfer in cases where PGTA/PGTSR is not performed.
Trial registration number: non applicable

P-510 Detailed investigation into the mosaic embryo karyotypes: multicenter data from 2280 trophectoderm biopsies obtained during preimplantation genetic testing cycles in IVF

F. Fiorentino[1], F. Spinella[1], A. Biricik[1], A. Victor[2], F. Barnes[2], C. Zouves[2], A. Ruberti[3], E. Cursio[3], M. Sofia[4], L. Corti[4], V. Bianchi[5], P. Viganò[4], M.G. Minasi[3], G. Ermanno[3], M. Viotti[2]

[5]Future for Family, Future for Family, Bologna, Italy

Study question: Which is the prevalent type of mosaicism affecting human mosaic embryos?
Summary answer: Single whole chromosome aneuploidy is the most prevalent form of mosaicism in preimplantation embryos with a majority involving gains.
What is known already: Chromosomal mosaic embryos are characterized by the presence of chromosomally different cell lines within the same embryo. Mosaicism may involve whole-chromosome, segmental (or partial), complex or a combination of such aneuploidies. We previously demonstrated that the reproductive potential of mosaic embryos is affected by the complexity of and the number of aneuploid cells present in trophectoderm (TE) biopsy. We also observed that the mosaicism involved specific chromosomes and that single (sub-chromosomal or whole-chromosome) aneuploidy was the prevalent type of chromosomal mosaicism. However, our study involved a limited number of mosaic embryos and data available were insufficient to test this hypothesis.
Study design, size, duration: This is a large-scale multicenter study on mosaic embryos to examine the patterns and prevalence of chromosome specific mosaicism in TE samples. The cohort consisted of 2280 consecutive mosaic embryos collected between May2016-May2019. All embryos were cultured to blastocyst stage; TE biopsy was performed on Day-5 or Day6/7of development. TE biopsies underwent comprehensive chromosome screening utilizing validated next generation sequencing (NGS). TE biopsies were classified as mosaic if they had 20%-80% abnormal cells.
Participants/materials, setting, methods: Mosaic embryos composed of mosaic chromosomes only were analyzed. Mosaicism was tabulated per chromosome, and chromosomal constitution and incidence of different type of mosaic embryos were also analyzed. For statistical analysis mosaic embryos were divided in three groups: whole-chromosome, segmental and mixed mosaicism. In addition, whole-chromosome and segmental mosaicism were divided based on chromosomal constitution in single (monosomy or trisomy), double, and complex aneuploidy (more than two different aneuploidies) group.
Main results and the role of chance: A total of 4850 aneuploidies were detected, whole-chromosome (3547/4850;74%) occurred more frequently than segmental (1303/4850; 26%) mosaicism (P<0.01). The highest prevalence of whole-chromosome imbalance leading to aneuploidy was seen for chromosome 14, 18, 21, 22 and X, while for segmental mosaicism was seen for chromosomes 1,2,5, and 16. Mosaicism rates for these chromosomes did not statistically vary when stratified by maternal age. For whole-chromosome mosaicism, trisomy was significantly more frequent than monosomy (p<0.05) but for segmental mosaicism trisomy was less frequent (P<0005). Regarding the type of mosaic embryos, 53% (1209/2278) were found to be composed of whole chromosomes, 30% (694/2278) of structural aneuploidies and 17% (375/2278) contained both whole-chromosomal and structural aneuploidies. Of the whole-chromosome embryos, single aneuploidy was significantly more frequent than complex (53%, vs 28%;p<0.001), and double aneuploidy (53%, vs 19%;p<0.001). Similarly, when grouped based on structural abnormalities, single segmental aneuploidy was significantly more frequent than double (80% vs 16%; p<0.0001) or complex segmental aneuploidy (80% vs. 4%; p<0.001). Structural mosaic and whole-chromosome aneuploidy blastocysts with >50% aneuploid cells accounted for 11% and 14% of analysed embryos, respectively.
Limitations, reasons for caution: This study was retrospective, demonstrating the relative frequency of different type of mosaic embryos but not offering any direct insight into the clinical relevance of the findings. Additional clinical data must be obtained to evaluate the clinical implication of chromosomal mosaicism in mosaic embryo outcome.
Wider implications of the findings: Our findings reported the prevalence of the different kind of mosaicism in human blastocyst. Furthermore the study provides a detailed description of the prevalence, distribution and level of mosaicism for each chromosome involved in mosaicism. These results contribute to the understanding of the nature and origin of mosaic embryos.

[3]King's Fertility, The Fetal Medicine Research Institute, London, United Kingdom ;
[4]CRGH, The Center for Reproductive and Genetic Health, London, United Kingdom ;
[5]University College London, Institute for Women's Health- Preimplantation Genetics Group, London, United Kingdom

Study question: How is structural genetic variation associated with the causes and prognosis of poor sperm parameters and embryonic aneuploidy using a whole genome sequencing (WGS) approach.
Summary answer: Males with severe sperm abnormalities present with significantly higher deletion length and increased amount of CNVs throughout their genome that could link to embryonic aneuploidy.
What is known already: Poor sperm parameters are associated with embryonic aneuploidy and linked to various polymorphic sites concentrated in the Y chromosome and several individual genes. Structural genomic variations in individuals have been linked abnormal sperm parameters. So far studies have shown that male infertility is the result of a combination of several genetic and environmental interactions but in most cases the approach was targeted to specific areas of the genome with varied results. The impact of genetic variation on sperm parameters and embryonic aneuploidy is not yet fully established. Whole genome sequencing can provide a more complete genomic snapshot of these conditions.
Study design, size, duration: Couples presenting with repeated implantation failure and/or recurrent miscarriage that went through PGT-A (2008 - 2015) were invited to provide DNA samples for WGS.
Several selection criteria were applied to the test group: i) referred for PGT-A >3 AR failures, ii) Normal karyotypes, iii) Female age less than 37, iv) Embryonic instability in their subsequent PGT-A cycles. Results were analysed according to insemination method, sperm parameters and associated with the PGT-A embryo results.

Participants/materials, setting, methods: From the invited individuals - 118 consented to WGS analysis. From the consented individuals, 36 (18 couples) passed all the selection criteria. Within that cohort, there were 12 males needing ICSI and poor sperm parameters and 9 males with normal sperm parameters (IVF cohort) and DNA from these participants was sequenced.
WGS was performed with a short-read BGI platform. Variant calling and genomic data analysis were performed with gold standard bioinformatic pipelines.
Main results and the role of chance: Whole genome sequencing provides a global view of the human genome and is a step towards a personalized approach to healthcare.

This study has found that males with severe sperm abnormalities present with high DNA deletion length and increased amount of copy number variations compared to less severely affected individuals and to males with normal sperm parameters. Specifically, the ICSI group had significantly higher total CNV deletion length than the IVF group. In addition, the total number of CNV's was significantly higher in the males with severe conditions like azoospermia compared with the males that presented with poor sperm parameters like oligospermia. These variations were found in several areas of the genome as well as in the Y chromosome or genomic areas related to fertility.

Several polymorphic sites found in the same genomes could contribute to an accumulated risk that is linked to poor sperm parameters and embryonic aneuploidy. For example, in severely affected individuals, structural variations were found in several genes associated with spermatogenic failure like AURKC, CATSPER1, CEP19. Variations in genes associated with increased prostate cancer risk observed in some men with poor sperm parameters. This could explain the highly heterogeneous associations in genetics of male infertility.
Limitations, reasons for caution: Ethnicity bias presented in relation to the bioinformatic analysis as variation is flagged based on frequencies mainly focused in Caucasian populations, so this has been considered especially for the SNP analysis. For future work, a normal fertility control group with preimplantation embryo results would facilitate further research.
Wider implications of the findings: A complex picture of a polygenetic/multifactorial risk is arising for certain infertility types, the results from such targeted population studies can help in the identification and subsequently the prediction of genetic risk for heterogeneous conditions. This study adds to the prognostic value of WGS in male infertility and embryo aneuploidy.
Trial registration number: Not applicable

P-512 A review of 1,504 autologous embryos evaluated using a non-invasive platform for preimplantation genetic testing for aneuploidy at a private clinic

M. Olcha[1], M. Elzaky[1], M. Jaremko[1], Z. John[1], B. Hensinger[2], S. Lu[2]

[1]New Hope Fertility Center, Reproductive Endocrinology, New York, U.S.A. ;
[2]Yikon Genomics, Genomics, Lewes, U.S.A.

Study question: To determine if a non-invasive approach for preimplantation genetic testing for aneuploidy (PGT-A) can successfully assess embryo ploidy status at a large-scale private practice setting
Summary answer: Non-invasive PGT-A can identify ploidy status in a large cohort of embryos. Furthermore, this technology can also distinguish mosaic embryos from aneuploid or euploid ones.
What is known already: PGT-A has been widely used around the world to identify ploidy status of embryos. The knowledge obtained can help assist clinicians and patients with prioritization of embryos for transfer. The transfer of single euploid embryos has be shown to improve per cycle pregnancy rate, reduce miscarriage rate, and prevent transfer of embryos harboring certain genetic anomalies such as Down Syndrome. The primary modality for obtaining DNA from blastocysts has been trophectoderm biopsy, which requires removal of embryonic cells. Recently, the advent of non-invasive methods for PGT-A allow embryonic DNA within spent media to be amplified for ploidy analysis.
Study design, size, duration: Retrospective data analysis of 1,504 blastocysts, which were evaluated using non-invasive PGT-A from August 1st 2019 to December 30th 2019. All embryos evaluated using non-invasive PGT-A were included except patients using donor eggs.
Participants/materials, setting, methods: Patients electing to have their embryos undergo PGT-A were offered to utilize a validated non-invasive approach instead of conventional trophectoderm biopsy after appropriate informed consent. Spent media collected from embryos on day 5, 6, or 7 was processed on site with the Non-Invasive Chromosomal Screening (NICS) platform (Yikon Genomics, Lewes, DE). NICS uses multiple annealing and looping-based amplification cycles (MALBAC) for whole-genome amplification followed by next-generation sequencing to obtain ploidy information on all 24 chromosomes.
Main results and the role of chance: The average patient age was 36.6 years old. Of the 1,504 media samples tested with the NICS platform, 86 (5.7%) were initially found be inconclusive. 62 of the 86 inconclusive embryos were thawed for overnight culture and next day repeat media collection based on patient preference. The remaining 24 inconclusive were not resampled. All retested embryos resulted in usable ploidy data. The proportion of Euploid, Mosaic, and Aneuploid calls in the 1480 resulted embryos (original and retested) were 22.9%, 32.6%, and 44.5%, respectively. Of the 62 retested embryos, 35.4% were euploid, 29.0% were mosaic, and 35.5% were aneuploid. Data was further stratified based on established Society for Assisted Reproductive Technology (SART) age groups. Excluding mosaic results, 51.1%, 38.0%, 20.8%, 26.4%, and 10.5% were found in be euploid in patients under 35, 35-37, 38-40, 41-42, and over 42, respectively.
Limitations, reasons for caution: While the NICS platform has been previous validated, the proportion of mosaic calls can vary depending on thresholds established within the Yikon pipeline. Additionally, caution should be taken when generalizing results as certain clinical and embryologic practice parameters could affect DNA capture and successful amplification.
Wider implications of the findings: The NICS platform can be utilized successfully in a private setting. Embryos resulting as inconclusive initially can be successfully retested. Furthermore, the use of a non-invasive methods to identify embryo ploidy may reduce risk to the embryo, however this has yet to be determined.
Trial registration number: not applicable

P-513 A homozygous missense mutation in an highly conserved autosomal gene coding poly(A)-binding protein cause female infertility due to oocyte maturation arrest at GV stage

O. Okutman[1], A.S. Gürbüz[2], U. Büyük[3], B. Rinaldi[4], S. Friant[4], J. Muller[5], S. Viville[1]

[1]Hôpitaux Universitaires de Strasbourg- Nouvel hôpital civil, Laboratoire de diagnostic génétique- UF3472 Infertilité, Strasbourg, France ;

[3]Hibrigen Biyotecnology, Research and Development, Gebze-Kocaeli, Turkey ;
[4]Centre National de Recherche Scientifique CNRS- Université de Strasbourg, Department of Molecular and Cellular Genetics- UMR7156, Strasbourg, France ;
[5]Hôpitaux Universitaires de Strasbourg, Laboratoire de diagnostic génétique, Strasbourg, France

Study question: Is it possible to identify the new causative genetic mutation responsible of an oocyte maturation arrest in a Turkish consanguineous family via whole exome sequencing?
Summary answer: Whole exome sequencing reveals a homozygous missense mutation for the three affected sisters in a Turkish familiy with multiple loops of consanguinity.
What is known already: Women undergoing controlled ovarian hyper stimulation prior to in vitro fertilization (IVF) are treated by various protocols aimed at inducing multiple follicular growths. Approximately 20%–30% of oocytes collected for IVF are meiotically immature at the time of oocyte retrieval. The complete failure of all oocytes to mature *in vivo* is very rare, but known as causes of primary female infertility. Recently mutations in two genes, TUBB8 and PATL2 have been identified in women with oocyte maturation arrest. However, for approximately 60% of cases, underlying genetic factors are still largely unknown.
Study design, size, duration: We have recruited a Turkish familiy with multiple loops of consanguinity comprising 3 sisters with repeating oocyte maturation arrest at GV stage. Different stimulation protocols have been tried nevertheless collected oocytes failed to proceed into mature oocytes, even after extended in vitro culture. All three sisters have normal karyotype; however their brother was diagnosed with Down syndrome.
Participants/materials, setting, methods: Blood samples from all siblings, parents and available non-affected family members were collected after obtaining signed consent form. Genomic DNA was extracted from peripheral blood using Hibrigen DNA Extraction-Blood kit (Hibrigen, Istanbul, Turkey), according to

the manufacturer's instructions. Exome sequencing of three affected sisters was performed by Integragen Genomics via Illumina technology. Bioinformatics analysis was executed using IG Constitutionel DNA pipeline V4.0. Detected variants were also scored and ranked by VaRank tool.

Main results and the role of chance: For three samples, at least 4.8GB DNA sequence were generated with >99% of the target exome was represented with >25-fold coverage. Exome sequencing reveals a homozygous missense mutation in an autosomal gene (*STBG1*) for all three affected sisters. The mutation was confirmed and segregation has been shown in available family members via Sanger sequencing; parents, the cousin and one aunt are heterozygous whether second aunt is wild type for the substitution. The coding protein is well conserved during evolution from lamprey to human. The identified mutation is in RNA recognition domain, predicted as disease causing/deleterious through different online tools. KO female mice are infertile, and could not generate mature oocytes neither in vivo nor in vitro. Functional studies are ongoing; the effect of the mutation is studied on budding yeast.

Limitations, reasons for caution: Our study is limited to one family only and the phenotype is very rare. We still have to screen a cohort of patients presenting the same phenotype.

Wider implications of the findings: Our results provide a new understanding for the pathogenesis of oocyte maturation arrest and help us to identify reason for GV arrest in our patients. It may help to define novel therapeutic approach to patients with similar symptoms.

Trial registration number: Not applicable

P-514 From molecular identification to PGT-M of a novel primary ciliopathy due to biallelic mutations in the TOGARAM1 gene

D. Zuccarello[1], V. Morbidoni[2], E. Agolini[3], K.C. Slep[4], L. Pannone[5], E. Grosso[6], G. Gai[6], B. Dallapiccola[7], A. Novelli[3], S. Martinelli[8], E. Trevisson[2]

[8]Department of Oncology and Molecular Medicine, Istituto Superiore di Sanità, Rome, Italy

Study question: How to eliminate the risk of recurrence of a genetic condition with unknown molecular basis?

Summary answer: By identifying the causative gene, ascertained by robust functional studies, it is possible to offer PGT-M to the couple.

What is known already: Dysfunction in non-motile cilia is associated with a broad spectrum of developmental disorders characterized by clinical heterogeneity. Despite over one hundred genes have been associated with primary ciliopathies, with wide phenotypic overlap, some patients still lack a molecular diagnosis.

Study design, size, duration: Whole exome sequencing (WES) analysis, *in silico*, *in vitro* and *in vivo* functional studies.

Participants/materials, setting, methods: Unrelated young parents were referred following 2 TOP due to multiple fetal malformations, including microcephaly, severe cleft lip and palate, microphthalmia, and brain malformations. Array-CGH on fetal DNA was normal. WES analysis was performed on DNA from 2 fetuses and its parents, and *in silico*, *in vitro* and *in vivo* (in *C. elegans*) functional studies were carried out to explore the impact of finding mutations on protein structure and function.

Main results and the role of chance: WES analysis identified in both fetuses a compound heterozygous genotype in the orphan gene *TOGARAM1*: NM_015091.3:c.1102C>T [p.(Arg368Trp)], and c.3619C>T [p.(Arg1207*)], each inherited from one parent. *TOGARAM1* encodes a protein regulating microtubule dynamics, it is highly conserved throughout evolution and *che-12*, its orthologue in nematodes, is expressed in the cilium of a subset of sensory neurons.

Mutant worms recapitulating the patients' genotype showed a shorter cilium in sensory neurons and in vitro experiments confirmed aberrant tubulin binding, indicating a causative role of *TOGARAM1* variants in the pathogenesis of this novel primary ciliopathy, characterized by a spectrum of defects consistent with the Meckel-Gruber phenotype,including microphthalmia, hydrocephalus and cleft palate.

The molecular identification of this new genetic disorder allowed to offer the couple the opportunity to perform the preimplantation genetic diagnosis (PGT-M).

Limitations, reasons for caution: We cannot predict accurately the post-natal phenotype associated with biallelic *TOGARAM1* mutations, because we have only observed fetal cases. Further studies are warranted to better define the clinical picture of this new severe disorder.

Wider implications of the findings: Our data strongly support the role of *TOGARAM1* as a novel causative gene of primary ciliopathy, which thus should be included in diagnostic gene panels for this heterogeneous group of disorders.

Trial registration number: not applicable

P-515 PGT-A: Who and when? A systematic review and network meta-analysis of RCTs

A. Pantou[1], K. Sfakianoudis[2], E. Maziotis[3], P. Tsioulou[3], S. Grigoriadis[3], A. Rapani[3], P. Giannelou[2], M. Asimakopoulou[3], K. Nikolettos[4], T. Kalampokas[5], G. Kokkali[2], K. Pantos[2], N. Vlahos[6], M. Koutsilieris[3], M. Simopoulou[3]

[1]Genesis Genoma Lab, Molecular Genetics, Athens, Greece ;
[2]Genesis Athens Clinic, Assisted Conception Unit, Athens, Greece ;
[3]National and Kapodistrian Univerisity of Athens, Physiology, Athens, Greece ;
[4]Assisted Reproduction Unit of Thrace "Embryokosmogenesis", Assisted Conception Unit, Alexandroupoli, Greece ;
[5]Aberdeen Maternity Hospital- Fertility Center, Assisted Reproduction Unit, Aberdeen, United Kingdom ;
[6]Aretaieion University Hospital, 2nd Department of Obstetrics and Gynecology, Athens, Greece

Study question: What is the optimal practice for preimplantation genetic testing for aneuploidy (PGT-A) considering the patients' age and the best day to biopsy?

Summary answer: PGT-A employing complete chromosomal screening appears to be beneficial only when performed on the basis of trophoectoderm biopsy, addressing predominantly women over 35 years old

What is known already: Following literature search, two schools of thought-if not more-are emerging with regards to "when" and "how" PGT-A should be employed. A number of prospective and retrospective studies revealed controversial results concerning the effectiveness of PGT-A cycles during fresh or frozen ART cycles. On one hand, the advocators support that performing PGT-A holds remarkable promise with regards to successful embryo implantation, especially when focusing on the distinct group of women of advanced maternal age. On the other hand, no difference and even lower live birth rates have been demonstrated when opting for PGT-A in comparison to IVF cycles without PGT-A.

Study design, size, duration: A systematic review and meta-analysis of 10 published studies including women who underwent IVF-Embryo Transfer cycles following complete chromosomal screening (CCS) of the preimplantation embryo.

Participants/materials, setting, methods: A systematic search of the literature was performed in the databases of PubMed/Medline, Embase and Cochrane Central Library, limited to articles published in peer-reviewed journals up to June 2019. The initial search yielded 1819 studies. From the total yield, 215 studies were duplicates and 1501 were excluded on the grounds of not fulfilling criteria for inclusion. Following thorough full-text screening and citation mining a total of 10 studies were included in the current meta-analysis.

Main results and the role of chance: A total of 10 Randomized Control Trials employing CCS were identified. PGT-A improved ongoing pregnancy/live birth rates both in the pooled results (RR:1.29; 95%CI:1.07-1.56) and in the over

35 years old subgroup (RR:1.52; 95%CI:1.01-2.28), when compared to the control group of morphological assessment for embryo selection. Interestingly, no statistically significant difference was observed in the younger than 35 years old subgroup (RR:1.10; 95%CI:0.81-1.48), when compared to the control group. When comparing D3 and D5 biopsy no statistically significant difference was observed between the groups regarding ongoing pregnancy/live birth rates (RR:0.87; 95% CI: 0.59-1.29). When comparing D3 biopsy to the control group no statistically significant difference was observed between the groups regarding ongoing pregnancy/live birth rates (RR:1.10; 95% CI: 0.75-1.60). Interestingly, only D5 biopsy provided enhanced rates regarding ongoing pregnancy/live birth (RR: 1.26; 95% CI: 1.04-1.53) when compared to the control group.

Limitations, reasons for caution: The multifaceted nature of PGT-A success may stand as a valid limitation when unravelling results and drawing conclusions. When reporting on what truly makes a PGT-A cycle successful we should clearly distinguish between efficiency of diagnosis and successful outcome of the cycle leading to a healthy offspring.

Wider implications of the findings: The results of the present study indicate that PGT-A may improve clinical outcomes and live birth rates only when performed on women aged over 35 years old and on blastocyst stage embryos. However, further RCTs investigating the exact requirements to ascertain a beneficial effect of PGT-A should be conducted.

Trial registration number: Not applicable

P-516 Pregnancy after oocyte donation in a patient with NLRP7 mutation and a history of recurrent hydatidiform molar pregnancy

F. Scheffler[1], C. Cozette[1], J. Massardier[2], I. Touitou[3], J. Gondry[4], H. Copin[1], M. Ben Khalifa[1], R. Cabry-Goubet[1]

[1]CHU Amiens Picardie SUD, Service de médecine et biologie de la reproduction-cytogénétique et CECOS de Picardie, Amiens, France ;
[2]CHU Lyon Sud, Centre Français des Maladies Trophoblastiques- Hospices Civils de Lyon- Pierre Benite, Lyon, France ;
[3]CHU Montpellier, Cellules souches- plasticité cellulaire- médecine régénérative et immunothérapies- INSERM- Université de Montpellier- Département de génétique médicale- maladies rares et médecine personnalisée- CEREMAIA, Montpellier, France ;
[4]CHU Amiens Picardie SUD, Service de gynécologie et obstetrique, Amiens, France

Study question: Is oocyte donation the best option in case of genetic hydatidiform moles?

Summary answer: Oocyte donation appears to be the best option for a normal and successful pregnancy in women with a history of recurrent complete hydatidiform moles

What is known already: Molar pregnancies are benign trophoblastic diseases associated with a risk of malignant transformation. If aetiology remains mostly unknown, the risk of recurrent molar pregnancy is around 1.5% after one molar pregnancy and around 25% after 2 molar pregnancies. Genetic mutations have been described, increasing hugely this risk of trophoblastic diseases. In case of mutations, the probability to obtain a normal pregnancy is estimated around 1.8%. In patient with pathogenic mutations in the NLRP7 gene, only 3 normal pregnancies and deliveries after oocyte donation have been published.

Study design, size, duration: Case report

Participants/materials, setting, methods: We report the case of a Caucasian 30-year-old woman whose previous five spontaneous pregnancies had a negative outcome: a spontaneous miscarriage and 4 complete hydatidiform moles, without gestational trophoblastic neoplasia. There was no history of recurrent pregnancy failures in her family. Genetic testing revealed that the patient carried two pathogenic mutations in the *NLRP7* gene (Y318CfsX7 and c.2982-2A>G).

Main results and the role of chance: We proposed an oocyte donation in order to obtain a normal pregnancy. Four mature oocytes were done and two embryos transferred on day 3. This technic enabled a complication-free, singleton pregnancy that resulted in a healthy term live birth of a 2900g female, in spite of a pre-eclampsia at the end of the pregnancy. The pathological placenta examination was normal and we could observe a spontaneous normalization of BHCG. The couple is now waiting for another oocyte donation.

Limitations, reasons for caution: none

Wider implications of the findings: Women presented with mutations in the *NLRP7, KHDC3L or PADI6* genes are unlikely to obtain normal pregnancies, with a major risk of reproductive failure. Our case is the first one for our national trophoblastic disease center. It confirms the effectiveness of oocyte donation to prevent recurrent hydatidiform moles.

Trial registration number: not applicable

P-517 Analysis of segmental aneuploidy and mosaicism in the human blastocysts. Is there any difference in pregnancy rates?

J.A. Ortiz[1], B. Lledo[1], R. Morales[1], E. Garcia-Hernandez[1], J. Ten[2], J. Llacer[3], A. Bernabeu[3], R. Bernabeu[3]

[1]Instituto Bernabeu, Biología Molecular y Genética, Alicante, Spain ;
[2]Instituto Bernabeu, Embriología, Alicante, Spain ;
[3]Instituto Bernabeu, Medicina Reproductiva, Alicante, Spain

Study question: What are the characteristics, associated factors and the clinical pregnancy of the embryos with segmental alterations?

Summary answer: The ongoing pregnancy rates of mosaic segmental embryos are similar to those of euploid embryos, therefore, embryo transfer with segmental mosaicism could be considered.

What is known already: Chromosomal abnormalities in IVF embryos can be detected by PGT-A. By using NGS or aCGH, it is possible to detect segmental (subchromosomal) errors that occur when small portions of DNA are duplicated or removed from the embryo. The origin of the segmental alterations is mainly mitotic and occurs in the first embryonic divisions. Many of the characteristics of these alterations have not been studied, such as: proportion of chromosomes with segmental errors, hot spot regions, type of segmental errors, length of alterations, or percentage of aneuploid cells. Moreover, the effect of segmental mosaicism in the pregnancy rate is still controversial.

Study design, size, duration: A total of 5286 embryos from 1822 PGT-A cycles were included in this study (October 2014-April 2019). The trophoectoderm biopsies on D5/D6 blastocysts were analysed by aCGH (46%) or NGS (54%). The detection of segmental alterations was validated by the analysis of embryos from patients with structural chromosomal alterations. Embryos with ≤25% aneuploid cells were considered euploid, between 25-50% were classified as mosaic and aneuploid with >50%. Only euploid or mosaic embryos were transferred.

Participants/materials, setting, methods: The main indications for PGT-A were advanced maternal age, abnormal sperm FISH and recurrent miscarriage or implantation failure. Embryo analysis were performed using Agilent SurePrint G3-8x60K-CGH microarrays or Veriseq-NGS (Illumina), with previous whole genome amplification. The comparison of ongoing pregnancy rate between euploid embryos, segmental mosaic and full chromosome mosaic was performed by a binary logistic regression in which maternal and paternal ages, embryo quality and day of biopsy were introduced as confounding factors (SPSSv20.0).

Main results and the role of chance: A total of 5286 embryos were analysed (41.3% aneuploid and 2.6% not informative). Segmental alterations were detected in 12.4% of the analysed embryos, 42.9% of these embryos presented segmental deletions, 25.1% duplications and 32.0% both. The average size of the segmental imbalances was 56.87 Mb (8 to 170 Mb). Interestingly, sites of chromosome breakage associated with segmental errors were not random. A 58.2% of the segmental alterations were located near the telomeres, 7.4% in the proximity of the centromere, 4.7% in the middle of the arms and 29.7% affect a whole arm. Analysing the factors associated to segmental errors, we observed an inverse correlation among segmental alteration and maternal age: 15.3% in women until 35y versus 10.3% in >36y women ($p<0.0001$). No factors of paternal origin showed any association. On the other hand, embryonic quality showed a strong association with segmental errors (A: 10.3%; B14.5%; C:18.4%, D:18.2%;$p<0.0001$). We also analyzed the clinical data of embryos with segmental mosaicism versus embryos with full chromosome mosaicism or euploid in single embryo transfer cycles. The ongoing pregnancy rate was higher for segmental mosaics compared with full chromosome mosaics (42.1% vs 22.7%;$p=0.066$) and similar to cycles where euploid embryos were transferred (42.1% vs 33.9%;$p=0.254$).

Limitations, reasons for caution: The main limitation of this study is the use of different techniques for the PGT-A. The NGS is more sensitive and specific to detect segmental errors than aCGH. To avoid this bias, the analysis technique (aCGH or NGS) was introduced into the statistical analysis as a confounding factor.

Wider implications of the findings: Segmental-chromosomal alterations are relatively frequent in embryos and chromosome breaks close to the telomere are more likely. Maternal age and embryo quality are risk factors. Finally, ongoing pregnancy rates of mosaic segmental embryos are similar to euploid embryos, consequently the transfer of mosaic segmental embryos could be considered.
Trial registration number: Not applicable

P-518 Embryo morphology affects euploid blastocysts implantation

M. Gomez Peña[1], L. Kopcow[2], M. Rocha[2], G. Terrado[2], M. Papayannis[1], E. De Martino[1], M. Horton[2], F. Sobral[2], I. De Zúñiga[2], A. Oubiña[2], C. Bisioli[1]

[1]Pregna Medicina Reproductiva, ART Embryology, Buenos Aires, Argentina ; [2]Pregna Medicina Reproductiva, Clinical department, Buenos Aires, Argentina

Study question: Is blastocyst euploidy the only relevant factor to predict implantation?
Summary answer: Good quality euploid blastocysts have a better implantation and pregnancy potential.
What is known already: Euploidy has been regarded in the literature as the only guarantee of a successful implantation and live birth. Thus, irrespective of other embryological and clinical variables such as patient age, blastocyst morphology or biopsy day. This assertion, however, remains controversial.
Study design, size, duration: Retrospective comparative study of 222 elective single frozen-thawed blastocyst transfers after preimplantation genetic testing for aneuploidy (PGT-A) via next generation sequencing (NGS). Sampling occurred between June 2016 and September 2019.
Participants/materials, setting, methods: We compared implantation (IR), ongoing pregnancy (OPR) and miscarriage (MR) rates between:

- Embryo biopsy day 5 (n= 138) vs. day 6 (n= 84).
- Female age <37 yo (n= 89) vs ≥ 37 yo (n= 133)
- Excellent/Good (n= 138) vs. Fair/Poor (n= 84) quality embryos.

Student's t-test and Chi-squared test were used as appropriate.
Main results and the role of chance: IR (43.5% (n=64/147) vs 38.8 % (n=33/85); p=NS), OPR (39.2% (n=49/138) vs 29.7% (n=25/85); p=NS) and MR (5.8% (n=8/138) vs 7.2% (n=6/84); p=NS) were similar between embryos biopsied on D5 vs D6 respectively.

We also found no differences regarding patients age <37 vs ≥ 37 in IR (49.5% (n=45/91) vs 38.0% (52/137); p=NS), OPR (39.3% (n=7/89) vs 31.5% (n=7/133); p=NS) or MR (7.8% (n=35/89) vs 5.3% (n=42/133); p=NS). Excellent and good quality blastocysts achieved better IR (49.0 (n=70/143) vs 31.7% (n=27/85); p=0.01) and OPR (39.85% (n=55/138) vs 26.2% (n=22/84); p=0.02) than fair and poor ones. MR was not significantly different between different quality embryos (7.2% (n=10/138) vs 4.8% (n=4/84); p=NS).
Limitations, reasons for caution: This study has biases due to its retrospective design. The small sample size and the strong subjectivity among embryologists when grading blastocysts are additional limitations.
Wider implications of the findings: Although euploidy is considered as a main predictor of reproductive success our analysis shows that embryo grading might also play a role. Therefore diploid chromosome number alone might not be sufficient to predict a successful implantation.
Trial registration number: Not applicable

P-519 Freeze-all cycles with or without preimplantation genetic diagnosis for aneuploidy superior to fresh embryo transfer in normo-responders?

M. Karacan[1], M. Keskin[2], M. Kurek Eken[2], M. Yanık[1]

[1]Yeni Yuzyıl University Medical Faculty, Department of Reproductive Medicine and Infertility, Istanbul, Turkey ; [2]Yeni Yuzyıl University Medical Faculty, Department of Reproductive Medicine and Infertility, İstanbul, Turkey

Study question: Are freeze-all cycles with or without preimplantation genetic diagnosis for aneuploidy superior to fresh embryo transfer in normo-responders?
Summary answer: Live birth rate with single blastocyst transfer with or without PGT-A in freeze-all strategy is not superior to fresh ET in normoresponders.
What is known already: Cryopreservation of human embryos is now a routine procedure in assisted reproductive technologies for better embryo-endometrium synchrony and the lower risk of ovarian hyperstimulation syndrome at the same time resulted in live births increased. However, there are some concerns need to be evaluated in freeze-all strategy such as the efficacy in normal or poor responders. Aneuploidy is a leading cause of implantation failure and a significant cause of failure in IVF cycle, PGT-A has been deemed as a promising approach to improve pregnancy rate but on the other hand PGT-A requires consideration of multipl factors
Study design, size, duration: This retrospective study includes patients who underwent ICSI-ET procedures at Istanbul Yeni Yüzyil University Department of Reproductive Medicine&Infertility between January 2016 and December 2018. Fresh embryo transfers (n:72) frozen-thawed embryo transfer(FET) (n:264) and frozen-thawed embryo transfer after PGT-A (FET-PGT-A) (n:56) were analyzed.
Participants/materials, setting, methods: Women aged< 42 years with normal uterine cavity , normo-responders who had 5-14 oocytes at retrieval, single blastocyst transfer, ovulation induction with gonadotropin-releasing hormone antagonist (GnRH-a), sperm found in ejaculate, endometrial thickness ≥ 7 mm on the day of hCG injection in fresh ET cycles or of progesterone start in FET cycles ,first complete cycle in the center. Only blastocysts having normal karyotypes were transferred in PGT-A cycles.
Main results and the role of chance: A total of 392 couples who had fresh embryo transfer or a first frozen embryo transfer with or without PGT-A after freeze-all cycles were analyzed in the study. Fresh ET, FET and FET+PGT-A groups were comparable with regard to number of oocytes collected (8.8±2.3, 8.7±2.9 and 9.1±2.4) and fertilized (5.9±2.3, 6.1±2.2 and 6.3±2.1) as well as the number of blastocysts (2.3±1.2, 2.3±0.9 and 2.4±1.3) available for the transfer, consecutively.

Positivity of β-hCG level (>5 IU/L) was detected in 38 (52.7 %) women in fresh ET group, 168 (63.3 %) women in FET group and 33 (58.9 %) women in FET+PGT-A group following single blastocyst transfer (p>0.05).

All pregnancies were singletons and no severe OHSS was observed in all groups. Moderate OHSS was detected in 3 cases (4%) in fresh ET cycles and 11 cases (3.4%) in all FET cycles.

Live birth rates were 24 (33.3%) for fresh ET group, 98 (37.1%) for FET and 24 (42.8%) for FET+PGT-A group. Although it was higher in FET+PGT-A group compared to fresh ET group it did not reach statistical significance (p>0.05).
Limitations, reasons for caution: The limitations of our study include its retrospective nature, the lack of hormonal assessments in the follicular phase and imprecise allocation of patients into each group (physician's or patient's preference).Otherwise, it was an advantage that all procedures were performed by the same embryologist.
Wider implications of the findings: This was first study comparing fresh ET with FET with and without PGT-A in the literature.Although live birth rate was higher in PGT-A and FET group than fresh ET group but did not reach statistical significance. There is a need for further prospective randomised studies to confirm this subject properly.
Trial registration number: 2019/71

P-520 Developmental incompetent preimplantation embryo: a two Societies consensus

[7]Laboratory of Seminology - Sperm Bank "Loredana Gandini" - Sapienza" University of Rome, On behalf of the Italian Society of Embryology- Reproduction and Research SIERR, Rome, Italy ;
[8]International Evangelical Hospital- Reproductive Medicine, On behalf of the Italian Society of Embryology- Reproduction and Research SIERR, Genoa, Italy ;
[9]Casa di Cura Villa Salaria in partnership with Institut Marques- Center for Reproductive Medicine, On behalf of the Italian Society of Embryology- Reproduction and Research SIERR, Rome, Italy ;
[10]Clinical Genetics Units- University Hospital of Padova, On behalf of the Italian Society of Human Genetics SIGU, Padova, Italy

Study question: What is the definition of "developmental incompetent" preimplantation embryos, which can therefore be discarded, in the absence of a clear regulatory reference law?
Summary answer: SIERR and SIGU define as "developmental incompetent" a preimplantation embryo with specific characteristics related to ploidy, type of cell division, chromosomal and molecular status.
What is known already: In 2010 SIERR published the first document on the definition of "developmental incompetent embryos", in the absence of a specific indication in the Italian IVF Law 40/2004 on which embryo can be discarded at the end of IVF process.
Nine years later, SIERR, in collaboration with SIGU felt the need to update and implement the document, in the light of the development of new diagnostic capabilities related to modern technologies. The present consensus redefines the criteria according to which a preimplantation embryo can be defined as developmental incompetent.
Study design, size, duration: Five SIERR embryologists and 2 SIGU geneticists (a clinician and a biologist), representative of their respective scientific societies worked as a committee in 6 board meetings, through 2018 and 2019, in order to draw up the document. The consensus was then approved by the steering committee of the two scientific societies and made open through publication on their respective websites.
Participants/materials, setting, methods: Over a hundred between scientific articles and guidelines have been selected through systematic research of specific reference items. The most recent morphology and morphokinetics studies and the most advanced preimplantation genetic diagnosis technologies, allowed the working committee to develop standard criteria to define a developmental incompetent embryo**.**
Main results and the role of chance: The criteria to define a developmental incompetent embryo have thus been established as: a) presence of a number of pronuclei different from two; b) no further cell division 24 hours after the previous observation; c) blastocyst affected by complex aneuploidy; d) blastocyst affected by complete or partial monosomy in homogeneous form of an autosome; e) blastocyst affected by complete or partial trisomy in a homogeneous form of chromosomes: 1, 2, 3, 4, 5, 7, 10, 11, 12, 14, 19; f) blastocyst affected by polyploidy or haploidy; g) blastocyst affected by *in uterus* lethal monogenic disease.
Limitations, reasons for caution: Regarding the genetic criteria identified to define a developmental incompetent embryo, it is necessary to take into account the percentage of diagnostic error intrinsic to each technique in preimplantation genetic testing as well as the possible detection of chromosomal mosaicism, which varies according to the technique adopted.
Wider implications of the findings: This document fills a legislative gap of Italian law while providing a useful tool to support the choice to not transfer. It allows the IVF centers to discontinue these embryos from further culture, reducing the number of cryopreserved embryos, and opens to the donation of incompetent embryos to scientific research.
Trial registration number: not applicable

P-521 Cystic Fibrosis: Complete CFTR gene analysis vs. CFTR genotyping on sperm donors carrier screening

M. Molina Romero[1], A. Yoldi Chaure[1], P. Navas Bastida[2], M. Gañán Parra[3], Á. Vaquero Argüelles[1], J.L. Del Pico Sánchez[1], J.P. Ramírez López[1], J.A. Castilla Alcalá[1]

[1]CEIFER Biobanco, Genetic Department, Granada, Spain ;
[2]CEIFER Biobanco, Genetic Department, Córdoba, Spain ;
[3]CEIFER Biobanco, Genetic Department, Sevilla, Spain

Study question: The cystic fibrosis carrier screening on sperm donors, is better to do it through a complete analysis of the CFTR gene by NGS or by genotyping?
Summary answer: We recommend to study the CFTR gene by NGS for the cystic fibrosis carrier screening on sperm donors.
What is known already: In accordance with the legal regulations in force in Spain and under the European Union (EU) Directive on human tissues and cells, gamete donors should be screened (tested) for autosomal recessive genes known to be prevalent. Due to the high prevalence of cystic fibrosis, many scientific societies recommend the cystic fibrosis carrier screening for sperm donors. However, none has specified whether the CFTR gene should be studied by complete sequencing and non-directed analysis of variants or by using a panel of targeted variants (genotyping panel).
Study design, size, duration: It is a descriptive observational study, with 935 men aged 18-35 years, who were evaluated in the framework of a sperm donation programme in Spain, from January 2014 to June 2019.
Participants/materials, setting, methods: We did the complete study of the CFTR gen by Next Generation Sequencing (NGS) in 935 caucasian sperm donors in a Spanish private sperm bank. We have determined the frequency of sperm donors carrying pathogenic variants of the CFTR gene and we have analysed the detection rate of these carriers that would have been detected by applying the genotyping tests for CFTR gene mutations that are most commonly used in the assisted reproduction in Spain.
Main results and the role of chance: Of the 935 sperm donors, 159 (17%) were carriers of at least one pathogenic variant in the CFTR gene. The frequency, therefore, was approximately one in six. In total, 39 different variants were found. Of the 39 variants found in the sperm donors, 22 variants (56,41%) would not have been detected by any of the four genotyping tests. And only four of the 39 variants (10,27%) would have been detected by all of the genotyping tests.
Our study shows there is great heterogeneity in the pathogenic variants of the CFTR gene that are included in the genotyping tests most commonly used in the context of assisted reproduction. Less than 50% of the variants included in the panels are common to all these tests. The number of carrier donors detected by genotyping would be 8.2%-51,6% from total number of carrier donors detected by NGS.
Limitations, reasons for caution: The limitations of this study is that it is not a population study (men had to meet exclusion criteria with excellent semen parameters), and second that it is a relatively homogeneous population which may not extend to other ethnic groups. In consequence, our population is biased in this respect.
Wider implications of the findings: The NGS presents a higher detection rate of cystic fibrosis carrier than genotyping. There is a significant high reproductive risk when targeted panels are used.
We recommend to study the CFTR gene by NGS for the cystic fibrosis carrier screening on sperm donors to reduce the risk of having offspring affected.
Trial registration number: N/A

P-522 Effects of the Differences in Trophectoderm (TE) Biopsy Procedures on the Results of Next-Generation Sequencing (NGS) Analysis

K. Takeuchi[1], Y. Kuwatsuru[2], Y. Kuroki[2], Y. Fukumoto[2], M. Tokudome[2], H. Moewaki[2], E. Hashimoto[2], M. Watanabe[2], T. Iwakawa[1], T. Tabira[3], T. Kato[4], H. Kurahashi[4], M. Takeuchi[3]

[1]Takeuchi Ladies Clinic / Infertility Center, Infertility, Aira-shi- Kagoshima-, Japan ;
[2]Takeuchi Ladies Clinic / Infertility Center, laboratory, Aira-shi- Kagoshima-, Japan ;
[3]Takeuchi Ladies Clinic / Infertility Center, Gynecology, Aira-shi- Kagoshima-, Japan ;
[4]Fujita Health University, Division of Molecular Genetics. Institute for Comprehensive Medical Science, Toyoake-shi- Aichi, Japan

Study question: We examined how differences in TE biopsy procedures affect the incidence of chromosomal abnormalities, embryo transfer rate, and embryo mosaicism based on NGS analysis.
Summary answer: Of 204 embryos, 53 (25.9%) were appropriate for transfer, while 37 (18.1%) were completely normal. Embryo mosaicism was less frequent when more cells were biopsied.
What is known already: According to recent studies, results for NGS-based preimplantation genetic testing (PGT) and incidences of embryo mosaicism differ depending on facilities and procedures. Currently, we are performing embryo biopsies with a laser procedure, but this procedure has yielded a certain

percentage of mosaic embryos. Therefore, we considered it necessary to re-examine the effects of different TE biopsy procedures.
Study design, size, duration: The subjects comprised 18 patients (204 embryos) who underwent NGS-based PGT for structural rearrangements (PGT-SR) from 2016 to 2019. In addition, 24 surplus embryos were subjected to rebiopsy and diagnosed with NGS. The average age of patients at oocyte retrieval was 35.1 ± 2.5 years.
Participants/materials, setting, methods: Analysis results were examined retrospectively. In addition, we performed three patterns of TE biopsy: (A) excessive laser irradiation of cells, (B) no washing of the cells obtained by biopsy during tubing, and (C) the flicking method. These results were compared with those obtained previously.
Main results and the role of chance: The rate of obtaining a normal embryo was 18.1% (37/204), while that of obtaining embryos appropriate for transfer in accordance with ESHRE regulations was 25.9% (53/204). The incidence of a mosaic pattern was 26.4% (54/204). Besides structural abnormalities, many abnormalities were found in chromosomes 4, 15, 16, 21 and 22.

Analysis of the rebiopsied embryos showed that a mosaic pattern occurred in two samples with small numbers of collected cells in A, with no other effects observed. In B, a mosaic pattern occurred in two samples, with an overall increase of noise observed. In C, fewer mosaic patterns were observed in all embryos. However, the average number of cells collected with the flicking method and the laser procedure was 8.5 and 5.1, respectively, suggesting that the number of cells available for TE biopsy affected the occurrence of a mosaic pattern.
Limitations, reasons for caution: The sites of mosaic patterns may vary based on which site of the embryo is biopsied.
Little data is available because only PGT-SR has been approved in Japan.
Wider implications of the findings: The flicking method seemed to produce fewer mosaic patterns. More samples remained unaffected by excessive laser irradiation, suggesting cell numbers available for TE biopsy affected the occurrence of mosaic patterns. In our hospital, we perform TE biopsy under conditions where we can obtain more TE cells by extending culture periods.
Trial registration number: not applicable

P-523 Laser-assisted trophectoderm biopsy does not affect the embryo ploidy and reproductive outcomes in following single euploid embryo transfer

J.Y. Hsieh[1], Y.P. Chang[1], T.H. Chuang[1], M.J. Lee[1], H.L. Wang[1], H.H. Lai[1]

[1]Stork Ladies Clinic, Stork fertility center, Hsinchu, Taiwan R.O.C.

Study question: Does laser-assisted trophectoderm biopsy affect the embryo ploidy in preimplantation genetic testing for aneuploidy (PGT-A) cycles and reproductive outcomes in following single euploid embryo transfer?
Summary answer: Laser-assisted trophectoderm biopsy does not affect the embryo ploidy and following reproductive outcomes.
What is known already: The laser plays an important role in assisted reproductive technology, such as assisted hatching and embryo biopsy. High energy light is emitted by laser and the derived heat dissolves cells, thus making cell separation easier and convenient. Previous studies indicated that degradation of DNA occurs at high temperature, which makes the double strand break and disintegrate. Laser-assisted trophectoderm (TE) biopsy is still an invasive intervention to the embryos, whether the derived thermal effect impairs the embryo genetic materials and implantation capacity is not known already.
Study design, size, duration: The data was retrospectively collected from January to December in 2018, 1303 blastocysts were analyzed. The methods of TE biopsy were classified into laser-assisted (LA) and non laser-assisted (non LA) biopsy groups, and the ploidy states of embryos between the two groups were compared. Only patients with following single euploid embryo transfers were included in the analysis of reproductive outcomes.
Participants/materials, setting, methods: The output of laser was 400 mW within 0.2-0.24 msec. The biopsies were tested via Veriseq PGT-A (Illumina) and analyzed by BlueFuse Multi. The comparison of embryo ploidies between LA and non-LA groups was by age (<35, 35-37, 38-40, >40 years), and by embryo morphology: good (AA, AB, BA), median (BB), and fair (BC, AC). The definitions of euploid, mosaic, and aneuploid were based on aneuploid percentage: [euploid] <20%, [mosaic] 20-79%, and [aneuploid] >79%.
Main results and the role of chance: No significant difference was observed in ploidy distribution between LA and non-LA groups in overall patients (p=0.10). Furthermore, no significant difference was found in mosaic and aneuploid rates between the two biopsy groups in different age spans. Divided by embryo morphology, there were no significant differences in ploidy distribution between the two biopsy groups within the same morphologic grading: [good] mosaic rate (p=0.92) and aneuploid rate (p=0.94); [median] mosaic rate (p=0.57) and aneuploid rate (p=0.66); [fair] mosaic rate (p=0.68) and aneuploid rate (p=0.48). In the analysis of reproductive outcomes, biochemical pregnancy rate (BPR), clinical pregnancy rate (CPR), implantation rate (IR), and miscarriage rate (MR) between the two biopsy groups were also comparable: [BPR] 65.9% vs. 71.5% (p=0.37); [CPR] 56.0% vs. 59.2% (p=0.63); [IR] 53.8% vs. 56.2% (p=0.73); [MR] 2.2% vs. 3.8% (p=0.5).
Limitations, reasons for caution: The main limitation of this study is the retrospective nature. The challenges of PGT-A may occur during both the manipulation and ploidy testing, including biopsied cell number or amplification artifacts.
Wider implications of the findings: The study showed that utilization of laser for TE biopsy does not affect the embryo ploidy and reproductive outcomes, and routinely using laser-assisted biopsy would not increase the risk of embryo damage.
Trial registration number: not applicable

P-524 A randomized controlled trial comparing the two trophectoderm biopsy protocols for preimplantation genetic testing for aneuploidies (PGT-A): a prospective sibling oocyte study

[6]Igenomix Italia, Genetics, Marostica, Italy

Study question: Is there any difference between the two most frequently used biopsytechniques in PGT-A cycles?
Summary answer: Embryo quality was superior in the direct trophectoderm biopsy approach without cleavage stage zona opening while blastocyst biopsied rate was equivalent.
What is known already: Selecting euploid embryos for embryo transfer during assisted reproductive treatment, preimplantation genetic testing for aneuploidy has now been increasingly utilized worldwide. Nowadays with improving technology, trophectoderm biopsy (TB) application at blastocyst-stage and subsequent comprehensive genetic screening by next generation sequencing is well applied and adopted in PGT-A cycles in clinical practice. Based on zona pellucida handling where differ by the time of zona opening before biopsy, there are two approaches for TB. However, there is not enough comparative evidence in the literature indicating the superiority of one approach to another.
Study design, size, duration: This prospective sibling oocyte study was performed in British Cyprus IVF Hospital between May and December 2019. The inclusion criteria were: ≥ 6 fertilised zygotes using fresh donor or own oocytes, PGT-A cycles using NGS by TB. Primary outcome measure is the rate of biopsied blastocysts out of the number of utilized MII. Sample size was set at 1224 biopsied embryos to exclude a difference of 7% between the two groups (alfa 0.05, beta 0.80).
Participants/materials, setting, methods: This interim analysis includes 58 cycles and 686 embryos. For each cycle, normally fertilised oocytes were randomly assigned into two groups. Embryos in group-I had zona opening with laser on day 3 to make trophectoderm cells herniate through the hole before the biopsy while group-II contains embryos without zona opening. Main secondary outcome measures were blastocyst morphology at the time of biopsy, number of biopsied cells, time of biopsy procedure and genetic analysis outcomes.
Main results and the role of chance: In this study, 58 patients are taken into analysis consisting total of 686 embryos (355 embryos in Group I, 331 embryos in group II). Between the study groups, no statically significant difference in the number of 2PN (p= 0.852), blastocysts developmental rate (p=0.724), total number biopsied embryos (3.41±2.30 vs 2.91±2.19, p= 0.233), average biopsy time per embryo (p= 0.223) and the biopsied cell count (p= 0.151) were

observed. Regarding to the biopsied embryo quality on day 5 and 6, the proportions of embryos in three categories (best, good, poor) were found to be statistically significant different among study groups (p=0.044). In detail, the higher proportions of best quality embryos in group II (p=0.015) and the good quality embryos in group I (p=0.022) were observed while no statistically significant differences were found regarding poor quality embryos (p=0.565). Furthermore, between the groups the percentage of euploidy rate in analysed embryos did not show statically significant difference (51.6 vs 53.4 %, p= 0.758). In detail, there was not significant discrepancy in no results rate (1.3 vs 1.7 %, p=0.750), type of aneuploidies as mosaicism (6.5 vs 9.3 %, p= 0.557) and complex aneuploidies (24.7 vs 20.4 %, p= 0.564) among groups

Limitations, reasons for caution: This is an interim and our results should be taken as preliminary; therefore, the clinical significance of the finding needs to be validated in the planned sample size. However, the study is already sufficiently powered to exclude major differences in the primary outcome measure.

Wider implications of the findings: This is the first study to evaluate different biopsy approaches by using sibling oocyte design that could assist embryologist while seeking more convenient approach during embryo biopsy for PGS if adequate evidence reached.

Trial registration number: non applicable

P-525 Do maternal and embryo MTHFR gene polymorphisms have any influence on embryo chromosomal abnormalities and the ongoing pregnancy rate?

G. Eva M.[1], R. Morales[1], H. Codina[1], A. Cascales[1], B. Lledo[1], J.A. Ortiz[1], J. Ten[2], J. Llacer[3], A. Bernabeu[3], R. Bernabeu[3]

[1]Instituto Bernabeu, Molecular Biology and Genetics, Alicante, Spain ;
[2]Instituto Bernabeu, Embriology laboratory, Alicante, Spain ;
[3]Instituto Bernabeu, Reproductive Medicine, Alicante, Spain

Study question: Is there any relationship between maternal and embryo *MTHFR* polymorphisms (c.677C>T and c.1298A>C) and embryo chromosomal abnormalities or the ongoing pregnancy rate of euploid embryos?

Summary answer: Maternal and embryo *MTHFR* polymorphisms do not increase the aneuploidy rate, as well as they are not correlated with the ongoing pregnancy rate.

What is known already: MTHFR enzyme is involved in folic acid metabolism and play a role in reproduction. Many investigations have linked point mutations in the *MTHFR* gene with embryo alterations and problems in pregnancy. The single-nucleotide-polymorphisms 677C>T and 1298A>C are the most relevant. Maternal genotype has been associated with embryo aneuploidy rate in previous studies. Moreover, a negative correlation between the embryo genotype and the implantation rate has been described. However, it is still a controversial issue. The aim of our study was to investigate the effect on embryo aneuploidies and mosaicism and the correlation with pregnancy rate.

Study design, size, duration: *MTHFR* genotype (677C>T and 1298A>C) was analysed in 77 women who performed an IVF/ICSI cycle with their own oocytes and also carried out a preimplantation genetic testing for aneuploidy (PGT-A) from January 2016 until December 2018. Moreover, *MTHFR* genotype was analysed in the 189 embryos biopsied in the PGT-A cycles from these patients. In addition, 218 DNA samples from trophoectoderm biopsies belonging to a different group of patients were also genotyped for *MTHFR* polymorphisms.

Participants/materials, setting, methods: *MTHFR* genotyping was determinated with TRF-plus Thrombosis Risk Panel (Elucigene Diagnostics). Embryo chromosomal analysis was performed using Agilent SurePrint G3-8x60K-CGH microarrays or Veriseq-NGS (Illumina), with previous whole genome amplification. The main parameters analysed among *MTHFR* genotypes (both in embryos and in patients were the embryo aneuploidy and mosaicism rate. Additionally, the ongoing pregnancy rate of euploid blastocysts (n=243) was assessed. The differences between groups were evaluated by chi-square and binary logistic regression and (SPSSv20.0).

Main results and the role of chance: The aneuploidy rates obtained were comparable in embryos coming from patients with homozygous normal genotype and those embryos from women with at least one mutated allele (54.7% in 677CC vs. 30.2% in 677CT/TT, p=0.058 and 37.8% in 1298AA vs. 42.7% in 1298AC/CC, p=0.212). Furthermore, no differences were observed in mosaicism rate (24.0% in 677CC vs. 13.8% in 677CT/TT, p=0.345 and 17.1% in 1298AA vs. 17.3% in 1298AC/CC, p=0.865).

If we consider the embryo *MTHFR* genotype, the aneuploidy rate was 22.3% in 677CC blastocysts vs. 15.7% in blastocysts with at least one mutated allele (p=0.464), and 17.9% in embryos 1298AA vs. 18.3% in embryos 1298AC/CC (p=0.988). On the other hand, the incidence of embryo mosaicism was 13.5% in 677CC group vs. 5.4% in 677CT/TT group (p=0.019) and 7.5% in 1298AA vs. 9.1% in 1298AC/CC group (p=0.817). The only significant difference was observed in mosaicism rate among 677C>T genotype.

The ongoing pregnancy rate was compared between different embryo genotypes and no differences were found (41.9% in 677CC vs. 39.5 in 677CT/TT, p= 0.611 and 37.4% in 1298AA vs. 43.6% in 1298AC/CC, p= 0.276). Morevoer, no differences were observed among different maternal genotypes.

Limitations, reasons for caution: The limited sample analysed precludes definite conclusions. Larger sample size studies are warranted to confirm our findings. Future studies focused on genes involved in embryo aneuploidy, implantation and pregnancy development are needed.

Wider implications of the findings: Our analysis suggests that neither maternal nor embryo MTHFR genotype influences the aneuploidy or ongoing pregnancy rate. The only correlation was observed in mosaicism rate among 677C>T embryo genotypes. Further research is need to clarify the role of this genotype on the processes that lead to mosaicism in the embryo.

Trial registration number: not applicable

P-526 Consistent results of non-invasive pre-implantation genetic testing for aneuploidy (niPGT-A) of human embryos using two different techniques for chromosomal analysis

B. Lledo[1], R. Morales[1], J.A. Ortiz[1], A. Rodriguez-Arnedo[2], J. Ten[2], J.C. Castillo[3], A. Bernabeu[3], J. Llacer[3], R. Bernabeu[3]

[1]Instituto Bernabeu, Molecular Biology, Alicante, Spain ;
[2]Instituto Bernabeu, Embriology, Alicante, Spain ;
[3]Instituto Bernabeu, Reproductive Medicine, Alicante, Spain

Study question: Are the results of niPGT-A similar when analysed with different genetic techniques?

Summary answer: Consistent results (diagnosis and concordance rate) are obtained with different genetic techniques used for niPGT-A, thus suggesting discordances might be attributable to mosaicism or DNA-contamination.

What is known already: The concept of niPGT-A has generated huge interest in reproductive medicine. Variable success and concordance rates have been reported and discordances seem related to embryonic mosaicism, favoured elimination of aneuploid cells, DNA contamination and the method used for analysis (amplification/detection). The niPGT-A efficacy has been restricted by technical complications associated with the low quantity and quality of the DNA, presenting technical challenges for genetic analysis. It is not clear which method is the most appropriate. The aim of this study was to assess the accuracy of niPGT-A by comparing two different chromosomal analysis techniques.

Study design, size, duration: A prospective blinded validation study was performed from September 2018 to December 2019, including 302 chromosomal analyses. Two hundred and seventy-six corresponded to trophectoderm biopsies (TE) from couples who attended our clinic for PGT-A and whose correspondent spent blastocyst medium (SBM) was evaluated by two methods. Eight blank-medium were evaluated for DNA contamination detection. Finally, to investigate the diagnostic discrepancies: TE-aneuploid embryos were thawed and re-analyzed using TE and inner cell mass (ICM) biopsies.

Participants/materials, setting, methods: Embryos were cultured in continuous media (Global Total LP) until D3, washed three times and cultured again until embryo biopsy. Embryos were biopsied on D5 or D6. TE analysis was carried out using Veriseq (Illumina®). Frozen euploid embryos according to the TE biopsy were thawed and transferred in the subsequent cycle. SBM collection was done following TE biopsy and samples were stored at -80°C. SBM chromosomal analysis was performed using Veriseq (Illumina®) and NICS (Yikon®).

Main results and the role of chance: We obtained genetic results in 96.8% of TE-samples vs 90.4% in SBM using both techniques(p>0.05). The mosaicism rate was higher in SBM (30.4% SBM-Yikon;28.3% SBM-Veriseq) compared to TE-biopsies (14.1%) (p= p=0.013; p=0.031) regardless of the technique used. We performed comparisons between both SBM techniques showing 95.2% of consistency in the diagnosis. Regarding diagnostic concordance (euploid-euploid vs aneuploid-aneuploid) between each SBM-technique and TE-biopsy, we obtained 74.6% SBM-Yikon vs 72.3% SBM-Veriseq. However, when we considered embryos

biopsied on D6 these rates reached up the 92.0% and 86.5%, respectively. Analysing the full chromosome concordance, the cytogenetic results were exactly the same as the TE-biopsy in 45.2% SBM-Yikon and 41.7% SBM-Veriseq. Moreover, in 20.1% SBM-Yikon and 23.3% SBM-Veriseq the results were discordant only in mosaicism diagnosis. The remaining were partial (22.6% SBM-Yikon vs 23.3% SBM-Veriseq) and complementary (4.8% SBM-Yikon vs 3.3% SBM-Veriseq) discordances. To identify the cause of discrepancies we reanalysed TE-aneuploid embryos, 55.6% of the discrepancies were due to DNA contamination (maternal origin), 22.2% to embryo mosaicism, 11.1% to low resolution in SBM-Yikon and 11.1% low resolution in both techniques. Finally, we analysed the IVF outcome, the ongoing pregnancy rate was 50% for TE-euploid-SBM-Yikon-aneuploid vs 33.3% TE-euploid-SBM-Veriseq-aneuploid.

Limitations, reasons for caution: The main limitation of the study is the sample size, especially for the subgroup analysis. Larger, prospective studies are warranted to draw definite conclusions on the accuracy of niPGT-A in representing the genetic constitution of the whole embryo with potential to improve pregnancy outcomes.

Wider implications of the findings: Diagnostic concordance between PGT-A and niPGT-A seems independent of the technique used for genetic analysis. Interestingly, concordance was higher for day-six-biopsied embryos. Therefore, niPGTA may be influenced by factors such as DNA contamination and embryo mosaicism. Optimization of culture conditions and medium retrieval constitutes potential targets to improve NIPGT-A reliability.

Trial registration number: NCT03879265

P-527 Morphine treatment prevents the X chromosome inactivation and maintains a long-term repression by SMCHD1 epigenetic regulator.

N. Subiran[1], I. Muñoa-Hoyos[1], M. Araola-Lasa[1], I. Urizar-Arenaza[1], M. Gianzo[1], J. Irazusta[1]

[1]University of Basque Country, Physiology, Bilbao, Spain

Study question: To elucidate how morphine can cause stable epigenetic changes on X-chromosome inactivation (XCI) process that can be memorized and persist in the long term.

Summary answer: Chronic morphine treatment prevents the XCI through PRC2 and *Dnmt1* in the short term and Smchd1 maintains this long-term repression in mESC and blastocysts.

What is known already: XCI is an important epigenetic process that exemplifies the developmentally controlled formation of silent chromatin, where one of the X chromosomes in females is inactivated for dosage compensation. The XCI involves several steps, which implies the initiation of chromosome-wide silencing by XIST, the formation of a repressive compartment through Polycomb complexes and finally the maintenance of the stable repression by DNA methylation and other epigenetic regulators in which SMCHD1 plays an important role. Although XCI is part of normal development, there is a big concern in understanding how environmental factors can cause stable epigenetic changes that lead to health problems.

Study design, size, duration: To evaluate if morphine can induce cellular epigenetic memory, OCT4-reported mESCs were chronically treated with morphine during 24h, 10^{-5}µM (P1). After morphine removal, mESCs were seeded and maintained in culture for 48h (P2) and 96h (P3). To elucidate the role of morphine in early embryo development, two cell- embryos stage were chronically treated with morphine for 24h and *in-vitro* cultured up to the blastocyst stage in the absence of morphine.

Participants/materials, setting, methods: Transcriptomic analyses and H3K27me3 genome wide distribution were carried out by RNA-Sequencing and Chip-Sequencing respectively. Validations were performed by RNA-RT-qPCR and Chip-RT-qPCR.

Main results and the role of chance: Dynamic transcriptional analyses identified a total of 932 differentially expressed genes (DEGs) at P1 and, in the absence of morphine, 1196 DEGs at P2 and 2138 DEGs at P3, providing strong evidence of the existence of transcriptional cellular memory induced by morphine. Chronic morphine led to a down-regulation of epigenetic regulators important for XCI, such as PCR2 complex and *Dnmt1* in the short term. High-throughput screening approaches showed up *Smchd1* as a key regulator of a long-term epigenetic cellular memory induced by morphine. Morphine caused a down-regulation of *Smchd1* gene expression that can persist over the time after morphine withdrawal. ChIP-sequencing analysis confirms a decrease of H3K27me3 enrichment on the whole coverage of the X chromosome. The *Smchd1* gene expression was also down-regulated in *in-vitro*-morphine-treated blastocysts, preventing the XCI in early embryo. This is consistent with the increase in blastocyst rate observed after morphine chronic treatment. Our results clearly prove that chronic morphine treatment prevents the XCI, modifying PRC2 and *Dnmt1* gene expression in the short term and maintaining the repression upon *Smchd1* in the long term. SMCHD1 plays a role as a key regulator of epigenetic cellular memory induced by morphine, conferring to the cell a stable activate state

Limitations, reasons for caution: To perform the *in-vitro* analysis.

Wider implications of the findings: Morphine alters normal X chromosome-wide silencing, providing insights into the epigenetic mechanisms underlying cell memory induced by morphine and establishing the bases to understand how environmental factors can cause epigenetic changes, which leads to health problems or diseases.

Trial registration number: DTS18/00142

P-528 Cigarette smoke alters the expression of genes involved in the inflammatory response in mouse uterus

M.C. Budani[1], E. Carletti[2], G.M. Tiboni[2]

[1]University "G. d'Annunzio" Chieti-Pescara- Italy, Department of Medicine and Aging Sciences, Chieti, Italy ;
[2]University 'G. d'Annunzio' Chieti-Pescara- Italy, Department of Medical- Oral and Biotechnological Sciences, Chieti, Italy

Study question: What are the effects of a whole body exposure to cigarette smoke on stress and toxicity pathways in the mouse uterus?

Summary answer: The *in vivo* cigarette smoke exposure induced an over-expression of pro-inflammatory cytokines and a down-regulation of extracellular matrix metallopeptidases in mouse uterus.

What is known already: Cigarette smoking was associated to a lower chance of clinical pregnancy and live birth rates, and a dramatic increase in the incidence of spontaneous miscarriages in women. The noxious effects of cigarette smoke exposure have been studied especially in the ovaries. Research linking smoking to uterus damage mainly relies on studies *in vitro* testing a single cigarette smoke-derived component. Smoke components seemed to exert adverse effects on endometrial angiogenesis in human primary endometrial cells and in mouse endometrial cells as well and on uterine cells proliferation with a role in decreasing the endometrial thickness.

Study design, size, duration: Female C57BL/6 mice (aged 8 weeks) were *in vivo* exposed to the smoke originated by 3 cigarettes once a day, 7 days/week for 2 months using a specific whole-body mainstream exposure system. Control mice were placed in a restrainer and exposed to room air only for the same time period.

Participants/materials, setting, methods: At the end of exposure, mice were euthanized and the uteri collected. From these, the extracted RNA was used to perform a real-time PCR using an array consisting of a panel of 84 key genes involved in stress and toxicity pathways. Representative genes with >2 fold differential expression identified in the array were validated by real-time PCR gene expression assays.

Main results and the role of chance: No adverse changes in body conditions and atypical behaviors were noted as result of cigarette smoke exposure. The genes that were significantly up-regulated in the gene array were as follows: reactive protein C (Crp, p-value < 0.05), growth arrest and DNA-damage-inducible45γ (Gadd45γ, p-value < 0.05), interferon γ (Ifnγ, p-value < 0.01), and interleukin1α (Il1α, p-value < 0.005). Cigarette smoke was associated in the gene array with a down regulation of matrix metallopeptidase-9 (Mmp9, p-value < 0.05) compared to control group. The qRT-PCR analysis validated the differential expression profile of the representative genes deregulated at least two folds in the array.

Limitations, reasons for caution: The experimental nature of the study limits the capacity to extrapolate to the human field.

Wider implications of the findings: This is the first study showing the capacity of *in vivo* cigarette smoke exposure in inducing an over-expression of inflammatory genes and concomitant down-expression of MMP9 in mouse uterus. These data support the idea that inflammation cigarette smoke-derived may interfere with the tissue remodeling process responsible for the embryo implantation.

Trial registration number: not applicable

P-529 To flick or to pull? The effect of trophectoderm biopsy methodology on mosaicism incidence

L. Coll[1], M. Parriego[1], S. Mateo[1], B. Carrasco[1], S. García[1], M. Boada[1], B. Coroleu[1], A. Veiga[1]

[1]Dexeus Mujer, Obstetrics- Gynecology- and Reproductive Medicine, Barcelona, Spain

Study question: Is mosaicism incidence related to differences in biopsy methodology?
Summary answer: Mosaicism incidence is not related neither to the number of laser pulses during biopsy nor to the use of flicking/pulling methodology.
What is known already: Chromosomal mosaicism may be an inherent feature in preimplantation human embryos. However, reported incidences vary widely among different IVF and PGT-A settings. Although such differences could be attributed to the use of different diagnostic methodologies and criteria, settings with the same diagnostic platforms have observed different mosaicism incidence. This points to the fact that extrinsic factors can also have an impact. Moreover, it has been speculated that the biopsy procedure itself and biopsied sample handling could induce the generation of artefactual mosaicism leading to an overestimation of such phenomenon.
Study design, size, duration: This is a prospective observational study analysing the chromosomal constitution of 484 trophectoderm biopsies from PGT-A cycles performed from May 2019 to January 2020 in a single IVF setting. Mosaicism incidence was evaluated in relation to different biopsy methodologies.
Participants/materials, setting, methods: Trophectoderm biopsies were performed by flicking or pulling depending on embryo characteristics and analyzed by NGS. Data on the quality of the biopsied sample (with or without lysed cells) was analysed with regards to biopsy methodology. Additionally, the number of laser pulses and the biopsy methodology (flicking or pulling) were analyzed for mosaicism incidence. Time from freezing to amplification was also assessed in relation to mosaicism.
Main results and the role of chance: In 73.8% of cases (357/484), ≤3 laser pulses were needed to obtain a biopsy. Moreover, in 34.3% of biopsies (166/484), the trophectoderm sample was obtained by pulling methodology vs 65.7% (318/484) in which the methodology was flicking. The percentage of samples showing signs of lysis was higher when flicking methodology was used compared to pulling (20.8% vs 10.8%; p-value = 0.01).
The incidence of mosaicism did not vary among different biopsy operators (p=0.1). In relation to biopsy methodology, similar mosaicism incidence was observed for pulling and flicking methods (13.9% vs 16.0%; p-value =0.5). The number of laser pulses applied was not related to mosaicism either (3.30±0.75 in mosaic embryos vs 3.33±0.66 in non-mosaic embryos; p-value = 0.67).
Concerning biopsied sample storage, no differences were observed regarding the elapsed time from biopsy to amplification (10.4d ±10.4 in mosaic embryos vs 11.0 d ±13.8; p-value=0.7).
Limitations, reasons for caution: These are preliminary results. For a deeper analysis controlling for potential confounding factors more data are needed. Embryologists were homogeneously trained and followed the same SOPs. As a consequence, there was small variability in biopsy methodology.
Wider implications of the findings: Each PGT setting can choose its own procedures as long as trophectoderm biopsy is performed within homogeneous methodology and high quality standards. However, it remains to be assessed whether different biopsy methodologies have an effect on embryo reproductive outcome.
Trial registration number: Not applicable

P-530 Euploidy and embryo quality with single step medium with or without renewal post assisted hatching (AH) in a PGT-A program using Embryoscope dishes.

A. Delgado Mendive[1], A. Mercader[1], L. Escrich[1], D. Beltran[1], A. Tejera[1], N. Grau[1], F. Insua[1], M. Nohales[1], A. Mifsud[1]

[1]Instituto Universitario IVI Valencia, ivf and pgd laboratory, Valencia, Spain

Study question: Is the culture medium affected by the heating of the EmbryoscopeÒ dish after the AH and how could it influence embryo development and euploidy rates?
Summary answer: The results regarding euploidy and embryo quality between both groups were similar and AH did not seem to modify the conditions of the culture medium.
What is known already: According to the embryonic culture protocol, the culture medium is usually renewed on day 3 of development, although currently the use of a single step medium makes it unnecessary. In the past, different techniques were used to perform AH. Nowadays in most laboratories, the use of laser has been unified. There have been studies on the technique and its usefulness, but due to its heterogeneity, there have been no conclusive results. In this way there are no specific data related to the heating of the dishes and the culture medium and their effect on the results.
Study design, size, duration: Three months retrospective study (October 2017- December 2017) with 190 patients of the PGT-A program. They were divided in two post-hatching categories on day 3: AHR (assisted hatching renewal) and AHNR (assisted hatching no renewal).
Participants/materials, setting, methods: The AHNR group included 94 patients and AHR group included 96 patients. The AH was performed by laser Octax Ò on day 3 directly on the EmbryoscopeÒ dish and the biopsy was done at blastocyst stage. Chromosomal analysis method was NGS (Thermo Scientific, INC., USA). For embryonic categorization, the ASEBIR classification was used being A cathegory the best prognosis blastocyst and D the worst. The statistical analysis was performed by Fisher's exact test.
Main results and the role of chance: A total of 1505 embryos were obtained, of which 238 were biopsied in the AHNR group and 242 in the AHR group. For the AHNR group, 105 blastocysts were euploid (44.12%) and 133 aneuploid (55.88%). Regarding the 242 of the AHR group, 110 were euploid (45.45%) and 132 aneuploid (54.55%). With reference to the the morphology by categories, the data for AHNR were A: 5.35%; B: 48.18%; C: 27.26%; D: 19.21% and for AHR A: 5.97%; B: 49.61%; C: 26.25% and D: 18.17%. No statistical differences were found between both groups (p>0.05).

Thus, it seems that renewing the culture medium on day three of development using single step medium does not provide an improvement with respect to the morphology of the blastocysts, as well as regarding the percentage of euploidy. Therefore, we can conclude that the single step medium is a reliable option for the PGT-A program since the AH does not modify the culture conditions.
Limitations, reasons for caution: Retrospective study and the limited number of cases. Further studies are necessary to corroborate these results. In addition, study conditions may vary from other laboratories, for example: culture conditions, the power of the laser and the medium used for embryo culture. Therefore, results may not be comparable between laboratories.
Wider implications of the findings: The introduction in the laboratories of the time-lapse technology with new and modern dishes as well as the use of one step media, has meant a change in the working protocols. The combination of both factors with AH requires more studies that show the possible influence on clinical outcomes.
Trial registration number: 1503-VLC-017-AM

P-531 Differential endometrium DNA methylation and gene expression patterns underline mechanisms of reproductive failure in women with unexplained recurrent miscarriage (RM) and recurrent implantation failure (RIF)

R. Zhang[1], S.W. Hung[1], X. Chen[2], T.C. Li[2], C.C. Wang[1]

[1]Chinese University of Hong Kong, Obstetrics and Gynecology, Hong Kong, Hong Kong ;
[2]Prince of Wales Hospital- The Chinese University of Hong Kong, ART unit-Obstetrics and Gynecology, Hong Kong, Hong Kong

Study question: What is the underlying mechanism cause the differential gene expression in endometrium in women with unexplained RM and RIF, and causes their endometrial receptivity disorder?
Summary answer: Differential endometrium DNA methylation-regulated genes for reproductive failure were identified. RIF and RM were associated with abnormalities in endometrium cell adhesion and metabolic pathway, respectively.
What is known already: Unexplained RM and RIF are two major challenging reproductive failure attribute to endometrium. Those women have normal uterus, parental karyotype and basal hormone level; negative for autoimmune antibodies and thromobophilia, uNK and plasma cells, and even good embryo quality. Abnormal endometrium in molecular levels may contribute to the failure. Our previous study of endometrium RNA sequencing (RNAseq) identified differential transcriptome profiles between RM and RIF. Epigenetics can modify gene expression without change in gene structure. Evidences have shown that

abnormal DNA methylation modification will result in abnormal endometrial genes expression and thereby reproductive failure.
Study design, size, duration: This is a prospective study of DNA methylation and gene expression of endometrium in genomic scale. Fertile control women and unexplained RM and RIF undergoing IVF treatment were recruited. 5 endometrium samples in each group were included for gene discovery study. Another 10 endometrial samples in each group were included for validation and functional studies. All the samples were collected and analysed in 2019.
Participants/materials, setting, methods: Endometrial samples were obtained from control fertile women, and women with RM and RIF. All samples were collected on LH+7 in natural cycle and stored in -80°C before assays. Whole genome bisulfite sequencing (WGBS) was used to assess DNA methylation and RNA sequencing (RNAseq) was used to assess transcriptome pattern in the same endometrium samples. Differential methylated genes (DMG) were selected and target methylation specific-PCR (MS-PCR), RT-qPCR and immunostaining were used to validate the results.
Main results and the role of chance: RNAseq identified 969 differentially expressed genes (DEGs) between RIF and controls, 370 DEGs between RM and controls, and 872 DEGs between RM and RIF. WGBS detected higher overall methylation level in RIF and controls than RM. 157989 differentially methylated regions (DMRs) were found in RM versus controls, 85834DMRs in RIF versus controls, and 133116 DMRs in RIF versus RM in all genome regions. If promoter region only, we found 79 differentially methylated genes (DMGs) in RIF versus controls, and 51 DMGs in RM versus controls, and 76 DMGs in RM versus RIF. For RIF, most DMGs were enriched in calcium ion binding and plasma membrane mainly into cell adhesion pathway. For RM, most DMGs were enriched in protein binding, integral component of membrane and mitotic cell cycle mainly into metabolic pathway. Based on biological and molecular functions, 4 DMGs including AQP3, AURKB, CRISP2, CRYBB2 were chosen for validation and functional studies.
Limitations, reasons for caution: Although we attempted to eliminate embryo factors by embryo morphology grading before transfer, molecular composition of the embryos was still unknown. Apart from DNA methylation, other epigenetic mechanisms, such as histone acetylation and methylation; and non-coding RNA, on the endometrium abnormalities are still not known.
Wider implications of the findings: Important endometrium genes regulated by DNA methylation for the reproductive failure were identified. This not only increases the understanding one of the underlying molecular mechanism for the conditions, but also provides potential therapeutic targets to improve the pregnancy outcomes in these women.
Trial registration number: CREC 2016.160-T

P-532 Identification of a unique epigenetic profile in women with diminished ovarian reserve

K.W. Olsen[1], J. Castillo-Fernandez[2], A.C.H. Chan[3], N.L.C. Freiesleben[4], A. Zedeler[5], M. Bungum[6], A. Cardona[7], J. Perry[7], S. Skouby[1], R. Borup[3], E.R. Hoffmann[3], K. Gavin[2], M.L. Grøndahl[1]

Study question: Does the epigenetic profile of mural granulosa cells (MGC) and leukocytes from women with diminished ovarian reserve (DOR) differ from other women?
Summary answer: MGC from human ovarian follicles have a distinctive epigenetic profile in women with DOR. The same does not apply for leukocytes.
What is known already: DOR is defined as a reduced number of oocytes and can be *physiological* due to advanced reproductive age or *pathological* due to premature loss of fertility. Previous studies have found an increase in apoptosis of MGC from women with DOR (Fan et al. 2019) and we have previously shown thatMGC have a distinctive epigenetic ageing profile compared with other somatic cell types (Olsen et al. under review). But whether the MGC from women with DOR differ from MGC from other women is not known.
Study design, size, duration: Multicenter cohort study based on a retrospective analysis of prospectively collected data (September 2016 – June 2018) and material (blood and MGC) derived from 119 healthy women undergoing IVF or ICSI treatment following controlled ovarian stimulation with a standard gonadotropin-releasing hormone antagonist protocol. The public fertility clinics at the Copenhagen University Hospitals in Herlev and Hvidovre, Stork IVF clinic and the fertility clinic at Skåne University Hospital included patients in the study.
Participants/materials, setting, methods: MGC were obtained from women with varying ovarian reserve status (defined from age dependent anti-Müllerian hormone (AMH) levels) by isolation from pooled follicles immediately after oocyte retrieval. DNA from the MGC aggregates was extracted and analysed with the Illumina EPIC array, at the Human Genotyping Facility Genetic Laboratory, Dept. of Internal Medicine Erasmus MC Rotterdam. Subsequently, the data went through a bioinformatic analysis. All analysis included adjustment for chronological age.
Main results and the role of chance: None of the epigenetic clock tools that were applied showed an association between age acceleration and ovarian reserve in either cell type. Performing a differential DNA methylation variability analysis by comparing DOR or high ovarian reserve samples to controls (normal ovarian reserve), differential variability between DOR and normal samples was observed at 4,199 CpGs in MGC, while only 447 between high and normal (FDR < 0.05). Regardless of ovarian reserve, very few signals were detected in leukocytes and no overlaps with the signals in MGC were found. Several genes central to folliculogenesis, i.e. inhibin subunit beta B (*INHBB), AMH,* insulin-like growth factor 2 (*IGF2*), were associated with variably methylated CpGs. Gene ontology analysis of genes associated with the variable CpGs in DOR in MGC revealed an enrichment for categories related to cell-to-cell adhesion ($p<0.001$). Furthermore, we found a higher number of epimutations in the MGC from women with DOR.
Limitations, reasons for caution: The granulosa cells were collected during ovarian stimulation which may influence DNA methylation. We were not able to correct for the FSH dose. However, we have previously shown no association between FSH dose and DNA methylation profile.
Wider implications of the findings: Clarification of a potential unstable methylome and epigenetic dysfunction in MGC being associated with the poor ovarian reserve found in women with DOR may be important for future treatment and prevention strategies.
Trial registration number: not applicable

P-533 Preferential allelic segregation of DNA triplet repeat expansion on PGT-M embryos from Myotonic Dystrophy type 1 and Huntington´s disease

P. Villa[1], R. Quintana[2], Q. Ramiro[3], M. Sandra[4], J.V. Martinez-Sanchis[5], M. De la Orden[5], I. Moya[5], T. García-Gimeno[3], A. Monzo[3]

[1]La Fe University Hospital-Joint First authors, Women's Health Area, Valencia, Spain ;
[2]La Fe University Hospital-Joint First authors, Women's Health Area, Valencia, Spain ;
[3]La Fe University Hospital, Human Reproduction Unit- PGD-Unit, Valencia, Spain ;
[4]La Fe University Hospital, Department of Genetics, Valencia, Spain ;
[5]La Fe University Hospital, Human Reproduction Unit. IVF Lab, Valencia, Spain

Study question: Are there any differences in parental origin of triplet repeat expansion in human embryos after PGT-M from Myotonic Dystrophy type 1 or Huntington's Disease carriers?
Summary answer: Triplet repeat expansion mutations in DMPK and HTT genes have a preferential gender pattern of transmission to embryo yield.
What is known already: Myotonic dystrophy 1 (MD1) and Huntington's disease (HD) are progressive autosomal dominant neurodegenerative disorders caused by a CGG or CAG repeat expansion in the *DMPK* or *HTT* genes, respectively. Preimplantation genetic testing (PGT) is a diagnostic procedure available for these individuals, because they carry a higher risk of transmitting this genetic condition to their offspring. It has been proposed preferential expansion depending on the gender parental carrier.

Study design, size, duration: Information about 82 PGT-M cycles performed from 2011 to 2019 in 14 MD1 and 18 HD couples was collected retrospectively. MD1: 21 PGT-M cycles in 9 female-carrier and 9 cycles in 5 male-carrier couples. HD: 39 cycles in 14 female-carrier and 13 cycles in 5 male-carrier couples.
Participants/materials, setting, methods: All procedures were performed at the Human Reproduction and Genetic Units in a tertiary University Hospital. PGT provided direct testing of embryos obtained after intracytoplasmic sperm injection, using polymerase chain reaction PCR of microsatellite markers (indirect method) and by expansion amplification (direct method) as the genetic testing protocol to detect the risk allele and the expanded CTG/CAG repeat in 366 day 3 embryos, 167 from MD1 and 199 from HD.
Main results and the role of chance: The percentage of non-affected embryos related to the parent-of-origin in DM1 was 35.5% (43/121) in female carriers and 19.6% (9/46) in male carriers. PGT-M in HD resulted in 39.6% (67/169) in female carriers and 16.7% (5/30) in male carriers.
In both conditions, we observed significantly higher ratio of non-affected embryos in female carriers when compared to male carriers. (38%: 110/290 vs 18.4% (14/76), respectively. Chi square test P=0.026).
Of the total sample, 38 embryos (10.4%) were misdiagnosed, mainly due to allele drop out (ADO) or amplification failure.
Limitations, reasons for caution: This study has a retrospective design. The number of patients is far low in some groups, although the number of embryos is adequate for statistical tests. Misdiagnosed embryos has a potential to bias results.
Wider implications of the findings: In both conditions, the observed non-affected embryos rate is far below of the theorical 50% expected, according to autosomal dominant inheritance. Our results must be taken into account in order to offer the appropriate genetic counseling in carrier patients before PGT-M.
Trial registration number: Not applicable

P-534 Probability of producing at least one healthy transferable cleavage-stage embryo after preimplantation genetic testing for fragile X syndrome

C. Sonigo[1], M. Sadoun[1], L. Hester[2], J. Steffann[3], A. Benoit[1], V. Gallot[1], N. Frydman[2], M. Grynberg[1]

[1]Antoine Béclère Hospital, Reproductive Medicine and fertility preservation, Clamart, France ;
[2]Antoine Béclère Hospital, reproductive biology unit, Clamart, France ;
[3]Necker Enfants Malades Hospital, Genetic Unit, Paris, France

Study question: What are the chances of obtaining a healthy transferable cleavage-stage embryo according to the number of mature oocytes in *FMR1*-mutated carriers undergoing preimplantation genetic testing?
Summary answer: Fifteen mature oocytes provide 69% chance of obtaining at least one healthy embryo after preimplantation genetic testing (PGT) in *FMR1*-mutated carriers.
What is known already: PGT may be an option to achieve a pregnancy with a healthy baby for *FMR1* mutation carriers. In addition, *FMR1* premutation is associated with a higher risk of diminished ovarian reserve and premature ovarian insufficiency. As a consequence, oocytes vitrification may be offer to these young women as a method of fertility preservation. The cryopreserved oocytes can then be used to achieve pregnancy, with or without PGT. The number of vitrified oocytes to allow the transfer of a healthy embryo following PGT has never been investigated.
Study design, size, duration: This is a monocentric retrospective observational study analyzing 33 premutated (n=17) or fully mutated (n=16) candidates for PGT for fragile X syndrome between 2006 and 2018.
In the meantime, 15 *FMR1* premutated carriers underwent oocyte vitrification for fertility preservation (FP).
Participants/materials, setting, methods: Eighty-five PGT cycles were performed for fragile X syndrome, 43 in premutated patients and 42 in fully mutated women. For each cycle, we estimated the number of mature oocytes for obtaining at least one healthy embryo after PGT using Visual Basic for Applications (VBA) analysis.
Main results and the role of chance: Overall, the total number of retrieved and mature oocytes were 12.1 ± 6.1 and 9.4 ± 5.2 respectively. Among the 7.2 ± 4.6 day-3 embryos obtained, a mean number of 3.4 ± 3.0 embryos were morphologically eligible for biopsy, leading to 1.5 ± 1.6 healthy embryo on average. The obtaining of 3 mature oocytes were associated with 28.6% chance of having at least one healthy embryo. This probability increased significantly with the number of mature oocytes. Ten mature oocytes led to more than 60% chance of obtaining a healthy embryo. This probability did not exceed 69% and plateaued from 15 metaphase II oocytes collected. In the FP group, the mean number of mature oocytes vitrified was 5.1 ± 3.6 per FP cycle. On average, 3 cycles of ovarian stimulation were performed per patient leading to a mean of 15 mature oocytes vitrified**.**
Limitations, reasons for caution: This study is retrospective, analyzing a limited number of cycles, without possibility to determine threshold values of oocytes that might predict the number healthy embryo.
Wider implications of the findings:
The present results should be confirmed by further analyzes. Patients included in a fresh PGT cycle usually show higher values of ovarian reserve tests when compared with *FMR1* premutated carriers seeking FP. Whether the oocyte competence differs in these groups of patients is unknown. This information might balance our conclusion.
Trial registration number: not applicable

P-535 Antral follicle responsiveness to exogenous FSH is not altered in FMR1 mutation carriers undergoing stimulation for preimplantation genetic testing.

M. Grynberg[1], M. Pinto[1], A. Naouel[1], V. Gallots[1], A. Mayeur[2], C. Sonigo[1]

[1]Hôpital Antoine Béclère, Reproductive Medicine & Fertility Preservation, Clamart, France ;
[2]Hôpital Antoine Béclère, Reproductive biology unit, Clamart, France

Study question: Is antral follicle responsiveness to exogenous FSH, assessed by the follicular output rate (FORT), altered in *FMR1*-mutation carriers?
Summary answer: FMR1-mutation carriers do not show alteration in antral follicle responsiveness to exogenous FSH assessed by the FORT index
What is known already: Female carrying *FMR1* mutation (premutation or full mutation) may be candidate to preimplantation genetic testing (PGT) to achieve a pregnancy with a healthy baby while avoiding the burden of prenatal genetic diagnosis and the risk of pregnancy termination. Several lines of evidence indicate that female carrying *FMR1* premutation are at higher risk of diminished ovarian reserve and further premature ovarian insufficiency. However, whether this genetic profile alter the capacity of small antral follicle to respond to exogenous FSH during controlled ovarian stimulation remains unelucidated.
Study design, size, duration: Monocentric retrospective observational study. Thirty-three patients carrying either *FMR1* premutation (n=17) or full mutation (n=16) were referred to our PGT centre from 2006 to 2018.
Participants/materials, setting, methods: Eighty-five PGT cycles for fragile X syndrome, 43 in premutated patients and 42 in fully mutated women, were analyzed. COS outcomes were compared to 85 PGT cycles performed for male translocation, matched on female age, BMI, antral follicle count, and protocol of stimulation. FORT was determined by the ratio between the pre-ovulatory follicle count (PFC, 16-22 mm) on the day of oocyte triggering × 100/ antral follicle count measured just before initiation of the stimulation.
Main results and the role of chance: By design, patients were comparable in terms of age, BMI and markers of the follicular ovarian status. Overall, after similar starting dose (253±91 vs. 247±82, p=0.7 and total dose of gonadotropin administered (2623±1071 vs. 2620±1029 IU, p=0.98), the numbers of oocytes recovered and mature oocytes (12.1±6.1 vs. 11.8±4.9, *p=0.70;* and 9.4±5.2 vs 9.9±4.1; *p=0.70,* respectively) were not significantly different in *FMR1*-mutation carriers and controls. In addition, FORT index remained similar between both groups (42.6±23.9% *vs* 42.4±27.2%, *p=0.96*, respectively).

Comparison of *FMR1* premutation and full mutation carriers showed lower values of ovarian reserve tests in permutated patients (AMH 3.5±3.2 *vs.* 6.2±3.6 ng/mL, p=0.0004 and AFC 18.7±9.4 *vs.* 22.9±8.9 follicles, p=0.03). Therefore, significantly higher doses of total FSH were needed (2988±1184 vs. 2256±867 IU, p=0.002) to obtain the similar oocyte yield (12.2±6.6 *vs.* 11.9±5.7, p=0.8) and number of mature oocytes (12.2±6.6 *vs.* 11.9±5.7, p=0.8). The FORT index was significantly higher in *FMR1* premutation carriers when compared to full mutation carriers (48.8±26.5 *vs.*37.4 ±19.5%, p=0.03).
Limitations, reasons for caution: This study is retrospective, analyzing a limited number of cycles. In addition, women included in a PGT program do not

reflect the whole population of *FMR1*-mutation carriers. Indeed, those with the lowest values of ovarian reserve tests are often not eligible for PGT.
Wider implications of the findings: *FMR1*-mutated carriers eligible for PGT may not require specific adjustments in their stimulation protocol. Further analysis is required to confirm these data on a larger population.
Trial registration number: not applicable

P-536 Difference in aneuploidy rates between embryos biopsied on day 5, 6 and 7, cultured in medium with and without granulocyte-macrophage colony-stimulating factor (GM-CSF)

A. Bruszczynska[1], M. Rusin[2], M. Fidzianska[2], M. Jagiello[2], A. Wozniak.[1], J. Liss[1,3], A. Knight[1], K. Lukaszuk[1,4,5]

[1]Invicta, Fertility and Reproductive Centre, Gdansk, Poland ;
[2]Invicta, Fertility and Reproductive Centre, Wroclaw, Poland ;
[3]University of Gdansk, Department of Medical Biology and Genetics, Gdansk, Poland ;
[4]Medical University of Warsaw, Department of Gynecological Endocrinology, Warsaw, Poland ;
[5]Medical University of Gdansk, Department of Obstetrics and Gynecological Nursing- Faculty of Health Sciences, Gdansk, Poland

Study question: Are aneuploidy rates different for embryos qualified for trophectoderm biopsy on day 5, 6 or 7 of culture, in medium with or without GM-CSF?
Summary answer: PGT-A results showed an increasing proportion of abnormal blastocysts on days 6 and 7 comparing to day 5 but not difference for cultures with/without GM-CSF.
What is known already: Chromosome analysis is performed to ensure that embryo transferred to the patient has a correct number of chromosomes to reduce the risk of abnormal pregnancy, miscarriage and failed implantation. Granulocyte-macrophage colony-stimulating factor has a beneficial effect on the development of human embryos in assisted reproductive technology (ART).
Study design, size, duration: This is a retrospective study performed using the medical records of patients who underwent IVF procedures with PGT-A between January 2017 and December 2019 at INVICTA Fertility Clinic, Poland. 1854 embryos cultured to a blastocyst stage were examined for aneuploidy. Trophectoderm biopsy was performed on day 5 of development or day 6 and 7 for slower growing embryos. Embryo culture medium was selected based on the clinicians and patients decision.
Participants/materials, setting, methods: Analysis included 655 treatment cycles. Median patient age was 37 (interquartile range: 33-39). Embryos were qualified for trophectoderm biopsy on days: 5, 6 or 7 depending on their development. PGT-A was performed using next generation sequencing (NGS). Additionally, the collected data was classified according to the type of culture medium – with GM-CSF (EmbryoGen/BlastGen, Origio) or without (G1 PLUS/G2 PLUS, Vitrolife).
Main results and the role of chance: Among the 1854 analyzed embryos, 584 were cultured in medium containing GM-CSF. In that group 229 embryos were qualified for biopsy on day 5. 68.1% of them were euploid and 31.9% aneuploid. On day 6, material was collected from 342 embryos - 52.6% euploid. On day 7, among 13 examined embryos and 23.1% were euploid. The differences in proportions of euploid embryos biopsied on different days were shown to be statistically significant ($p<0.001$).
Among the 1270 embryos cultured in the standard medium (i.e., without GM-CSF), on day 5, biopsy was performed on 405 embryos and 64.2% of them were euploid. On day 6 – 55.9% were normal, on day 7 – 50.0%. This comparison showed that with each next day, the percentage of embryos with normal PGT results decreases. The differences in proportions of euploid embryos were statistically significant ($p<0.001$).
There also appears to be a linear trend in the decrease of euploidy rate with each additional day needed to the embryo to reach qualification for biopsy (GM-CSF: $p<0.001$, no-GM-CSF: $p<0.001$).
No significant difference was observed in general percentage of correct result between embryos cultured with or without GM-CSF (58,1% vs 59,9%).
Limitations, reasons for caution: The possible limitation is that embryo culture medium selection was not randomized but rather based on medical indications (outcomes of previous cycles) and also on financial resources of the patients, as GM-CSF supplementation was more expensive for the patient.
Wider implications of the findings: Presented results suggest that addition of GM-CSF does not change the general percentage of euploid embryos. Although no benefit of GM-CSF on percentage of chromosomally normal embryos was observed in this study, there is a need for further randomized studies that could correlate findings with other factors.
Trial registration number: not applicable

P-537 Adopting machine learning (ML) and artificial intelligence (AI) methods to minimize the use of invasive biopsy techniques in embryo assessment and selection

N. Zaninovic[1], J. Sierra[2], J. Barnes[3], P. Khosravi[3], I. Hajirasouliha[3], Q. Zhan[1], J. Malmsten[1], Z. Rosenwaks[1]

[1]Weill Cornell Medicine, The Center for Reproductive Medicine, New York- NY, U.S.A. ;
[2]The Manhattan College, Computational Biology, New York, U.S.A. ;
[3]Weill Cornell Medicine, Department for Precision Medicine, New York- NY, U.S.A.

Study question: Can an AI-informed technique be developed to select embryos with a high probability of euploidy and indicate when more invasive methods (PGT) should be adopted?
Summary answer: Incorporating AI-ML methodology for embryo assessment results in a high-fidelity embryo ploidy prediction model that can provide guidance when more invasive assessment techniques are required.
What is known already: Selecting the best embryo for transfer is an enduring objective in IVF treatments. Embryo grading and time-lapse technology have helped to determine key attributes of embryo quality that correlate to clinical outcomes. The development of a noninvasive method of embryo screening as an alternative to invasive and expensive PGT is vital.
Study design, size, duration: This is a retrospective study of blastocysts (N=10491) of known ploidy status with embryo morphokinetic and morphology annotations and associated patient clinical profiles.
Participants/materials, setting, methods: Patients undergoing their first or second ICSI cycle using PGT were included. All embryos were cultured with a time-lapse (TLM) system. Variables studied included the morphokinetic timings, TLM images of the embryos, and blastocyst grades of the ICM, trophectoderm, and expansion. Ploidy was determined by PGT methods conducted on-site.
Main results and the role of chance: Multiple ML approaches and AI (deep learning) algorithms were implemented to determine the most expedient and reproducible method to provide a reliable assessment of embryo ploidy. To address the role of chance, 80:20 bootstrapping methods were used to develop ranges in the model parameters and predictions. The area under the receiver operating curve (AUC) obtained from the ML model was 0.734. This model, using a preset threshold, was able to detect 25% of blastocyst ploidy status with high accuracy (95% pos. and 94% neg.) that an invasive biopsy was not necessary. For the remaining 75% of the population, the model estimates could be incorporated into other clinical information to determine the acceptable level of risk to undertake an invasive biopsy. The deep learning model, trained on embryo images of blastocysts at 110 hours, showed an accuracy of 62.5%. The addition of embryological information improved the accuracy of the model to 70.4%.
Limitations, reasons for caution: The single-center and retrospective nature of the analysis could be a limiting factor, although the findings were validated through a large dataset.
Wider implications of the findings: The implementation of AI/ML algorithms trained on a large data set of blastocysts of known ploidy suggests that noninvasive approaches may be used to assess embryos with a high level of confidence. These techniques may also help us to identify embryos for which PGT is recommended.
Trial registration number: not applicable

P-538 Pericentromeric DNA transcripts are involved in the formation of membraneless mitochondria-associated structures at the end of oocyte maturation in human..

N. Enukashvily[1], A. Dobrynin[1], N. Korchagina[2], A. Prjibelski[3], D. Shafranskaya[4]

[1]Institute of Cytology- RAS, The Non-Coding DNA Lab, St. Petersburg, Russia C.I.S. ;
[2]Ava-Peter-Scandinavia Clinics, Embryology Dept, st. Petersburg, Russia C.I.S. ;
[3]St. Petersburg State University, Center for Algorithmic Biotechnology, St.Petersburg, Russia C.I.S. ;
[4]St. Petersburg State University, Biology Dept, St.Petersburg, Russia C.I.S.

Study question: Whether maternal long non-coding RNAs (lncRNAs) transcribed from pericentromere non-coding tandemly repeated (TR) DNA are involved in the formation of membraneless structures in GV-MI oocytes.
Summary answer: In late preovulatory oocytes, pericentromere tandemly repeated DNAs are transcribed. The transcripts are clustered in some membraneless RNP structures containing helicases and associated with mitochondria.
What is known already: Tandemly repeated DNA (TR DNA) constitutes approximately 10% of the human genome. TR DNA family includes microsatellites, minisatellites, and satellites. Classical human satellites 1, 2, 3 (HS1, HS2, HS3) underlie the pericentromere region. Pericentromeric satellites transcripts play an important role in mammalian embryogenesis. Transcripts of satellite DNA are present in mouse embryos prior to zygotic activation. However there are no data about pericentromeric TR RNA in human oocytes.

In mammals, pericentromeric transcripts are involved in assembling membraneless bodies. However, in mammalian oocytes membraneless bodies enriched in non-coding RNAs and helicases are believed to be disassembled in the meiosis I prophase.,
Study design, size, duration: GV and MI donor oocytes are not used for gametes banking and are usually discarded. They were donated for scientific purposes after the local ethic committee permission was granted and a donor informed consent was signed.
The HS 2,3 transcripts distribution, their colocalisation with helicases and mitochondria were studied in GV (n=12), MI (n=8) oocytes. The presence of HS2,3 transcripts in published transcriptomes of healthy donors was verified with computational methods.
Participants/materials, setting, methods: The HS 2, 3 transcripts distribution was studied with RNA-DNA FISH. The colocalisation of the transcripts with helicases was estimated by immunoFISH. Double immunostaining was used to study the spatial relationship of helicases and the import receptors Tom20 of mitochondrial preprotein translocases of the outer membrane (Tom). The presence of HS2,3 transcripts in published transcriptomes of healthy donors was verified with computational analysis of published healthy donors transcriptomes
Main results and the role of chance: HS2, 3 transcription increased in in oocytes after the GV stage. In GV oocytes, the intranuclear DDX5 helicase was adjacent to the heterochromatic ring surrounding the post-nucleolar body. In late GV-MI and in MI, the HS2, 3 transcripts were colocalised with the helicases granules that overlapped with the oocyte mitochondria. In published transcriptomes, several polyadenylated transcripts from different datasets were detected. All the transcripts belonged to HS TR DNA families. The cDNAs had the typical signatures of HS sequences. One of transcripts contained the sequence we previously identify in transcriptomes of cancer and fetal cells.
Thus, in late preovulatory oocytes, different HS families of TR DNA are transcribed. The transcripts are clustered in some membraneless RNP structures that contain helicases and are closely associated with mitochondria being therefore similar to Balbiany bodies described previously in early mammalian oocytes. To date no membraneless granules associated with mitochondria were described in oocytes at the late stages of maturation. Mitochondria associated membraneless coacervate bodies assembled on the base of pericentromeric transcripts might be a place for such spatial sequestration in the same way as in early oocytes.
Limitations, reasons for caution: The experiments were performed on fixed cells. The in vivo visualisation of the structures will be carried out to prove the existence of the granules in a living oocyte
Wider implications of the findings: Transcription of HS2,3 occurs in late maturing oocytes that were assumed to be transcriptionally silent. The existence of membraneless bodies was demonstrated for the first time. The obtained results give a new perspective to study the late oogenesis.
Trial registration number: not applicable

P-539 Transcription of human pericentromeric non-coding DNA at the end of human oocyte maturation

M. Dobrynin[1], A. Prjibelski[2], N. Korchagina[3], D. Shafranskaya[4], N. Enukashvily[1]

[1]Institute of Cytology of Russian Academy of Sciences, Laboratory non-coding DNA, St. Petersburg, Russia C.I.S. ;
[2]St. Petersburg State University, .Center for Algorithmic Biotechnology, St. Petersburg, Russia C.I.S. ;
[3]Ava-Peter – Scandinavia ART Clinic, Clinic on Nevsky prospect, St. Petersburg, Russia C.I.S. ;
[4]St. Petersburg State University, Faculty of Biology, St. Petersburg, Russia C.I.S.

Study question: Whether maternal long non-coding RNAs (lncRNAs) transcribed from pericentromere non-coding tandemly repeated (TR) DNA are accumulated in late maturating oocyte
Summary answer: The maternal transcripts of pericentromere TR DNA are accumulated in the late oocyte maturation. They are present in transcriptomes of MI, MII oocytes.
What is known already: Non-coding RNAs play an important role in mammalian gameto- and embryogenesis. Human pericentromere is built on TR DNA of "classical" satellites family - human satellite (HS) 1, 2, 3 (HS1, HS2, HS3). Blocking the pericentromere TR DNA transcription leads to embryo development arrest in mouse. Transcripts of TR DNA are present in mouse embryos prior to zygotic activation in small quantities suggesting they are not only transcribed in embryo but are accumulated in maternal ooplasm. However there are no data about pericentromeric TR DNA and their transcripts in human oocytes.
Study design, size, duration: We analysed 8 RNA-Seq published datasets of healthy donors MI and MII oocytes obtained by 4 independent research groups. The biocomputational analysis results were verified by fluorescence in situ hybridization (FISH). FISH was carried out on MI human preovulatory oocytes without morphological abnormalities from healthy donors. These oocytes were excluded from egg donation program and were used in the present study if an informed consent was signed by a donor.
Participants/materials, setting, methods: Raw reads were quality- and adapter-trimmed in order to check the presence of sequences containing homology regions with the HS2,3 probe. Only transcripts containing highly confident matches with HS2,3 were selected . Several polyadenylated transcripts were detected (length 300-640 bp). They were analyzed for regions of similarity, multiple sequence alignment. The same probe as in transcriptome analysis was used as a DNA-RNA FISH probe.
Main results and the role of chance: All four selected transcripts belonged to pericentromere TR DNA families. Multiple alignment of all the 4 transcripts and pairwise alignment of sequences revealed that they are not identical and belong to different families of classical satellites. All the assembled transcripts shared homology (identity more than 75%) with different satellite lncRNA previously obtained by from heat-shocked HeLa cells. One of the transcripts we assembled shared high degree homology (> 80%) with the boundary region between centromeric DNA and pericentromeric HS. Moreover, the same transcript contained the complete HS3 sequence that we had found earlier transcribed in some cancer cell lines, senescent lung fibroblasts and some tissues of a developing human embryo. The transcripts revealed by computational analysis were detected in MI oocytes by RNA-FISH. The transcripts were associated in granules scattered throughout the ooplasm.
Limitations, reasons for caution: The sample size for FISH analysis in this study was small due to difficulties in obtaining human preovulatory oocytes without morphological abnormalities. Further studies, including analysis of transcription of HS2,3 dynamics by live-cell imaging, may help define the role that perform of these transcripts in oocyte maturation and early embryogenesis.
Wider implications of the findings: According to our data, transcription of HS2,3 occurs in late maturing oocytes that were assumed to be transcriptionally silent. The appearance of HS3 transcripts in the MI oocyte suggests that these transcripts might be important for oocyte maturation or early embryogenesis.
Trial registration number: not applicable

P-540 correcting a PLCζ mutation in the human germ line to overcome hereditary infertility

B. Bekaert[1], A. Boel[1], M. Popovic[1], P. Stamatiadis[1], R. Reddy Guggilla[1], S. Chuva de Sousa Lopes M. C.[2], P. De Sutter[1], P. Coucke[3], B. Heindryckx[1]

[1]UGhent, Department of Human structure and repair, Ghent, Belgium ;
[2]Leiden University Medical Center, Department of Anatomy and Embryology, Leiden, The Netherlands ;
[3]UGhent, Department of Biomolecular Medicine, Ghent, Belgium

Study question: Can clustered regularly interspaced short palindromic repeats (CRISPR)/Cas9 gene editing be used for correction of a single base pair substitution in phospholipase C zeta (PLCζ)?
Summary answer: CRISPR/Cas9 administration during ICSI enables the correction of a single base pair substitution in PLCζ, possibly by interhomologue homologous recombination.
What is known already: Mutations in the *PLCZ1* gene, encoding for phospholipase C zeta (PLCζ) -the sperm-related oocyte activating factor- can result in failed fertilization after ICSI, which can be overcome with assisted oocyte activation (AOA). However, children may still inherit the disease-causing mutation resulting in the need for future reproductive treatment. A possible method to overcome mutation transmission is gene correction with CRISPR/Cas9 during ICSI. From previous studies using CRISPR/Cas9 in the human germline, it is still called into question whether gene correction predominantly occurs through interhomologue homologous recombination or the use of the added repair template.
Study design, size, duration: We aimed to correct a failed fertilization-related paternal mutation by delivering CRISPR/Cas9 components during ICSI. A gRNA-Cas9 protein complex specifically designed to target the mutant allele, and a repair template harboring the desired base pair substitution and an additional synonymous mutation, were injected together with patient's sperm. AOA was performed following ICSI to overcome fertilization failure. Fertilized zygotes were cultured for 3-5 days. These reconstructed embryos (n=12) were thoroughly analyzed to assess gene editing efficiency.
Participants/materials, setting, methods: We recruited one male patient with a heterozygous base pair substitution in *PLCZ1* (c.136-1G>C) leading to failed fertilization in all oocytes after routine ICSI. Donated *in vitro* or *in vivo* matured oocytes containing clusters of smooth endoplasmic reticulum were targeted, next to a control group without gene editing. Targeted next-generation sequencing was used to assess correction potential and short tandem repeat (STR) analysis to characterize whether mutation-carrying or wild-type sperm gave rise to the embryo.
Main results and the role of chance: In the control experiments where no CRISPR/Cas9 was added, ICSI with the patient's sperm and AOA treatment, resulted in a mutation distribution of approximately 50%. High specificity of the designed CRISPR/Cas9 components for targeting the paternal mutant *PLCZ1* allele was demonstrated by the absence of unspecific insertions/deletions (indels) in embryos originating from wild-type sperm (n=5). When the mutant *PLCZ1* allele was observed, indicated by the presence of the mutant chromosome-related STR markers, either no editing (n=3), additional mutagenesis (indels) (n=2) or correction (n=2) occurred. Remarkably, our results suggest that the correction process may not require the presence of a repair template, due to the absence of the synonymous mutation incorporated into the repair template in the DNA sequence of the corrected embryos. In addition, for the STR markers close to the Cas9 cut site only one novel (presumably the maternal) allele was present, while both maternal and paternal alleles were identified for STR markers further upstream and downstream from the Cas9 cut site. This suggests that the correction resulted from interhomologue homologous recombination, by which the maternal wild-type allele is used as a template to repair the double-strand break.
Limitations, reasons for caution: One of the major limitations of CRISPR/Cas9 is the occurrence of mosaicism and off-target editing, which still remains to be evaluated. Moreover, the number of targeted embryos should be increased to more reliably estimate the accuracy and efficiency of the CRISPR/Cas9 protocol.
Wider implications of the findings: Our findings demonstrate that CRISPR/Cas9 may serve to correct heritable infertility mutations in the germ line. Our results further confirm the occurrence of interhomologue homologous recombination, which may lead to loss of heterozygosity. Additional studies should be undertaken to evaluate the safety/efficiency of this method prior to clinical applications.
Trial registration number: not applicable

P-541 Immunostaining of global 5mC and 5hmC levels of DNA in differentially protaminated human sperm chromatin

M. Olszewska[1], O. Kordyl[1], M. Kamieniczna[1], M. Fraczek[1], P. Jedrzejczak[2], M. Kurpisz[1]

[1]Institute of Human Genetics- Polish Academy of Sciences, Poznan, Poland ; [2]Poznan University of Medical Sciences, Department of Infertility and Reproductive Endocrinology, Poznan, Poland

Study question: To determine the relationship between 5mC and 5hmC according to the sperm chromatin protamination, in 3 sperm populations: normally protaminated, less protaminated, and deprotaminated, in fertile and infertile males
Summary answer: High DNA 5mC level is a marker for well-protaminated spermatozoa, documenting proper spermatogenesis. 5mC/5hmC levels are highest in properly-protaminated spermatozoa, but disrupted in oligoasthenozoospermia
What is known already: A special role in etiology of male infertility play epigenetic modifications, including methylation (5mC) and hydroxymethylation (5hmC) of DNA. Global DNA methylation level is high in normozoospermia, which confirms a correct spermatogenesis. Published data also indicate the link between sperm quality and the protamination state of sperm chromatin.
Study design, size, duration: 50 patients with oligo-/oligoasthenozoospermia and reproductive failure (P group) vs. 30 normozoospermic controls (K group). Both groups: normal karyotype (46,XY), 25-30 years old, and a lack of smoking habits, any stimulants/drugs usage, and toxic work environment.
Participants/materials, setting, methods: For the first time, a sequential staining protocol was applied, which allowed to analyze the 5mC/5hmC levels revealed by immunofluorescent (IF) stainings using the same spermatozoa with previously determined chromatin protamination status (aniline blue staining). Also TUNEL examination was performed to check the sperm DNA fragmentation status.
Main results and the role of chance: In the P group, both: the protamination level of sperm chromatin, as well as 5mC and 5hmC levels were decreased, when compared to the K group. Results obtained in P group also pointed out a higher interindividual heterogeneity. The 5mC and 5hmC levels were diversified in respect to the chromatin protamination status: protaminated sperm cells showed the highest 5mC and 5hmC values, in both: K and P groups. A negative correlation was found between 5mC level vs. correct protamination (both groups of males; $p<0.05$). Negative correlation was also identified for 5hmC level vs. correct protamination in the K group, in contrast to the P group, where 5hmC level increased concurrently with the chromatin protamination status ($p<0.05$). Sperm DNA fragmentation was higher in the P group vs. K group.
Limitations, reasons for caution: Analyzes on bigger number of patients are required
Wider implications of the findings: Measuring of 5mC/5hmC status of sperm DNA evidences the correctness of spermatogenesis and its disruption may be a marker of reproductive failure.

P-542 Transfers of chromosomal-abnormal "mosaic" and "aneuploid" embryos in patients previously refused such transfers at centers were embryos had been produced

D. Barad[1], D. Albertini[2], E. Molinari[2], N. Gleicher[1]

[1]Center for Human Reproduction, n/a, New York, U.S.A. ; [2]Center for Human Reproduction, Laboratories, New York, U.S.A.

Study question: What are outcomes of transfers of chromosomal-abnormal embryos ("mosaic" and "aneuploid") after patients were refused such transfers by their IVF centers, where those embryos were established?
Summary answer: Transfers of such embryos result in significant life birth rates with basically no risk for births of chromosomal-abnormal offspring.
What is known already: Like earlier studies, the STAR study recently again failed to demonstrate outcome benefits from chromosomal testing of embryos prior to transfer (PGT-A). Moreover, hundreds of chromosomal-normal offspring have been reported born following transfer of chromosomal-abnormal embryos ("mosaic" and "aneuploid"), without even a single chromosomal-abnormal birth. Yet, PGT-A practice continues, and most IVF centers still refuse transfers of embryos, by PGT-A declared "mosaic" and/or "aneuploid."
Study design, size, duration: Prospective observational study of 50 patients who moved 278 allegedly chromosomal-abnormal embryos (per PGT-A) between June 2016 and October 2019 to our center after having been refused transfer of some of these embryos at the centers where those embryos had been produced. The center's experience preceding 2016 has been reported before.

Participants/materials, setting, methods: PGT-A was performed by NGS or CGH. Consents pointed out risks of chromosomal-abnormal pregnancies. Without evidence for a 80% threshold of "aneuploid" DNA between "mosaic" and "aneuploid" biopsies, and no differences in reported outcomes, we do not differentiate between "mosaic" and "aneuploid" embryos. Transfers are recommended in absence of 3 or less known "survivable" chromosomal abnormalities. Patients are, however, entitled to override. Consents since 2014 oblige to early prenatal diagnostics and termination with aneuploidies.
Main results and the role of chance: 32 patients underwent transfers (age 40.6 ± 4.1 years); 31/32 (96.9%) had at least one previous IVF cycles (total, n=176); 20/32 (62.5 %) had at least one prior pregnancy (overall, n=40); but only 6/32 (18.8%) prior live births. In 32 transfers, 101 embryos were placed (median 3; range 1-5), 74 embryos were mosaic, 19 aneuploid and 8 undetermined. Three live births and two ongoing pregnancies beyond 20 weeks (total likely live birth rate 5/32 (15.6%) were established; 4 pregnancies were miscarried (total pregnancy rate 28.1%), 2 concordant with PGT-A results, 1 discordant (normal 46,XX - the patients had SLE), and 1 patient refused testing.
Limitations, reasons for caution: At mean age 40.6, patients in this study are significantly older than in any previously reported patient population receiving "abnormal" embryos. Here presented data, therefore, likely underestimate pregnancy and live birth outcomes and overestimate miscarriage rates for younger women.
Wider implications of the findings: Transfer of selected, by PGT-A designated to be chromosomal-abnormal embryos, whether "mosaic" or "aneuploid," under current reporting standards is safe, and results in delivery of significant chromosomal-normal offspring which never would be born if these embryos had not been transferred.
Trial registration number: n/a

P-543 A whole genome analysis for simplified a preimplantation genetic testing of a rare and a complex interchromosomal reciprocal insertion: thorough investigations for a straightforward interpretation.

R. Zenagui[1], I. Bernicot[1], T. Anahory[1]

[1]Montpellier Hospital, PGT depatment, Montpellier, France

Study question: Should whole genome sequencing (WGS) be considered for the diagnosis of complex chromosomal abnormalities before a preimplantation genetic testing of structural rearrangement (PGT-SR) attempt?
Summary answer: WGS should be considered to establish the complexity of chromosomal abnormalities with accuracy before PGT-SR investigations.
What is known already: Insertions are rare events and interchromosomal reciprocal insertion (IRI) with four breakpoints are exceptional, with only 11 cases reported to date. To the best of our knowledge, no preimplantation genetic testing for structural rearrangement (PGT-SR) was performed to investigate the management of patients with IRI abnormalities.
Study design, size, duration: A male carrier of rare IRI 46,XY,ins(14;22)(q11.2 ;q11.2) and his partner were directed to our center for PGT analysis after three spontaneous miscarriages. The patients were informed of the investigations and gave their consent before participation in the study.
Participants/materials, setting, methods: A genome sequencing of a male carrier was conducted at the French National Research Centre for Human Genomics. Library generation was performed with TruSeq® DNA PCR-free kit. The genome was sequenced on a HiSeq X5 following the manufacturer's instructions. DNA sequences were mapped to the reference human genome sequence (GRCh37). Structural variations were called using MANTA. FISH assays were used to detect all chromosome segments involved in chromosomal rearrangement and to identify transferred normal/balanced embryos.
Main results and the role of chance: Whole genome sequencing analysis allowed to determine accurately the chromosomal breakpoint numbers between the chromosome 14 and the chromosome 22. Against all odds, two breakpoints were identified instead of four as expected in IRI rearrangements. The junction fragments sequencing confirmed the location and the number of both breakpoints. Finally, the patients were informed that the chromosomal abnormality was a reciprocal translocation instead of interchromosomal reciprocal insertion. Thereby, a FISH probe strategy was adapted to highlight all chromosomal imbalances, PGT-SR attempt was achieved and a healthy baby was born.
Limitations, reasons for caution: No FISH probes could be established between the centromeres and the chromosomal breakpoints on either or both involved chromosomes. This limitation may lead to a misintepretation of breakpoints number affecting chromosomes.
Wider implications of the findings: FISH techniques aren't capable of identifying all complex chromosomal rearrangements, mainly those involving centromeric regions of acrocentric chromosomes, investigations of those abnormalities should be performed with a sensitive methods.The advent of new technologies allowed better appreciations of a genome complexity.WGS brought a required information to explain the occurred genomic events.

P-544 Comparison of aneuploidy rates between embryos obtained from fresh and frozen oocytes in the same patients: Analysis more than 1000 embryos in the UAE.

Y. Alhelou[1], S. El Shawarby[1], M. Fakih[1], A. Hellani[2], N.A. Mat Adenan[3], J. Ali[4]

[1]Fakih IVF Fertility Center, IVF Department, Abu Dhabi, United Arab Emirates ;
[2]Viafet genomics, PGD Lab, Dubai, United Arab Emirates ;
[3]University of Malaya, Obstetrics and Gynaecology, Kuala Lumpur, Malaysia ;
[4]University Of Malaya, Obstertrics and Gynaecology, Kuala Lumpur, Malaysia

Study question: Does oocyte vitrification affected the chromosomal content of the resulting embryos?
Summary answer: There is no significant aneuploidy rate between the embryos that resulted from fresh oocytes versus that resulted from frozen oocytes in the same patients.
What is known already: Oocyte vitrification is one of the routine practices in assisted reproduction. It gained more popularity after achieving high survival rates of more than 90% and pregnancy rates comparable to fresh oocytes. Therefore, there is a need to know if oocyte vitrification can affect embryo euploidy
Study design, size, duration: Retrospective data analysis was performed on 1050 embryos of 84 patients under age of 35 years between November 2017 and December 2019. Every patient was performed an oocyte vitrification cycle followed by a fresh ICSI cycle. On the same day of the fresh ICSI cycle, the vitrified eggs were warmed and ICSI was performed. The embryos resulting from both fresh and vitrified eggs had day 5 biopsy followed by PGS..
Participants/materials, setting, methods: Every patient was done an oocyte vitrification cycle followed by a fresh ICSI cycle. On the same day of the fresh ICSI cycle, the vitrified eggs were warmed and were done ICSI. The embryos resulted from both fresh and vitrified eggs were done day 5 biopsy followed by Preimplantaion Genetic Screening (PGS) using Next Generation Sequencing with High Resolution (NGS HR PGS). The structural and numerical chromosomal abnormalities were analysed and compared.
Main results and the role of chance: The biopsied embryo that resulted from fresh oocytes had an aneuploidy rate of 49.2% versus 53.8% aneuploidy rate for embryos resulting from frozen oocytes. The p value was 0.13 which means the result is statistically insignificant. In addition, the rate of monosomies, trisomies and complex abnormalities did not show any statistical significance.
Limitations, reasons for caution: The frozen/thawed oocytes were not recruited from the same fresh ICSI cycle. The retrospective nature of he study and the population of the study are all 35 years and younger
Wider implications of the findings: The study provides reassurance to young patients undergoing oocyte freezing for variance indications that the technology itself does not affect the rate of chromosomal abnormalities and aneuploidy rate.
As far as we know this is the first study in the UAE that investigate the aneuploidy in fresh and frozen oocytes.
Trial registration number: not applicable

P-545 Evaluation of Severe Male Infertility in the Light of New Genetic Variations

M. Gavaz[1], B. Umay Kara[1], F. Gokdagli Sagir[1], B. Yuksel[1], M. Cetinkaya[1], S. Kahraman[1]

[1]Istanbul Memorial Hospital, Assisted Reproductive Technologies and Reproductive Genetics Center, Istanbul, Turkey

Study question: Is it possible to classify the severe male infertility cases and predict their treatment outcome/prognosis according to causative genetic variation(s)?

Summary answer: The genetic variations identified in severe male infertility cases were correlated to the morphological sperm findings and the outcome with the genetic variations.

What is known already: The majority (30–60%) of infertile males do not receive a clear diagnosis; therefore, they are reported as idiopathic with a strong suspicion of genetic underpinnings. This is particularly evident in cases of infertility and repetitive ART failures with normal semen parameters. Genome-wide association studies in male infertility have affected several genomic regions, and all exome sequencing studies have identified coding variants associated with male infertility. WES has been successful in identifying new genes such as TEX15, MAGEB4, SUN5, SRA1 in all categories of etiologic spermatogenic dysfunction (quantitative, qualitative, hypothalamic-pituitary axis and ductal obstruction or dysfunction).

Study design, size, duration: We carried out a cohort study at Istanbul Memorial Hospital from December 2018 to December 2019. We included 25 patients with severe familial male infertility without identified etiology after standard genetic assessment (karyotype and Y chromosome microdeletion). We classified male infertility under 3 groups such as non-obstructive azoospermia (NOA) (n=7), oligoasthenoteratozoospermia (n=7), motility and morphological (n=11) defects. Successful treatment outcome was evaluated as being able to reach ongoing pregnancy.

Participants/materials, setting, methods: We obtained blood samples from all patients. Genomic DNA was extracted using the QIAampDNA Mini QIAcube Kit (Qiagen, France) according to the manufacturer's instructions. Whole exome sequencing was performed by NovaSeq 6000 Series Sequencer via Illumina technology. The coverage of target sequence sequencing is not less than 99%. Patients gave their informed consent to undergo genetic testing to uncover the etiology of male infertility.

Main results and the role of chance: Totally, 30 different previously identified genes that related with male infertility were detected. The most common variants were detected in NANOS1, AR, CCDC40 and RSPH1 genes. We detected five unique variants at NANOS1 gene in 5 patients. including a deletion of serine (p.S83del) residues that was identified as pathogenic. From five men with definitive sperm factors, two patients were identified heterozygous variations in CCDC40 gene: c.1318-14A>G which altered the protein sequence and resulted in the ultrastructural defects in the microtubule structure of cilia. In another patient, a variation in the CCDC40 gene that caused p.Asp284His at c.850G>C was identified as disease-causing. Different types of variants in the RSPH1 gene were detected in three patients with a history of parental consanguineous marriage. No positive pregnancy was obtained in NOA patients with variations in RSPH1, ZYMND15, SEPT12, DNAAF1, CCDC40 and NANOS1. Variation (c.849-20dup) in SPATA16 gene was found in 2 patients with morphological defect phenotype. Five of the sixteen patients with variants associated with primary ciliary dyskinesia had positive pregnancy and four had negative pregnancy, and three patients had been waiting for embryo transfer. Variants in the DNAAF5, RSPH1 and DNAI2 genes are the most common in patients resulting in negative pregnancies.

Limitations, reasons for caution: The main limitation of our study is the small number of patient. This study should be extended to include more patients from the same family who suffer from male infertility.

Wider implications of the findings: Our findings identified new variations responsible of the severe male infertility phenotype. This study provides an understanding of undefined variations involved in male spermatogenesis and progress in the diagnosis of infertility.

P-546 Telomere length in oocyte- and sperm-derived metaphase chromosomes in human triploid zygotes

O. Efimova[1], A. Pendina[1], M. Krapivin[1], I. Mekina[2], E. Komarova[2], A. Tikhonov[1], O. Chiryaeva[1], Y. Sagurova[3], V. Baranov[1], A. Gzgzyan[2], I. Kogan[2]

[1]D.O. Ott Research Institute of Obstetrics- Gynecology and Reproductology, Genomic Medicine, St. Petersburg, Russia C.I.S. ;
[2]D.O. Ott Research Institute of Obstetrics- Gynecology and Reproductology, Assisted Reproductive Technologies, St. Petersburg, Russia C.I.S. ;
[3]St. Petersburg State University, Genetics and Biotechnology, St. Petersburg, Russia C.I.S.

Study question: Does telomere length in human triploid zygotes differ between oocyte- and sperm-derived sets of metaphase chromosomes and is it associated with maternal and paternal age?

Summary answer: In human triploid zygotes, sperm-derived telomeres are longer than oocyte-derived telomeres; telomere length does not depend on either maternal or paternal age.

What is known already: Telomeres represent complexes of short tandem DNA repeats and proteins that protect the ends of chromosomes. Telomere shortening caused by cell divisions, exogenous factors or genetic effects leads to chromosomal end fusion, degradation of chromosomes and cell death. Considering that telomere length (TL) in preimplantation embryo may be an important predictor of its developmental potential, the question about TL regulation in gametogenesis and embryogenesis is of high importance. In contrast to telomeres in sperm which become longer with age, oocyte telomeres are short. Whether these gamete-specific patterns are maintained after fertilization in zygote is unclear.

Study design, size, duration: A total of 23 triploid zygotes were obtained from 20 couples referred for in vitro fertilization during a ten month period. The maternal age ranged from 23 to 39 years (mean 32.04±0.8); the paternal age ranged from 23 to 45 years (mean 34.15±1.2). The study was approved by the Institutional Ethics Committee; the participating couples signed informed consent.

Participants/materials, setting, methods: For metaphase preparations, the zygotes were treated with colchicines, hypotonic solution and fixed on glass slides. Parental origin of chromosomes was identified immunocytochemically by weak DNA methylation and strong hydroxymethylation in the sperm-derived (paternal) chromosomes versus strong DNA methylation and weak hydroxymethylation in the oocyte-derived (maternal) chromosomes. Relative TL was assessed using quantitative fluorescence in situ hybridization (qFISH) (Telomere PNA FISH Kit/Cy3, Agilent) by dividing the telomeric fluorescence by the subtelomeric fluorescence measured in ImageJ1.49v.

Main results and the role of chance: Out of 23 triploid zygotes, four zygotes had additional maternal chromosome set and 19 zygotes had additional paternal chromosome set. According to the relative TL values, the zygotes were categorized into four types. In most zygotes (21 out of 23), the relative TL values were higher in the paternal chromosomes. In two zygotes, the relative TL values appeared to be higher in the maternal chromosomes. In two zygotes with additional paternal chromosome sets, only one out of two paternal sets had higher relative TL values compared to the maternal one. In two zygotes with additional maternal chromosome sets, only one out of two maternal sets had lower relative TL values compared to the paternal one. The Wilcoxon matched pairs signed rank test showed that the relative TL was significantly higher in the paternal chromosomes compared to the maternal ones ($p<0.0001$). A few zygotes demonstrating unusual patterns of the relative TL values seem to be the exception rather than the rule. This observation may suggest that some cases of developmental arrest in triploid embryos are due to the altered TL pattern. The relative TL neither in sperm-derived nor in oocyte-derived chromosomes correlated with paternal ($r=-0.058$; $p=0.736$) or maternal age ($r=0.155$; $p=0.44$), respectively.

Limitations, reasons for caution: As normal diploid zygotes were not available, the study was performed on triploid ones. The developmental potential of triploid human embryos is confirmed by their capacity for implantation and even a full-term development suggesting that basic developmental processes in triploid zygotes could be similar/identical to those in normal ones.

Wider implications of the findings: Our findings may suggest that after fertilization, TL in sperm-derived chromosomes is "reprogrammed". Being hypomethylated, paternal chromosomes are prone to recombination and, thus, to alternative lengthening of telomeres (ALT). ALT may be crucial for cleavage capacity and explains the absence of correlation of TL in sperm-derived chromosomes with paternal age.

Trial registration number: not applicable

P-547 Frequency of mitochondrial genetic variations in human cumulus cells and their association with mitochondrial function, embryo quality and BMI

K. Kumar[1], M. Venturas[2], D. Needleman[2], C. Racowsky[3], D. Wells[4]

[1]University Of Oxford, Nuffield Department of Women's & Reproductive Health, Oxford, United Kingdom ;
[2]Harvard University, MCB and SEAS, Cambridge- MA, U.S.A. ;
[3]Harvard Medical School, Brigham & Women's Hospital, Boston-MA, U.S.A. ;
[4]Juno Genetics Ltd, Juno Genetics Ltd, Oxford, United Kingdom

Study question: What is the frequency of mitochondrial genetic variations in human cumulus cells and are these associated with mitochondrial function, embryo quality or patient BMI?
Summary answer: Neither cumulus cell mtDNA quantity nor the presence of specific mtDNA genetic variants were associated with embryo quality. However, associations with patient BMI were detected.
What is known already: Cumulus cells fulfil a vital role in support of oocyte developmental competency. Cumulus cell function relies on adequate energy production, which in turn depends on the quantity and genetic competence of its mitochondria. Mitochondrial DNA mutations can be inherited or they can accumulate in somatic cells over time, potentially contributing to ageing. Such mutations may be homoplasmic (affecting all mtDNA in a cell) or they may display varying levels of heteroplasmy (affecting a proportion of the mtDNA). Currently, little is known concerning the frequency or associations between mitochondrial genetic variation in cumulus cells and oocyte health.
Study design, size, duration: Human cumulus cells, associated with 290 oocytes from 85 IVF patients, were analyzed. Patient age, body mass index (kg/m2), infertility diagnosis, fertilization status and embryo development were recorded with respect to each cumulus complex. Mitochondrial DNA quantity was measured using a validated quantitative PCR method. A subset of 119 samples had their entire mitochondrial genomes sequenced using a high-depth massively parallel sequencing approach. Metabolic functions were assessed non-invasively using fluorescence lifetime imaging microscopy (FLIM).
Participants/materials, setting, methods: Massive parallel sequencing not only permitted accurate detection of mutations, but also precise quantification of levels of mutations in cases of heteroplasmy. Sequence variants in the mtDNA were evaluated using Mitomaster and HmtVar to predict their potential impact. FLIM allowed measurement of the autofluorescence of NADH and FAD+, which are crucial for mitochondrial function. Multivariate generalized linear regression models were used to assess correlations among variables. P<0.05 was considered statistically significant.
Main results and the role of chance: Sequencing the entire mitochondrial genome in 119 cumulus cell samples revealed a total of 952 synonymous single nucleotide variants (SNVs) with respect to the reference genome (i.e. no amino acid change) and another 626 non-synonymous SNVs (altered amino acid sequence). Most SNVs were homoplasmic and therefore presumed to have been inherited, but 21 were heteroplasmic and potentially acquired by somatic mutation. Additionally, 104 homoplasmic variants detected in 63 samples were predicted to be pathogenic, with a likely impact on ATP production. A significant association was observed between BMI and the number of non-synonymous variants (p=0.037) and the quantity of mtDNA in cumulus cells (p<0.001). Significant difference was also observed for FLIM measurements of flavin adenine dinucleotide (FAD) long lifetime in cumulus cells that had pathogenic mtDNA mutations (p=0.046). Grouping samples according to patients' mitochondrial haplogroups revealed a significant association of nicotinamide adenine dinucleotide (NADH) long lifetime (p=0.025) and NADH short lifetime (p=0.012) with haplogroup. This suggests that mitochondrial metabolism varies between haplogroups. Moreover, the number of detected potentially pathogenic variants were also significantly different among mitochondrial haplogroups (p=0.005). No correlations were observed with respect to cumulus cell mtDNA quantity and patient age, infertility diagnosis, fertilization status or embryo quality.
Limitations, reasons for caution: Although, a large number of samples were analysed in this study, an expanded sample size is needed to determine whether subtle relationships do exist among between mtDNA mutation/copy number and patient/oocyte/embryo characteristics. We are continuing to process more samples.
Wider implications of the findings: No relationship was detected between cumulus cell mtDNA quantity or sequence variants (including pathogenic) and clinically relevant endpoints for corresponding oocytes. Nonetheless, some of the findings raise interesting biological questions, particularly regarding the interplay of metabolism and BMI.
Trial registration number: NOT APPLICABLE

P-548 A novel test for IVF miscarriage risk: Annexin A5 M2 haplotyping in IVF patients and preimplantation embryos

B.R. Rana[1], R. Zimmerman[1], D. Marin[1], J. Xu[1], E. Messick[1], L. Tellier[1], D. Egli[3], S. Fishel[2], N. Treff[1]

[1]Genomic Prediction Clinical Laboratory, Clinical Laboratory, North Brunswick, U.S.A. ;
[2]Care Fertility Group, Care Fertility Department of Research and Development, Nottingham, United Kingdom ;
[3]Columbia University, Department of Pediatrics, New York, U.S.A.

Study question: To develop a test for evaluating miscarriage risk in IVF patients and preimplantation embryos.
Summary answer: Development and validation of a novel M2 saliva test for screening patients with infertility, and the first method capable of M2 haplotyping in preimplantation embryos.
What is known already: Thrombophilia is linked to increased risk of miscarriage and other placental mediated pregnancy complications (PMPC). Expressed on the apical surface of the syncytiotrophoblast, the anticoagulant protein Annexin A5 (ANXA5), helps maintain placental vasculature. Genetic variation, known as the M2 haplotype, in the core promoter of the *ANXA5* gene reduces protein levels and increases the risk for adverse pregnancy outcomes. Infertile couples are 14% more likely to be carriers than the general population. Low dose heparin treatment is an effective strategy to combat the complications in carrier couples, but direct testing on preimplantation embryos may serve as a more effective alternative.
Study design, size, duration: Test performance was measured by comparing Sanger sequencing on parental blood DNA and quantitative real-time (q)PCR on saliva DNA, cell line 7-cell replicates, cell line 7-cell samples and corresponding purified DNA, trophectoderm biopsies and DNA isolated from the corresponding embryonic stem cell line, Mendelian inheritance expectations in embryos, embryo sanger sequencing, and SNP microarray-based linkage analyses. Embryo qPCR allele dropout rates, M2 frequencies observed in an IVF patient population, and inheritance patterns in IVF-derived embryos.
Participants/materials, setting, methods: Initial assay development was performed on 6 IVF patient samples. Additional data was obtained from 14 cases of PGT where parental and embryo biopsy DNA (n=107) were available for research and 55 patients ordering clinical M2 testing. M2 testing was performed at Genomic Prediction Clinical Laboratory under CLIA certification and CAP accreditation.
Main results and the role of chance: Concordance rates between sanger sequencing and qPCR was 93% (13/14) on parental blood DNA and 100% (6/6) on saliva DNA. Concordance rates between all replicates of the cell line 7-cell samples were 100% (24/24). Concordance rates between 7-cell aliquots and corresponding bulk DNA was 100% (20/20). The concordance rate between trophectoderm biopsies and DNA isolated from the corresponding embryonic stem cell line was 100% (1/1). Concordance between qPCR and Sanger sequencing on trophectoderm biopsies was 100% (2/2). Trophectoderm biopsy qPCR results were 97% (104/107) concordant with expectations from Mendelian inheritance rules and 100% (107/107) when including SNP array based linkage analyses. There was an M2 frequency rate of 18% in patients ordering clinical testing. When one parent was a carrier, half (33/66) of the embryos were M2 carriers. In families where both parents were carriers, 76% (16/21) of embryos were M2 carriers.
Limitations, reasons for caution: Embryo biopsy qPCR displayed a 7% allele drop out rate and required concurrent SNP array based linkage analysis to obtain accurate genotypes.
Wider implications of the findings: We have developed and validated a saliva DNA-based M2 haplotyping test for infertile patients, and a new ability to perform "PGT-M2 haplotyping" for carrier couples undergoing IVF. Future work will include prospective analysis of clinical outcomes following embryo selection and non-selection with PGT for M2 carrier status.

POSTER VIEWING SESSION
REPRODUCTIVE ENDOCRINOLOGY

P-549 None of The Parameters of Bologna and Poseidon Criteria Has a Significant Impact on Pregnancy Rates

B. Devranoglu[1], H. Bozdag[2], E. Özkaya[1], Ç. Yayla Abide[1], E. Çöğendez[1], E. Tozkır[1], E. Darici[1]

[1]University of Health Science- Zeynep Kamil Maternity and Childeren's Diseases Health Training and Research Hospital, Department of Obstetrics and Gynecology, istanbul, Turkey ;
[2]Health Sciences University Sultan Abdülhamid Han Training and Research Hospital, Department of Obstetrics and Gynecology-, istanbul, Turkey

Study question: What are predictive values of the individual parameters of Bologna and Poseidon criteria for clinical pregnancy and cycle cancellation in women with poor ovarian reserve or previous poor response?
Summary answer: These criteria, Bologna or Poseidon, did not have any benefit to ameliorate management to obtain a better outcome.
What is known already: Even several authors have attempted to define the diagnosis of poor ovarian response (POR), this terminology has not been clarified among international publications. According to a published systematic review of 47 randomized controlled trials, there were 41 different POR definitions. To outline the POR definition in a standardized manner, Ferraretti et al. have proposed new definitive criteria known as "Bologna Criteria.". A New strategy, POSEIDON, has been introduced to predict the prognosis of patients undergoing ovarian stimulation for IVF.
Study design, size, duration: Seven hundred twenty-two cases were retrospectively screened from the database and reclassified based on both Bologna and Poseidon criteria separately, and assisted reproductive technology (ART) outcomes were compared for each corresponding group. The diminished ovarian reserve was defined according to basal follicle-stimulating hormone (FSH) value >10 IU/L, antral follicle count <6, or anti-Müllerian hormone <1.1 ng/mL and/or a previous poor ovarian response. The presence of one of these criteria made us diagnose poor ovarian reserve.
Participants/materials, setting, methods: Poor ovarian reserve was determined in patients who fulfilled the above-mentioned criteria. Individualized gonadotropin dose and protocol were selected based on our institutional conventional ovarian hyperstimulation protocols defined for cases with poor ovarian reserve. All these cases were retrospectively screened from the database and reclassified based on both Bologna and Poseidon criteria separately, and ART outcomes were compared for each corresponding group.
Main results and the role of chance: The highest pregnancy rate was observed in Poseidon group 1 (10.1 % vs. 4.8 % in Poseidon group 2, 4.6 % in Poseidon group 3, 4.3 % in Poseidon group 4) however the difference between groups did not reach statistical significance ($p > 0.05$). No pregnancy was observed in Bologna groups which included cases fulfilled the criteria age and ovarian reserve or age and oocyte number, on the other hand, Bologna group with oocyte number and ovarian reserve criteria had 4.7 % pregnancy rate, and pregnancy rate was 3.7 % in group of women who fulfilled all criteria of Bologna classification. Pregnancy rates were not found to be statistically significant ($p > 0.05$).
Limitations, reasons for caution: This was a retrospective study and no data available in terms ongoing and live birth rates.
Wider implications of the findings: Our data showed that Bologna or Poseidon did not have any benefit to change management to obtain better outcomes but may be utilized to provide better and precise information and counseling for the patients with poor ART outcomes before starting the treatment cycle.
Trial registration number: not applicable

P-550 Adenosine deaminase activity in the follicular fluid of infertile women with diminished ovarian reserve can act as a predictor of ovarian reserve

G. Keskin[1], B. Bacanakgil[1], H.H. Kalem[2], A. Köse[2], A. Atıcı[1], S. Yalcınkaya[1], M. Ayyildiz[3]

[1]Health Science University Istanbul Research and Education Hospital, Department of Obstetrics and Gynecology, Istanbul, Turkey ;
[2]Health Science University Istanbul Research and Education Hospital, Department of Embriyology, Istanbul, Turkey ;
[3]Health Science University Istanbul Research and Education Hospital, Department of Biochemistry, Istanbul, Turkey

Study question: Does the activity of total Adenosine deaminase (ADAT) in the follicular fluid have a relation with ovarian reserve and clinical parameters linked to IVF outcomes?
Summary answer: Follicular fluid(FF) ADAT activity in DOR group was higher and had a negative correlation with BMI,a positive correlation with FSH and no relation with IVFoutcomes.
What is known already: In the human reproductive tract,the function of the enzymes that affect adenosine metabolism,especially ADA,have been investigated.The activity of ADA was evaluated in the male reproductive system. Inhibition of ADA activity increases adenosine levels and it resulted an improvement of sperm fertilisation.In addition, it is suggested that ADA receptors might have a role in capacitation and acrosome reaction.Alteration in ADA activity seemed to be related with male infertility.For the female reproductive system,that women with elevated ADA activity have the highest risk for recurrent spontaneous abortion.To the best of our knowledge,ADA activity has not yet been systematically addressed in the female infertility.
Study design, size, duration: This study is a retrospective cohort study. The data of all individuals, who underwent their IVF/ICSI at IVF Unit of Istanbul Research and Education Hospital from May 1st 2019 to July 31st 2019 were retrospectively reviewed. Total of 106 women were eligible and enrolled in this study.
Participants/materials, setting, methods: The women were between 23–45 years old, had an infertility etiology of diminished ovarian reserve(DOR),tubal factor(TF),male factor(MF) or unexplained infertility. Patients were excluded if they had two or more type of infertility etiologies, diseases of the immune system, hematologic malignancies, ovarian tumors, endocrine disorders or smoking. Blood samples were drawn before oocyte retrieval. FF from the first aspirated follicle was used for ADAT measurement.Its relation with ovarian reserve markers and IVF outcomes were determined.
Main results and the role of chance: A total of 106 infertile women were enrolled in the study. Thirty-three of the women had DOR, 22 had TF, 21 had unexplained infertility and 30 had MF infertility.

AMH level of DOR group was significantly lower than that of the other groups ($p<0.01$). FSH level of DOR group was significantly higher than that of the other groups ($p<0.05$). Mean level of serum estradiol on the day of hCG administration ($p<0.01$), total number of oocytes retrieved ($p<0.01$) and MII oocyte count ($p<0.01$) of DOR group were significantly lower than that of the other groups. There was no statistically significant difference among the other groups ($p>0.05$).

Plasma lymphocyte, monocyte and eosinophil counts were not statistically different between groups ($p>0.05$).

Activity of plasma ADAT was significantly higher than activity of FF ADAT in all of the infertile groups ($p<0.01$). Activity of FF ADAT was higher in DOR group than the others ($p<0.01$).There was no statistically significant difference among the other groups ($p> 0.05$).

The relation of ADAT activity with BMI showed a negative correlation in DOR group (r:-0.507). Additionally, ADAT activity of DOR group and FSH levels, showed a positive correlation (r:0.352).
Limitations, reasons for caution: Study population was small and ADA enzyme activity could be calculated as ADA1 and ADA2 rather than ADAT.
Wider implications of the findings: Increased ADAT activity can lead to reduced adenosine levels, which might be resulted in disturbed fertility process. The activity of FF ADAT activity might be important for fertility work-up. Further studies are needed.
Trial registration number: IRB: IEAH7/2019

P-551 Predictive factors influencing pregnancy rate in frozen embryo transfer.

N. Hayashi[1], N. Enatsu[1], T. Iwasaki[1], J. Otsuki[2], Y. Matsumoto[1], S. Kokeguchi[1], M. Shiotani[1]

[1]Hanabusa Women's clinic, medical office, Kobe, Japan ;
[2]Okayama University Assisted Reproduction Technology Center, medical office, Okayama, Japan

Study question: What factors influence pregnancy rate (PR) in frozen embryo transfer (FET)?
Summary answer: Endometrial thickness and the position of transferred air bubbles influenced clinical pregnancy in FET cycles.
What is known already: There have been many reports evaluating single factors which affect embryo transfer (ET) outcomes including embryo quality,

female age, endometrial thickness and the technique of the transfer procedure. Most studies have confirmed that the PR is better in women with a thicker endometrium than those with a thinner endometrium. Another significant variable was the position of the transferred air bubble, which is often regarded as an indicator for the position of the transferred embryo. However, precisely which factors and the degree to which they each affect ET outcomes is still unknown.

Study design, size, duration: This study was a retrospective study, and included 938 FET cycles involving single frozen-thawed good quality blastocyst (Gardner grade ≥ 3BB) between August 2017 and January 2018 in a single fertility clinic.

Participants/materials, setting, methods: FET was performed with either a hormone-replacement cycle or natural-cycle protocol. The primary outcome of this study was clinical pregnancy defined as the detection of gestational sac in the uterus by using transvaginal ultrasound at 5 weeks gestational age. The significance of several parameters including endometrial thickness, position of the transferred air bubble, self-evaluation score by physicians, and the uterus direction at ET as predictors of clinical pregnancy were evaluated using univariate and multivariate analysis.

Main results and the role of chance: Among 938 ET cycles, 462 (49.3%) were considered clinically pregnant. Among the variables, endometrial thickness was positively associated with clinical pregnancy in a linear trend. The clinically acceptable threshold was calculated as 10.0mm. The position of the transferred air bubble and the clinical pregnancy rate showed a curvilinear relationship indicating that the clinical PR increased as the air bubble position got closer to 6 mm apart from uterine fundus, remained steady until 10 mm, and began decreasing after 10 mm. The clinical PR was significantly higher in cases with a self-evaluation rating of A, compared with ratings of B or C (50.2% vs 42.1%, p<.05). Comparing the clinical PR based on uterus direction, there was no difference between the anteflexion, retroflexion, and straight groups (59.5%, 47.6%, and 42.9% respectively, p = .45). Univariate analysis of predictive parameters identified endometrial thickness, self-evaluation score by physicians, and position of air bubbles as significant predictors of clinical pregnancy, of which endometrial thickness and position of air bubbles appeared to be independently related to clinical pregnancy (odds ratio; 1.56 and 1.34, 95% confidence interval; 1.20 – 2.03 and 1.02 –1.77 respectively, p<.05).

Limitations, reasons for caution: Patients with slight complication such as leiomyoma or hydrosalpinx without surgical indication and adenomyosis were included in this study. Therefore, we could not completely exclude the influence of these factors Additionally, this study was a non-randomized, retrospective study, and a larger prospective study would be needed to optimize ET strategy.

Wider implications of the findings: We recommend that physicians should focus on maintaining their patients' endometrial at the greatest possible thickness during the ET cycle. Moreover, the transferred air bubbles, that means a position of the transferred embryo, should be placed between 6 to 10 mm from the fundus during ET procedure.

Trial registration number: not applicable

P-552 Analysis of Nonylphenols (NPs), Mirex and selected endocrine disrupting chemicals (EDCs) in the follicular fluid (FF) of women undergoing intracytoplasmic sperm injection (ICSI)

T. Trapphoff[1], A. Bullach[2], S. Zühlke[2], M. Spiteller[2], S. Dieterle[1]

[1]Kinderwunschzentrum Dortmund, Dortmund Fertility Centre, Dortmund, Germany ; [2]Technische Universität Dortmund, Analytische Chemie und Umweltchemie INFU, Dortmund, Germany

Study question: Are selected EDCs including Mirex and NPs present in the FF of women undergoing ICSI, and are they associated with clinical and socioeconomic parameters?

Summary answer: NP, Mirex and selected EDCs can be quantified in FF and may lead to a reduced maturation and fertilization rate in patients undergoing ART.

What is known already: EDCs are exogenous substances known to interfere with the mammalian hormone system. EDCs mostly origin from synthetic chemicals used in industry, pharmacy or agriculture. Exposure to EDCs has been shown to affect female reproduction. It is known that different EDCs alter the embryonic development, spindle formation, chromosomal alignment or gene expression of oocytes and embryos. Besides well studied EDCs like Polychlorinatedbiphenyls (PCB), Polybrominateddiphenylethers (PBDE) or Dichlorodiphenyltrichloroethane (DDT)/Dichlorodiphenyldichloroethylene (DDE), less is known about two extensively utilized EDCs: Mirex and the technical mixture of nonylphenols.

Study design, size, duration: Consecutive patients undergoing ICSI due to male subfertility were included. Patients with endometriosis or polycystic ovaries were excluded. Human FF was collected at the Fertility Center Dortmund between 2016 and 2017 (*n*=210). Only FF from the first two punctured follicles was collected. An additional multiple-choice questionnaire was provided to identify potential sources of EDC, because the social environment, consumers behaviour and food habits may play an essential role regarding EDC uptake.

Participants/materials, setting, methods: The concentration of Mirex, five different NP isomers, DDT/DDE, six PCB and four PBDE congeners in the FF was analysed using gas-chromatography coupled with mass-spectrometry using selected ion monitoring. The samples were extracted and derivatized before quantification of selected EDC. Standard solutions of pre-named concentrations and solvent blanks were injected with every measurement. To identify a potential association between EDC-exposure, -uptake, clinical parameters and socioeconomic factors, a statistical evaluation was performed.

Main results and the role of chance: All investigated EDCs were present in every FF sample showing a broad distribution of concentrations between individual samples. NP was present in the FF at 10.4±11.1ng/g FF [mean±sd], Mirex at 1.1±0.9ng/g FF, PCBs at 0.1±0.1ng/g FF, PBDEs at 0.04±0.02ng/g FF and DDT/DDE at approximately 0.7±0.8ng/g FF. There was no significant correlation between EDC concentration and the number of retrieved oocytes. With regard to clinical parameters, an increased concentration of NP, Mirex, DDT/DDE, PCB153, PBDE99, 100 and BB153 in FF samples correlated negatively with the maturation rate (p<0.05). Nearly all examined EDCs including NP isomers and Mirex lead to a relative decrease in the number of 2PN and hence a significantly reduced fertilization rate (p<0.05). In contrast to the maturation and fertilization rate, no significant influence of EDC concentration on clinical pregnancy rate could be observed.

Regarding socioeconomic factors, no impact was observed regarding patients' residential area, diet, source of food products, nicotine or caffeine consume, stays abroad as well as professional life. However, a significant correlation between EDC concentration and source of supply of textiles (fashion discounters vs. retail shop vs. fashion boutiques) was found (p<0.05), in particular for NP.

Limitations, reasons for caution: Limitations of this study include difficulties in extrapolating the findings to the general population, because no data of women not undergoing ICSI are available. Data regarding the exact molecular mechanism of NP and Mirex respectively, are limited.

Wider implications of the findings: EDC uptake and exposure to NP, Mirex, PCB, PBDE or DDT/DDE may adversely affect female reproductive outcome. Higher EDC levels in the FF correlate negatively with the maturation and fertilization. Consumers´ behaviour play an essential role regarding the individual EDC uptake.

Trial registration number: NCT01385605

P-553 Aging attenuates ovarian circadian rhythm

G.L. Ding[1], Z.R. Jiang[1], K.X. Zou[1], H.F. Huang[1]

[1]The International Peace Maternity and Child Health Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, China

Study question: The objective of our study was to investigate the effect of aging on ovarian circadian rhythm.

Summary answer: Subfertility in older women is partially due to ovarian circadian dysrhythmia as a result of aging.

What is known already: The circadian clock is also known as the physiological clock. In mammals, the circadian clock system is composed of coordinated and synchronized cell and tissue clocks, including the central clock located in the suprachiasmatic nucleus (SCN) of the basal hypothalamus and the peripheral clock in the various tissues of the body.The ovarian circadian clock is a peripheral circadian clock that is regulated by neuroendocrine signals from the SCN, playing an important role in the physiological process of the normal reproductive system, such as ovulation and steroid release. However, the effect of aging on the ovarian clock has hardly been explored.

Study design, size, duration: Human granulosa cells were obtained by follicular aspiration from women undergoing in vitro fertilization (IVF), which were divided into two groups, 34 cases of young group (under 40 years old) and 18

cases of old group (over 40 years old). Female C57BL/6 mice of 12-week-old were determined as young group and 8-month-old as old group. Three to five mice per group were sacrificed every fourth hour to collect liver and ovary tissues.

Participants/materials, setting, methods: The ovarian luteinized granulosa cells from young and old patients were isolated. Anti-Müllerian hormone (AMH) was examined. For mice, the stage of the estrous cycle was determined by vaginal smears. During proestrus, three to five mice per group were sacrificed every fourth hour (ZT 0, ZT 4, ZT 8, ZT 12, ZT 16, ZT 20) to collect liver and ovarian tissues. Real-time quantitative PCR was used to detect the expression of clock genes.

Main results and the role of chance: All the examined circadian clock genes (Clock, Bmal1, Per1, Per2, Cry1 and Rev-erbα) in human granulosa cells showed a downward trend in expression with aging. And, the mRNA expression levels of the circadian clock genes were negatively correlated with age ($P<0.05$). Older patients (≥ 40 years of age) had significantly reduced serum anti-Müllerian hormone (AMH) levels. Except for Rev-erbα, all the other examined circadian clock genes were positively correlated with the level of AMH ($P<0.05$). The circadian rhythm in the ovaries of older mice was changed significantly, although the circadian rhythm in the livers of older mice was basically consistent with that of young mice. There was no difference between the two groups in the expression of the differentiation marker LHCGR and the expression of the internal reference β-actin, suggesting that the decreased expression of clock genes was indeed related to age but was not related to a reduction in the extent of granulosa cell differentiation.

Limitations, reasons for caution: Our findings from human granulosa cells suggested a difference in the expression of circadian clock genes at certain time points. But the effect of aging on the rhythm of the ovarian clock could not be verified in human samples. So we also carried out mouse experiments in our study.

Wider implications of the findings: In our study, we found that age is closely related to ovarian circadian clock. Subfertility in older women is partially due to ovarian circadian dysrhythmia as a result of aging. More studies will be needed to explain mechanistically how aging affects the circadian clock of the ovary.

Trial registration number: not applicable

P-554 Embryo transfer strategy for patients with normal P level on hCG day: a large sample retrospective cohort study

S. Yang[1], L. Rong[1], Z. Xiumei[1], W. Lina[1], W. Haiyan[1], M. Caihong[1], L. Ping[1], Q. Jie[1]

[1]Peking University Third Hospital, Reproductive Medical Center, Beijing, China

Study question: The present study was aimed to investigate the transfer strategy for patients with different level of "normal" P level on hCG day.

Summary answer: The clinical outcomes of fresh embryo transfer were better with lower P level on hCG day.

What is known already: The "normal" P level might also affect the clinical outcomes of IVF/ICSI. More and more clinicians consider the "frozen-all" strategy safe and effective, but is this strategy proper for everyone and is there more individualized choice for patients?

Study design, size, duration: It is a single-center retrospective cohort study, and the study period was patients accepted oocyte pick-up between 1st Jan. 2011 and 31th Dec. 2016. During the study period, 20,658 cycles were full-filled the inclusive and exclusive criteria, including 4915 cycles of frozen-all patients had accepted frozen-thawed embryo transfer by the end of Jun. 2019 (first frozen-thawed cycles after frozen-all in fresh cycles). There were 15,473 fresh cycles and 4,915 frozen-thawed cycles were analyzed respectively.

Participants/materials, setting, methods: The cycles were divided into two groups depending on the embryo transfer strategy, fresh embryo transfer or frozen-all. And both groups were further divided into four subgroups depending on Quartile of P level and embryo stage (D3/D5).

Main results and the role of chance: The clinical outcomes of fresh embryo transfer refer to clinical pregnancy rate (CPR), implantation rate (IR), and live birth rate (LBR) were decreased with increasing P level, especially when P>3.56nmol/l, which were lower than those accepted frozen-thawed embryo transfer ($p<0.05$). The patients accepted D3 embryo transfer and P≤3.56nmol/L, the fresh embryo transfer outcomes were better than frozen-thawed cycles, including higher CPR, IR, LBR, and lower miscarriage rate ($p<0.05$). The clinical outcomes were comparable in blastocyst embryo transfer cycles, between different P level with fresh or frozen-thawed embryo transfer. The clinical outcomes of frozen-thawed cycles were comparable between patients with different P level on hCG day. For patients with P ≤3.56nmol/L, we suggested fresh embryo transfer. And for those p>3.56 nmol/L, we suggested blastocyst embryo transfer with fresh embryo or frozen-thawed embryo transfer.

Limitations, reasons for caution: The present study was a single center retrospective study, the cut-off level of progesterone only suitable for our center.

Wider implications of the findings: The present study suggest individualized embryo transfer strategy for patients with different progesterone levels, and pointed out that there should not be "one for all" strategy in IVF/ICSI cycles.''

Trial registration number: NOT APPLICABLE

P-555 Melatonin – a new fertility wonder drug? A systematic review on the impact of melatonin on fertility

M. Mejlhede[1], U.B. Knudsen[2]

[1]Aarhus University, Health, Aarhus, Denmark ;
[2]Aarhus University, Clinical Institute of Medicine, Aarhus, Denmark

Study question: How does melatonin effect assisted reproductive technologies (ART)-outcomes?

Summary answer: Most of the included studies showed a significant improvement in one or more ART-outcome but not in clinical pregnancy rate or live birth rate.

What is known already: ART are associated with significant levels of oxidative stress, which can have a negative impact on the pregnancy rates by modifying the quality of oocytes, embryos and sperm. The anti-oxidant melatonin has been investigated as a supplement in *in vitro* fertilization embryo-transfer (IVF-ET) protocols to see if it can improve the ART-outcomes.

Study design, size, duration: A systematic review in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA). Systematic data-search of PubMed, Embase and Cochrane Central Register of Studies from the earliest available online year of indexing up to April 2019 was conducted. Fifteen trials were included. The total number of patients was 1.781. One retrospective cohort study reported the results in embryo transfer cycles and thereby contributing with 13.372 unique embryo transfer cycles.

Participants/materials, setting, methods: The population consisted of infertile women/men undergoing IVF-ET including intracytoplasmic sperm injection (ICSI).

The intervention was melatonin in vivo/vitro.

The primary outcome was clinical pregnancy rate (CPR).

The secondary outcomes were live birth rate (LBR), sperm quality-parameters, fertilization rate, oocytequantity/quality, quality of embryos and implantation rate.

Methodological quality was assessed for each study using the CHECKLIST from the European Society of Human Reproduction and Embryology (ESHRE).

Main results and the role of chance: No significant changes in CPR in relation to use of melatonin were demonstrated. The majority of studies did not show effect on LBR. One study showed a significant reduction in LBR. Three studies showed a significant improvement of fertilization rate and one study showed a significantly higher implantation rate. Eight studies demonstrated a significant rise in embryo quality. Oocyte quality and/or quantity were showed to be significant improved by seven studies. The two studies, who investigated sperm quality parameters, both demonstrated a significant improvement in the measured parameters. Ten studies had poor methodological quality.

Limitations, reasons for caution: The included studies were small and the methodological quality of the studies low or very low. Therefore, there is insufficient evidence to make any conclusion on whether melatonin could influence the result of ART.

Wider implications of the findings: A systematic review and meta-analysis from 2013 demonstrated a pooled risk ratio of 1.21 for CPR in favour of melatonin. A Cochrane Systematic Review investigated the effects of use of antioxidants including melatonin on female subfertility. The CPR improved (not statistically significant) in the group receiving melatonin compared to control-group.

Trial registration number: not applicable

P-556 The transfer of an extra low quality embryo: Is it ever worth it?

D. Braga[1,2], A. Setti[1,2], R. Ferreira[3], A. Iaconelli Jr.[4], E. Borges Jr.[2,4]

[1]Fertility Medical Group, Scientific research, Sao Paulo, Brazil ;
[2]Instituto Sapientiae - Centro de Estudos e Pesquisa em Reprodução Assistida, Scientific research, Sao Paulo, Brazil ;
[3]Fertility Medical Group, IVF laboratory, Sao Paulo, Brazil ;
[4]Fertility Medical Group, Clinical department, Sao Paulo, Brazil

Study question: Is it ever worth it to add an extra low-quality embryo to a high-quality embryo transfer in IVF cycles?
Summary answer: The transfer of an extra low-quality embryo is worth it for patients >37 years-old. For younger women, this dramatically increases the risk of multiple pregnancies.
What is known already: Although morphological evaluation has been the main strategy applied in order to select embryos for transfer, it has been shown that even aneuploid embryos are able to reach high morphological scores and vice versa. In an effort to promote singleton gestation and reduce the number of multiple pregnancies, guidelines for the limits on the number of embryos to be transferred in IVF cycles have been published. Recommendations strict the number of embryos transferred considering patients age and treatment prognosis. Information concerning the developmental stage is also provided, however, less is known about the quality of transferred embryos.
Study design, size, duration: Data analyzed in this historical cohort study were obtained via chart review of 1249 patients undergoing intracytoplasmic sperm injection (ICSI) cycles between 2016 and 2018. For all cycles one or two embryos were transferred on day five. The embryo morphology was assessed 16–18h post-ICSI and on the mornings of days two, three, and five of embryo development and all evaluated parameters were used for the classification of embryos into top- or low-quality embryo.
Participants/materials, setting, methods: This study was performed in a private university–affiliated IVF center. Cycles were split into groups depending on the number and quality of transferred embryos. Group Top-Quality (n=871), in which a single top-quality embryo was transferred, Group Mixed-Quality (n=378), in which one top-quality and one low-quality embryo were transferred. The impact of the transfer of extra low-quality embryos on singleton and multiple pregnancies rates, in different female age ranges was investigated by general mixed models.
Main results and the role of chance: The pregnancy rate was significantly increased when the double embryo transfer, including one top-quality and one low-quality embryo, was compared with the single top-quality embryo transfer, regardless of the age: 33.5% vs 44.6%, p=0.003, for patients <35 years-old, 27.9% vs 36.9%, p<0.027, for patients between 35 and 37 year-old, and 25.4% vs 24.1%, p=0.041 for patients >37 years-old, for Top-Quality and Mixed-quality groups respectively. The transfer of an extra low-quality embryo also increased the multiple pregnancy rates in younger patients: 0.0% vs 41.3%, p<0.001, for patients <35 years-old and 27.9% vs 36.9%, p=<0.001 for patients between 35 and 37 year-old, for Top-Quality and Mixed-quality groups respectively. For patients >37 years-old, no differences in the multiple pregnancy rate was noted when one (high-quality) or two (one high- and on low-quality) embryos were transferred: 15.3% vs 21.1%, p=0.694, for Top-Quality and Mixed-Quality groups respectively. The increment of one low-quality embryo increased the odds of multiple pregnancies in 37% for patients <35 years-old (OR: 0.631, CI: 0.487 - 0.817, p<0.001) and in 44% in patients between 35 and 37 year old (OR: 0.563, CI: 0.340 – 0.932, p=0.026). The miscarriage rates did not differ among the groups, for any age.
Limitations, reasons for caution: Retrospective nature of this study and the small sample size may be a reason for caution.
Wider implications of the findings: The addition of an extra low-quality embryo may increase the pregnancy rate and be valuable for older patients, in which the pregnancy chance is lower. However, for younger patients, this results in increased multiple pregnancy chance, raising the question on whether taking on this level of risk is worth it.
Trial registration number: Not applicable

P-557 The contribution of the rescue in vitro maturation to ICSI cycles

R.C. Ferreira[1], D. Braga[2,3], A. Setti[2,3], A. Iaconelli Jr.[4], E. Borges Jr.[3,4]

[1]Fertility Medical Group, IVF Laboratory, São Paulo, Brazil ;
[2]Fertility Medical Group, Scientific research, São Paulo, Brazil ;
[3]Instituto Sapientiae - Centro de Estudos e Pesquisa em Reprodução Assistida, Scientific research, São Paulo, Brazil ;
[4]Fertility Medical Group, Clinical department, São Paulo, Brazil

Study question: Is it ever worth it to add an extra embryo derived from an immature oocyte, when an embryo derived from metaphase-II (MII) oocyte is transferred?
Summary answer: The transfer of an extra embryo, derived from rescue in vitro maturation (rIVM) is not worth it.
What is known already: In vitro maturation (IVM) has been reported mostly in women with polycystic ovary syndrome, where, oocytes are on purpose recovery at immature stages in natural cycles or after low-dose gonadotropin stimulation. Success rates after IVM appear inferior to in vivo-matured oocytes. Unlike in scheduled IVM, in stimulated cycles, pharmacologic doses of gonadotrophins induce the growth of follicles, which, under natural conditions, would become atretic. Ovarian stimulation leads to the retrieval of oocytes at different nuclear stages and some may spontaneously mature in vitro. Whether rIVM of oocytes retrieved from stimulated cycles may improve the ICSI outcomes is to be elucidated.
Study design, size, duration: Data analyzed in this historical cohort study were obtained via chart review of 2021 patients undergoing controlled ovarian stimulation for ICSI cycles, between 2016 and 2018. After ovum-pickup oocytes were assessed for nuclear status. Mature oocytes that had released the first polar body were used for ICSI. Immature oocytes, at prophase I (PI) and metaphase I (MI) stages, were cultured. Those that spontaneously matured in vitro were eventually injected and transferred.
Participants/materials, setting, methods: Cycles, performed in a private university–affiliated IVF-center, were split into groups depending on the origin of transferred embryos: Group-Single-MII (n=454, one embryo, derived from an MII-oocyte was transferred), Group-Double-MII (n=1483, two embryos, derived from MII-oocytes were transferred, Group-Double-Mixed-MI (n=72, one embryo derived from an MII-oocyte and one from a MI-oocyte were transferred, and Group-Double-Mixed-PI (n=12, one embryo derived from an MII-oocyte and one from a PI-oocyte were transferred). Outcomes were compared among the groups.
Main results and the role of chance: Overall 21,220 oocytes were retrieved, in which 15,200 (71.6%) were in the MII-stage, 1830 (8.6%) were in the MI-stage, and 4,190 (19.7%) were in the PI stage. When adjusted for the age and endometrial thickness, the pregnancy rate was increased when two MII-derived embryos were transfer in comparison with the transfer of a single MII-derived embryo, however, no significant differences were noted when a single MII-derived embryo transfer or a double embryo transfer, including one MII-derived embryo and one MI- or one P1-derived embryo, was performed (18.0%, 39.4%, 33.3% and 15.3.0%, p<0.001, for Group-Single-MII, Group-Double-MII, Group-Double-Mixed-MI and Group-Double-Mixed-PI, respectively). The same results were observed for the implantation rate: the Group-Double-MII, presented the higher implantation, followed by the Group-Single-MII and Group-Double-Mixed-MI, while the Group-Double-Mixed-PI, presented the lowest rate (17.7%, 29.4%, 20.8% and 11.8%, p<0.001, for Group-Single-MII, Group-Double-MII, Group-Double-Mixed-MI and Group-Double-Mixed-PI, respectively). The miscarriage rate did not differ among the groups (9.9%, 9.3%, 9.1% and 25.0%, p=0.911, for Group-Single-MII, Group-Double-MII, Group-Double-Mixed-MI and Group-Double-Mixed-PI, respectively).
Limitations, reasons for caution: The embryo quality may be a source of bias and a reason for caution.
Wider implications of the findings: These findings raise the question about the contribution of rIVM in ICSI cycles. Although previous studies demonstrated that rIVM may increase the number of embryos available for transfer, the quality of these embryos must be carefully evaluated, since its implantation potential seems to be limited, especially for PI-derived embryos.
Trial registration number: Not Applicable

P-558 Serum sex hormone–binding globulin (SHBG) levels during controlled ovarian hyperstimulation as a predictor of ovarian response in women without polycystic ovary syndrome

J. Zhai[1], S. Li[1], Y. Zhu[1], Z.J. Chen[1], Y. Du[1]

[1]Ren Ji Hospital- School of Medicine- Shanghai Jiao Tong University, Center for Reproductive Medicine, Shanghai, China

Study question: Is the serum SHBG level during controlled ovarian hyperstimulation (COH) associated with ovarian response? What's the difference between polycystic ovary syndrome (PCOS) and non-PCOS patients?
Summary answer: Serum SHBG levels, especially SHBG on hCG-day, could be recognized as a predictor of ovarian response during COH in non-PCOS, but not in PCOS participants.
What is known already: Previous study reports the positive correlation of serum SHBG levels with the total number of follicles in infertile women with tubal and/or male-factor who undergo IVF and Recent literature has also stressed the importance of SHBG measurement in the diagnosis and management of PCOS. However, the correlation between serum SHBG levels and ovarian response in COH cycles and the difference between PCOS and non-PCOS patients remain unclear and need to be investigated.
Study design, size, duration: This is a prospective study. A total of 120 participants undergoing the first IVF cycle were recruited to our study. The serum SHBG levels were detected to analyze the role of SHBG in the prediction of ovarian response in both PCOS and non-PCOS patients. The duration of this study is from August 1st, 2018 to October 1st, 2019.
Participants/materials, setting, methods: A total of 120 participants (60 non-PCOS and 60 PCOS participants) receiving GnRH-antagonist protocol were recruited to our study. The serum samples were collected every 2 days from each participant and the concentrations of serum SHBG and sex hormones were tested to investigate the relationship between serum SHBG levels and ovarian response during COH. Additionally, the number of follicles and the endometrium thickness were monitored using B-ultrasound.
Main results and the role of chance: Serum SHBG concentrations decreased along the COH cycle of GnRH antagonist protocol both in PCOS and non-PCOS participants. Serum SHBG levels on human chorionic gonadotropin (hCG)-day were positively correlated to numbers of retrieved oocyte and embryo in all participants. Furthermore, both basal and hCG-day SHBG levels of high responders (>15 retrieved oocytes) significantly increased compared with those of normoresponders (4-15 retrieved oocytes) in the analysis of all participant (n=120). However, when we analyzed separately, the positive correlation between serum SHBG levels and ovarian response was only observed in non-PCOS participants, without any association in PCOS group. Finally, receiver operating characteristic (ROC) curve analysis demonstrated that serum SHBG levels on hCG-day could be used as a predictor of ovarian response in the non-PCOS group (P=0.0015), but not in the PCOS group (P=0.5142).
Limitations, reasons for caution: This study did not investigate the relationship between serum SHBG level and pregnancy outcomes due to the frozen embryo transfer protocol. Secondly, we limited the treatment protocol, age, AMH and other indicators in order to control the interfering factors. Thus, the relationship between SHBG and these factors can't be studied.
Wider implications of the findings: This study provides a means to reassess the clinic value of using serum SHBG levels, especially before COH and on the hCG-day as an ovarian response predictor in non-PCOS patients. Moreover, it also improves our understanding of the intrinsic mechanisms of folliculogenesis and the difference between PCOS and non-PCOS patients.
Trial registration number: N/A

P-559 The circadian clock gene functions as a novel therapeutic target for constant darkness-induced insulin resistance and hyperandrogenism of polycystic ovary syndrome

S. Li[1], J. Zhai[1], W. Chu[1], X. Geng[1], Z.J. Chen[1], Y. Du[1]

[1]Ren Ji Hospital- School of Medicine- Shanghai Jiao Tong University, Center for Reproductive Medicine, Shanghai, China

Study question: What are the mechanisms underlying metabolic and reproductive dysfunction caused by arrhythmic circadian clock and their involvement in polycystic ovary syndrome (PCOS)?
Summary answer: The arrhythmic expressions of circadian clock genes due to constant darkness induced the metabolic and reproductive hallmarks of PCOS in rats.
What is known already: As a complex endocrine condition characterized by oligo/anovulation, high androgen levels and polycystic ovaries, PCOS is closely associated with genetic susceptibility, and environmental risk factor plays an important role in the expression of those genetic traits. Environmental toxins, diet and nutrition, socioeconomic status, and geography are suggested to be potentially involved in the etiology, prevalence, and modulation of PCOS phenotypes. Together environmental factors with genetics contribute to the complicated pathology of PCOS. As a strong environmental risk factor, circadian clock is essentially involved in various diseases. However, the functional role of circadian clock in PCOS remains to be elaborated.
Study design, size, duration: We tried to elaborate the influence of altered circadian clock gene expression caused by constant light or darkness exposure on traits of PCOS in rats and to explore the effects of 5 different rescue treatments. We utilized HepG2 cells and KGN cells to verify the molecular mechanisms. Additionally, human leukocytes and serum of PCOS (n=20) and non-PCOS (n=20) patients were collected to measure expressions of circadian clock genes and other target genes.
Participants/materials, setting, methods: The influence of circadian disruption on hallmarks of PCOS in rats and the effects of rescue treatments were evaluated by estrus cycle detection, ovary morphology, hormone and metabolic factor measurements. And the expressions of circadian clock genes in different rat models and patients were measured with quantitative PCR and western blot. The roles of circadian genes in hyperinsulinemia, hyperandrogenism and apoptosis of ovarian granuloma cells were investigated with small interfering RNA-mediated knockdown and plasmids-mediated overexpression.
Main results and the role of chance: After exposure to constant darkness, decreased brain and muscle ARNT-like protein 1 (BMAL1) promoted insulin resistance *via* glucose transporter 4 (GLUT4), and decreased period (PER) 1 and PER2 promoted androgen excess *via* insulin-like growth factor-binding protein 4 (IGFBP4) and sex hormone binding globulin (SHBG) in the liver. Hyperinsulinemia and hyperandrogenism shared a bidirectional link promoting aberrant expression of circadian genes and inducing apoptosis of ovarian granuloma cells. Notably, the altered expressions of circadian clock genes in darkness-treated rats matched those of PCOS patients. Furthermore, melatonin treatment relieved the hyperinsulinemia and hyperandrogenism of darkness-treated rats *via* BMAL1, PER1, and PER2. Restoring normal light/dark exposure for 2 weeks reversed these conditions *via* BMAL1.
Limitations, reasons for caution: We couldn't compare circadian genes in liver or adipose from women with/without PCOS due to the scarcity of samples. Although the adipose of rats kept in continual darkness exhibited abnormal BMAL1 expression, we did not conduct experiments to account for the unchanged expression in P-AKT pathway under the same conditions.
Wider implications of the findings: Our findings provide a theoretical basis for illustrating the critical function of circadian clock genes, especially *BMAL1*, *PER1*, and *PER2* in PCOS, which might aid the development of feasible preventive and therapeutic strategies for PCOS in women with biorhythm disorder.
Trial registration number: not applicable

P-560 Effect of Ovarian Stimulation on IUI Outcomes - Managing Expectations

B. Wusk[1], F. Roth[1], V. Hungerbuehler[1]

[1]fiore lab, Institute of Reproductive Medicine, St. Gallen, Switzerland

Study question: IUI - natural vs FSH stimulation: how much affects an individual medication the outcome - a single-center, retrospective database analysis over 11 years.
Summary answer: Compared to natural cycles, the application of individual FSH regimen led to a significant increase of 32% of βHCG-positive pregnancies (10.3% vs 13.6%, p≤0.001).
What is known already: A number of contributing factors during ART lead to the concern that children conceived by ART might be exposed to increased health risks as compared to naturally conceived children.
IUI is a simple and non-invasive technique with minimal monitoring and risks. It can be performed without expensive infrastructure with a reasonable success rate within a few cycles in most centers. IUI is undoubtly a more cost effective and patient-friendly strategy than ART (Pennings and Ombelet 2007).
Study design, size, duration: A single-center, retrospective database analysis over 11 years (2008-2019). Exclusion criteria were: HIV, AID, cryopreserved sperm, leucospermia. From a total of n=7164 IUI cycles, 6148 (85.8%) were included in the study . The average IUI attempt per couple was 2.9 (2097 couples with 6148 cycles).
Participants/materials, setting, methods: The study population represented daily clinical IUI practice. Average age of the female population has been:

34.0+4.6 years. Administration or not of FSH has been expressed as yes or no (68% vs 32%). Initial progressive motility (59.8±16), increased after gradient density preparation by 32% (78.4±13).
Main results and the role of chance: From 2008-2019, our overall IUI pregnancy rate (βHCG+) was 12.6% per cycle. For natural cycles, the pregnancy rate per heterologous insemination was 10.3% (n=201/1946), whereas for stimulated IUI cycles the pregnancy rate (573/4202; 13.6%) was significantly increased by 3.3% (p≤0.001).
Limitations, reasons for caution: Since we used center specific sperm preparation procedures (density gradient preparation, constant temperature setting of 34.5°C, HEPES buffer) data comparison with other studies are limited.
Wider implications of the findings: Here, we add substantial information how FSH stimulation can affect the outcome of individual IUI cycles and could assist in couple counselling and planning.
Trial registration number: not applicable

P-561 The mental health of women with polycystic ovary syndrome: a systematic review and meta-analysis

C. Chan[1,2], X. Yin[2], Y. Ji[2], C. Chan, Lai Wan[2]

[1]University of Hong Kong, Centre of Assisted Reproduction and Embryology, Pokfulam, Hong Kong ;
[2]The University of Hong Kong, Department of Social Work and Social Administration, Hong Kong, China

Study question: How is the generalized mental health status of women with PCOS?
Summary answer: The mental health situation of PCOS patients was quite worrisome, which has highlighted the importance of developing psychological health care interventions for them.
What is known already: PCOS has been proposed to be associated with several mental health problems, including somatic symptoms, anxiety, depression, body dissatisfaction, and eating disorders, diminished sexual satisfaction, and lowered health-related quality of life, etc.
Study design, size, duration: A systematic review and meta-analysis of published literature comparing the mental health of women with and without PCOS. Ten English and Chinese databases were searched up to 12/31/2018. 46 studies, including 30,989 participants (9,265 women with PCOS and 25,638 controls), were qualified for review according to the inclusion criteria.
Participants/materials, setting, methods: Random effect models were introduced, and subgroup analysis, sensitivity test, and meta-regression were carried out to determine the source for heterogeneity among studies.
Main results and the role of chance: Twenty-eight studies reported depression symptoms, 22 studies were on anxiety, 16 studies showed QoL status, 12 studies were about sexual dysfunction, five on emotional distress, four on binge eating, and four on somatization. Women with PCOS reported significantly higher depression (SMD=0.64; 95%CI: 0.50-0.78), anxiety (SMD=0.63; 95%CI: 0.50-0.77), lower QoL (SMD=-0.55; 95%CI: -0.71 to -0.39), and not significant sexual dysfunction (SMD=-0.23; 95%CI: -0.51 to 0.04). Studies from different countries, adopting various diagnosis criteria, using diverse instruments, as well as in different years, have reported heterogenetic results. Women with PCOS in China reported a larger effect size of depression and anxiety than patients from other countries.
Limitations, reasons for caution: Although subgroup analysis, meta-regression, and sensitivity tests were carried out to determine the source for high heterogeneity, only 81.63% of the heterogeneity can be explained by this study. There were still unknown sources for heterogeneity among included studies on the depression of PCOS patients.
Wider implications of the findings: PCOS patients suffer from depression, anxiety, and experience a lower QoL, whereas their sexual function is not distinct from that of healthy control. Studies using different instruments, from different countries, and adopting different diagnosis criteria, reported heterogenetic results. PCOS patients in China reported a high level of depression and anxiety.
Trial registration number: N/A

P-562 Inhibin A - a promising predictive parameter of oocyte maturity in ovarian stimulation for IVF/ICSI

B. Lawrenz[1], L. Depret Bixio[2], C. Coughlan[1], C. Andersen[3], B. Kalra[4], G. Savjani[4], L. Melado[1], H. Fatemi[1], A. Kumar[4]

[1]IVIRMA Abu Dhabi, IVF department, Abu Dhabi, United Arab Emirates ;
[2]IVIRMA Abu Dhabi, Statistical department, Abu Dhabi, United Arab Emirates ;
[3]University of Copenhagen, Laboratory of Reproductive Biology- The Juliane Marie Centre for Women- Children and Reproduction-, Copenhagen, Denmark ;
[4]Ansh Labs, Hormonal laboratory, Webster, U.S.A.

Study question: To evaluate the role of Inhibin A as a potential predictive marker of oocyte maturity in ovarian stimulation cycles for IVF / ICSI
Summary answer: On the day of final oocyte maturation, Inhibin A correlates better with the number of retrieved and mature oocytes as compared to E2
What is known already: Monitoring of ovarian stimulation for IVF/ICSI by transvaginal ultrasound (TVUS) and measurement of E2-levels is critical for the planning of final oocyte maturation and oocyte retrieval. E2-levels are supra-physiological due to multifollicular growth and do not facilitate an accurate determination of oocyte maturity. In contrast to E2, Inhibin A levels increase when a minimum follicular size of 12-15mm is attained , the minimal follicular size required to retrieve a mature oocyte . Therefore, the combination of Inhibin A measurement and TVUS may present a more reliable predictive parameter of oocyte maturity as compared to E2 plus TVUS.
Study design, size, duration: Prospective observational study, performed from September 2018 to January 2019, including data of 145 patients recorded at the beginning of ovarian stimulation and 136 patients on the day of final oocyte maturation.
Participants/materials, setting, methods: Patients with primary / secondary infertility and an indication for IVF/ICSI, undergoing ovarian stimulation in a GnRH-antagonist-protocol, were included. On day 2 / 3, AFC was recorded and blood samples were taken.Monitoring of the stimulation was performed according to clinical routine and blood samples were repeated on the day of final oocyte maturation. For measurement of E2, Inhibin A and Inhibin B, samples were thawed and analysed with the same batch of reagents.
Main results and the role of chance: Hormonal results and ovarian stimulation parameters from the IVF-treatments were available from 145 patients at stimulation start (day 2/3) and from 136 patients on the trigger day. 9 patients did not undergo oocyte retrieval. Patient characteristics include (mean ± SD): age 35.4 ± 6.5 years, BMI 28.2 ± 4.8 kg/m², infertility duration 3.9 ± 3.0 years, previous stimulations 3.1 ± 4.2. Correlations were calculated using Pearson´s (ρ) coefficient and probability values (p-value).

On the trigger day, a strong correlation (Pearson´s Coefficient) was found between the total follicle number and Inhibin A / E2 (ρ 0.78 / 0.71) and between the number of follicles ≥ 15 mm and Inhibin A (ρ 0.72). Pearson´s Coefficient showed a strong correlation between Inhibin A and the number of retrieved and mature oocytes (ρ 0.82 / 0.77), whereas E2 had a moderate correlation (ρ 0.69 / 0.69) respectively, for these parameters.
The area under the curve (AUC) for Inhibin A as a predictor for ≥ 10 mature oocytes was ρ 0.91 (CI95% [0.87 ; 0.96]) and ρ 0.84 (CI95% [0.7769 ; 0.9124]) for E2. The optimal predicted threshold level of Inhibin A for ≥ 10 mature oocytes was 668.1 pg/mL (sensitivity=88.0%, specificity=82.0%).
Limitations, reasons for caution: The limitation of the study is that the decision, when to administer medication for final oocyte maturation, was based on E2-level and follicle size, as the Inhibin A results were not available and therefore not used as a decision tool in this setting.
Wider implications of the findings: As Inhibin A on the trigger day correlates better as compared to E2 with the number of follicles ≥ 15 mm and the number of retrieved and mature oocytes, Inhibin A in combination with ultrasound monitoring of follicular development may present a promising tool to facilitate planning of oocyte retrieval.
Trial registration number: clinicaltrials.gov., number NCT03607409

P-563 Intra-Uterine Insemination + Controlled ovarian hyperstimulation versus In Vitro Fertilization in Unexplained Infertility: A systematic review and meta-analysis

A. Nandi[1], R. Gangopadhyay[2], D. White[1], T. El-Toukhy[1]

[1]Guy's and St Thomas' Hospital NHS Trust, Assisted Conception Unit, London, United Kingdom ;
[2]Watford General Hospital- Hertfordshire- UK, Department of Obstetrics and Gynaecology, Wembley, United Kingdom

Study question: What is the relative efficacy of IUI+COH compared with IVF in couples with unexplained infertility?

Summary answer: Results showed a higher success rate following IVF compared to IUI+COH, particularly in older women, but no difference in younger women.

What is known already: Unexplained infertility is a diagnosis of exclusion when all standard fertility investigations, namely tests of ovulation, tubal patency and semen analysis, are normal. The two most applied treatment options are intra-uterine insemination and IVF. However, there is an ongoing debate on the effectiveness of the treatments and the United Kingdom (UK) National Institute for Health and Care Excellence (NICE) fertility guidelines recommend IVF treatment rather than IUI after 2 years of expectant management. We sought to conduct a systematic review of existing evidence to assess the relative efficacy of the two treatments.

Study design, size, duration: We searched Medline, Embase, CIHNL, Pscy Info, and Cochrane Library from 1980 till November 2019. Only RCTs comparing IUI + COH (using either clomiphene citrate or injectable gonadotropins or both) with IVF with female patients aged 18 - 43 years and diagnosed with unexplained infertility were included for the systematic review.

Two authors reviewed citations from primary search independently and any disagreement was resolved by mutual discussion and consultation with a third author.**Participants/materials, setting, methods:** The titles and abstracts were scrutinised to identify relevant articles. The full texts of all potentially relevant articles were retrieved and reviewed to identify articles, which fulfil the study inclusion criteria. Study characteristics including study type and setting, inclusion criteria, recruitment procedure, intervention and outcome data were extracted. All included studies were then assessed for trial quality as per Cochrane guidelines. From each primary study, data were pooled and analysed using Revman software 5.2 versions.

Main results and the role of chance: In total eight RCTs were included. The quality of evidence was moderate to low quality due to inconsistency across the trials and imprecision. The pooled result showed that IVF was associated with a statistically significant higher live birth rate (RR 1.53, 95% CI 1.01 – 2.32, P <0.00001 I^2 = 86%) with no significant difference in multiple pregnancy rate or OHSS rate. Sensitivity analysis based on women's age and a history of previous IUI or IVF treatment showed no significant difference in the live birth rates (RR 1.01, 95% CI 0.88 -1.15, I^2 = 0%, 3 RCTs) between the two treatments in treatment-naïve women younger than 38 years. In women over 38 years, the live birth rates were significantly higher in the IVF group (RR 2.15, 95% CI 1.16 – 4.0, I^2 = 42%, 1 RCT).

Limitations, reasons for caution: The main limitation encountered in this review was the considerable clinical and methodological heterogeneity present among the primary studies, including differences in the definition of unexplained infertility, study design and inclusion criteria as well as treatment protocols used for IUI+COH and IVF.

Wider implications of the findings: Our study included only direct comparisons between IUI+COH and IVF as they are the most commonly applied treatment and showed overall higher success with IVF but no difference in young women <38 years. This will certainly enable clinicians to individualise the care to these couples.

Trial registration number: not applicable

P-564 Agonist vs antagonist administration: is there an age-related difference? A retrospective analysis

F. Roth[1], **B. Wusk**[1], **V. Hungerbuehler**[1]

[1]*FIORE, IVF Lab, St. Gallen, Switzerland*

Study question: Agonist vs antagonist: Is there a best practice/algorithm to suggest for a specific age group of the female idiopathic patient?

Summary answer: In the age group of ≥35 years, a significantly increased pregnancy rate (βHCG+) for the agonist protocol has been observed.

What is known already: Controlled ovarian hyperstimulation (COH) is a fundamental step in ART. GnRH antagonist stimulation protocol has shorter duration of treatment and reduced administration of gonadotropins. GnRH agoinst protocol has shown to be better in folliculogenesis and pregnancy rate, despite its costly and time-consuming.

Study design, size, duration: A single-center, retrospetive database analysis of 1538 antagonist- and 422 agonist protocols over a 10y year period (2009-2019) has been analyzed. Female patients have been divided into four age groups: 26-30 years; 31-35 years; 36-40 years and 41-45 years. Excluded were cases of: disovulation, endometriosis and TESE, MESA or cryopreserved sperm.

Participants/materials, setting, methods: Age-dependant comparison of agonist vs antagonist protocols have revealed a slight to distinct increase of pregnancy rates in favor of agonistic stimulation.

age group	βHCG+ (%) agonist	n	βHCG+ (%) antagonist	n	p value
26-30y	53.2	62	52.7	203	ns
31-35y	53.2	188	49.6	470	ns
36-40y	51.6	153	39.9	592	p=0.009
41-45y	42.1	19	23.4	273	p=0.07

Main results and the role of chance: The agonist protocol yields in higher pregancy rates (βHCG+) in females ≥35 years as compared to the antagonist protocol, whereas in age groups ≤ 34 years no differences were observed.

Limitations, reasons for caution: The retrospective character of the analysis limits the statement of a general recommendation.

Wider implications of the findings: Age-related administration of GnRH should be confirmed by prospective, randomized, clinical studies.

Trial registration number: not applicable

P-565 Randomised control trial comparing the effects of myoinositol to metformin on ART outcome in women with PCOS undergoing In-vitro fertilisation (IVF) cycle

K. Rajasekaran[1], **N. Malhotra**[1]

[1]*All India Institute of medical sciences AIIMS, Department of obstetrics and gynaecology, new delhi, India*

Study question: Does Myoinositol in comparison to metformin in infertile PCOS women, improves the ART outcomes, oocyte quality, pregnancy rates and decreases the incidence of OHSS

Summary answer: Myoinositol reduces unsuitable oocytes, improves the menstrual pattern, insulin resistance, hormone profile, quality of embryos, IVF outcomes and clinical pregnancy without significant change in OHSS.

What is known already: Myoinositol and metformin are insulin sensitisers. Metformin reduces testosterone concentrations, optimises IVF outcome, reduces risk of OHSS in PCOS but is associated with gastrointestinal side effects and lactic acidosis resulting in reduced patient's compliance. Myoinositol improves ovarian function, oocyte quality, LH/FSH ratio, reduces serum androgens, improves ovulation and fertility outcome without the side effects of metformin. Myoinositol acts at the level of insulin receptors and improves hyperinsulinemia, positively correlate with quality and maturity of oocytes reducing mean number of immature and degenerated oocytes, quantity of gonadotropins or units of FSH necessary for ovarian stimulation in IVF protocols.

Study design, size, duration: The present study is a randomised controlled trial conducted after the ethical committee approval, in the ART Clinic, department of Obstetrics and Gynaecology, All India Institute of Medical sciences, New Delhi from March 2017 to March 2019. A total of 231 patients infertile PCOS women undergoing IVF cycles were enrolled in the study and asses for eligibility and 102 were randomised and allotted as 50 and 52 in group 1(Myoinositol) and group 2(Metformin) respectively.

Participants/materials, setting, methods: Recruited patients received myoinositol 2gm twice daily(group1) and metformin 850mg twice daily(group 2). Pre and post treatment clinical(menstrual pattern,BMI), hormonal profile(LH,FSH,Testosterone, prolactin, AMH), biochemical parameters(HOMA IR, fasting glucose, insulin) and side effect profile assessed. After 3 months of therapy, patients were recruited for IVF cycles involving controlled ovarian stimulation, cycle monitoring, oocyte recovery, insemination of oocytes and follow up with fertilisation, cleavage, transfer of good grade cleavage embryos or blastocysts pregnancy outcomes and OHSS incidence

Main results and the role of chance: Myoinositol had significant fertilisation rate(p<0.001), embryos retrieved(p<0.001), cleavage rate(p 0.008), grade 1 embryos(p 0.042) with no significant difference in implantation

rate(p 0.537),number of oocytes retrieved(p0.097),metaphase II oocytes(p 0.176) and Grade1 oocyte(p 0.204). Embryo transfer cancelled was significantly high in metformin group(p 0.035). Starting dose of FSH, total dose of FSH and duration of gonadotropin stimulation were comparable.

Clinical pregnancy rate was significantly high in Myoinositol group 36.0% (18/50); 95% CI 18.0(0.9,35.0) p value 0.043) compared to metformin(18% (9/50)). The spontaneous pregnancy rate were comparable, but Group 1 had higher number of patients conceived spontaneously(13,26%) compared to Group 2(6,12%) (p value 0.074).The total number of IVF pregnancy rates (p value 0.715), total number of IVF pregnancy rate per number of IVF cycles (p value 0.314) and the total number of IVF pregnancy rate per embryo transfer (p value 0.368) were also comparable between the Groups. Incidence of OHSS was 10% (5/50) and 20% (10/50) in Group 1 and Group 2 respectively, comparable between both Myoinositol and Metformin Group (p value 0.001).
Myoinositol group had increased regularity in menstrual pattern(0.001) and improvement in fasting insulin (p 0.001),HOMA IR (p 0.001),Serum AMH(p 0.001) and Serum SHBG(p 0.032) thereby suggesting decreased insulin resistance.

Limitations, reasons for caution: Most patients with PCOS recruited in our study were brittle PCOS, with high LH, AMH and hyperandrogenemia with sub-optimal response during ovulation induction and IUI. In IVF cycles only fresh embryo transfer and not FET cycles were analysed. These were attributed to be the reason for lower Pregnancy outcomes.

Wider implications of the findings: Myoinositol in comparison to metformin in infertile PCOS women has better IVF outcome and oocyte quality, however to make these results more robust, a large multi-centric trial with larger sample size and longer duration is necessary.

Trial registration number: CTRI/2018/05/014196

P-566 A randomised, assessor-blind, controlled phase 3 non-inferiority trial assessing the efficacy and safety of individualised follitropin delta dosing regimen in Japanese IVF/ICSI patients

O. Ishihara[1], M. Kitamura[2], J.C. Arce[3], X. Japanese Follitropin Delta Phase 3 Study Group[4]

[1]*Saitama Medical University, Department of Obstetrics & Gynaecology, Iruma-gun- Saitama, Japan ;*
[2]*Ferring Pharmaceuticals, Development, Tokyo, Japan ;*
[3]*Ferring Pharmaceuticals, Reproductive Medicine & Maternal Health, Copenhagen, Denmark ;*
[4]*On behalf of the participating sites, Fertility clinics, Japan, Japan*

Study question: To establish the efficacy and safety of controlled ovarian stimulation with follitropin delta individualised fixed-dose regimen versus follitropin beta conventional dosing in Japanese women.

Summary answer: Individualised treatment with follitropin delta versus follitropin beta resulted in non-inferiority in number of oocytes retrieved, comparable clinical pregnancy rates and significant reduction of OHSS.

What is known already: The follitropin delta dosing regimen stratifies patients according to response potential and applies an individualised dose based on an ovarian biomarker (AMH) and a patient characteristic (body weight). This approach has in previous clinical trials conducted outside of Japan been demonstrated to optimise ovarian response and reduce OHSS risk without compromising success rates.

Study design, size, duration: Randomised, assessor-blind, controlled trial conducted in 347 Japanese women, 20-40 years (mean 34.1), undergoing their first IVF/ICSI cycle. Randomisation was stratified by AMH at screening (<15 pmol/L, ≥15 pmol/L). The primary endpoint was number of oocytes retrieved with a prespecified non-inferiority margin (lower limit of 95% confidence interval (LL 95% CI) >-3.0 oocytes). A GnRH antagonist protocol was applied. Clinical pregnancy was assessed 5-6 weeks after single blastocyst transfer. OHSS was classified using Golan's system.

Participants/materials, setting, methods: The follitropin delta (REKOVELLE, Ferring Pharmaceuticals) dose was individualised based on serum AMH and body weight, and was fixed throughout stimulation – AMH <15 pmol/L: daily dose of 12 µg, AMH ≥15 pmol/L: daily dose decreasing from 0.19 to 0.10 µg/kg body weight by increasing AMH (min-max 6-12 µg). Elecsys® AMH, Roche Diagnostics was used. The follitropin beta (FOLLISTIM/PUREGON, MSD) dose was 150 IU/day for the first five days and could thereafter be adjusted.

Main results and the role of chance: The primary objective of the trial was met, as non-inferiority was established for the number of oocytes retrieved for follitropin delta compared to follitropin beta (9.3 vs 10.5; LL 95% CI 2.3). Among patients with AMH <15 pmol/L (40.9%), the proportion of women with <4 oocytes was similar in the two treatment groups (11.6% vs 12.3%). Among patients with AMH ≥15 pmol/L (59.1%), treatment with follitropin delta resulted in significantly ($p<0.05$) fewer patients with ≥15 oocytes (22.0% vs 42.0%) or ≥20 oocytes (8.0% vs 19.0%). Blastocyst transfer was performed for 79.4% and 79.7% in the follitropin delta and follitropin beta groups, respectively, and the clinical pregnancy rate for these women was 31.9% and 29.8%, respectively. The clinical pregnancy rate per started cycle was 25.3% for follitropin delta and 23.7% for follitropin beta. The occurrence of OHSS was reduced to approximately half with follitropin delta compared to follitropin beta, with an incidence of 11.2% vs 19.8% ($p<0.05$) for OHSS of any grade, and 7.1% vs 14.1% ($p<0.05$) for moderate/severe OHSS. Two patients in the follitropin beta group were hospitalised due to OHSS for a duration of 16 and 33 days, respectively, while there were no hospitalisations in the follitropin delta group.

Limitations, reasons for caution: The individualised follitropin delta dosing regimen based on the patient's serum AMH and body weight was developed after completion of a phase 2 trial in non-Japanese women. Based on a subsequent phase 2 trial conducted in Japan, the individualised dosing regimen was evaluated to also be applicable to Japanese women.

Wider implications of the findings: This trial confirms that the ovarian response associated with the individualised dosing of follitropin delta preserves pregnancy rates and results in an improved OHSS risk profile for Japanese IVF/ICSI patients as already observed in non-Japanese women.

Trial registration number: NCT03228680

P-567 Midfollicular gonadotropin dose increases do not appear to change the ovarian response determined by the dose selected at the start of the stimulation

J.C. Arce[1], B. Klein[2]

[1]*Ferring Pharmaceuticals, Reproductive Medicine & Maternal Health, Copenhagen, Denmark ;*
[2]*Ferring Pharmaceuticals, Global Biometrics, Copenhagen, Denmark*

Study question: Can gonadotropin dose increases during stimulation lead to more oocytes or blastocysts compared to maintaining a fixed dose selected based on biomarkers and patient characteristics?

Summary answer: Gonadotropin dose increases in the midfollicular phase do not appear to alter the ovarian response or blastocyst availability defined by the starting dose.

What is known already: Studies have indicated that increasing the gonadotropin dose after the first 5 days (or later) in anticipation of low ovarian response does not rectify the response (van Hooff et al, 1993; Khalef et al, 2002). As follicular recruitment occurs in the late luteal and early follicular phase, such dose increases during the stimulation cycle does not lead to increasing the number of oocytes retrieved.

Study design, size, duration: Post-hoc analysis of a randomised, assessor-blind, controlled trial in 1,326 women, 18-40 years, undergoing their first IVF/ICSI cycle. Patients randomised to follitropin alfa (GONAL-F, Merck) (N=661) received a daily starting dose of 150 IU for the first five days which thereafter could be adjusted by 75 IU. Patients randomised to follitropin delta (REKOVELLE, Ferring Pharmaceuticals) (N=665) received an individualised dose based on AMH and body weight, and the dose was fixed throughout stimulation.

Participants/materials, setting, methods: Investigators were blinded to treatment allocation. The frequency of investigator-requested dose increases on stimulation day 6 was similar in the two treatment groups, with 24.5% (n=162) in the follitropin alfa group and 22.6% (n=150) in the follitropin delta group. The investigator's requests for gonadotropin dose adjustments were only implemented in the follitropin alfa group, while patients in the follitropin delta group remained on the assigned daily dose.

Main results and the role of chance: The follicular development and serum endocrine profile on stimulation day 6 were comparable between the women in the follitropin alfa and follitropin delta groups for whom the investigator recommended to increase the dose. These women had 12.3±5.8 and 12.8±6.7 follicles in the follitropin alfa and follitropin delta groups, respectively, of which there were 4.8±3.6 and 4.2±3.4 follicles ≥10mm. The median [interquartile

range] estradiol was 1509 [898;2264] pmol/L for follitropin alfa and 1228 [762;2076] pmol/L for follitropin delta, while inhibin B was 434 [263;706] pg/mL and 430 [282;637] pg/mL, respectively. Among the women with investigator-requested dose increases, the ovarian response and blastocyst development were comparable between the follitropin alfa patients with dose increases and the follitropin delta patients on a fixed dose. For follitropin alfa and follitropin delta, respectively, these women had 7.4±5.0 versus 7.4±5.1 oocytes retrieved, 2.5±2.4 versus 2.3±2.4 blastocysts, and 1.3±1.7 versus 1.3±1.9 good-quality blastocysts. The dose increases in the follitropin alfa group logically influenced the gonadotropin consumption. The mean daily gonadotropin dose in this sub-population was 196±26 IU (14.4±1.9 µg) follitropin alfa versus 10.2±2.4 µg follitropin delta, with a mean total gonadotropin dose of 1865±607 IU (137±45 µg) follitropin alfa versus 99±26 µg follitropin delta.

Limitations, reasons for caution: Although the population with investigator-requested dose increases was similar in the follitropin alfa and follitropin delta groups, it should be noted that the decision to request an increase of the starting gonadotropin dose was per the investigator's judgement and not based on protocol-specific criteria.

Wider implications of the findings: These findings stress the importance of appropriate dose selection before starting stimulation. The data indicate that increasing the dose during stimulation does not modify the ovarian response that can be obtained with a fixed-dose regimen. Maintaining a fixed-dose regimen throughout treatment is convenient for both the patient and clinic staff.

Trial registration number: NCT01956110

P-568 differences between steroids gene expression in subcutaneous fat of PCOS and non-PCOS pregnant women

N. Emami[1], A. Alizadeh[1], A. Moini[2], M. Shahhosseini[3]

[1]Royan Institute for Reproductive Biomedicine- ACECR- Tehran- Iran, Department of Embryology- Reproductive Biomedicine Research Center, tehran, Iran ;
[2]Royan Institute for Reproductive Biomedicine- ACECR- Tehran- Iran, Department of Endocrinology and Female Infertility- Reproductive Biomedicine Research Center-Breast Disease Research Center BDRC- Tehran University of Medical Sciences- Tehran- Iran- De, ;
[3]Royan Institute for Reproductive Biomedicine- ACECR- Tehran- Iran-, Department of Genetics- Reproductive Biomedicine Research Center- Royan Institute for Reproductive Biomedicine- ACECR- Tehran- Iran- Department of Cell and Molecular Biology- School o,

Study question: Are there differences between gene expression related to steroid metabolism in abdominal subcutaneous AT in PCOS and non- PCOS pregnant women?

Summary answer: PCOS SAT(subcutaneous adipose) showed significantly higher level of those gene incorporated in glococorticoids and mineralocorticoids but not sex steroids genes

What is known already: A series of steroidogenic and steroid-inactivating enzymes have been detected in human adipose tissue. The abnormal conversion of androgen precursors to both active and inactive forms at the receptor level is important for the pathogenic of metabolic diseases found in PCOS..Most recently, it has been suggested that adipose tissue may contain the steroidogenic machinery necessary for the initiation of steroid biosynthesis *de novo* from cholesterol.

Study design, size, duration: . Samples and demographic data were collected from three hospitals in Tehran, Iran. The Subjects were 45 Iranian pregnant women underwent cesarean section; 13 PCOS (poly cystic ovarian syndrome) and 32 were non–PCOS, whose samples from subcutaneous fat of abdomen were taken.Diagnosis of these PCOS subjects is responsibility of the medical practitioner related to Royan Institute.At the time of caesarean section, the surgeon took 3-4 g subcutaneous fat upon entering the abdomen were collected .

Participants/materials, setting, methods: Total RNA extraction and removal of genomic DNA from the adipose tissue were performed using the RNeasy lipid Mini Kit (Qiagen, cat. no: 74004).Twenty nanograms of total RNA was used for cDNA synthesis according to manufacturer's instruction. Messenger RNA quantification was performed by qRT-PCR on the Step-One RT-PCR system (Applied Biosystems, USA).Gene expression data were analyzed using $2^{-\Delta\Delta Ct}$ algorithm to calculate the 15 steroids gene mRNA level relative to the level of GAPDH mRNA level.

Main results and the role of chance: No significant differences were found with respect to age and body mass index (BMI) among non-PCOS and PCOS pregnant women. We detected expression of *17BHSD1*,3,5.7.12., *star*, *CYP11A1*, *CYP17A1*, *CYP21A1*, *CYP19A1*,*3BHSD1-2.11BHSD1-2* in the subcutaneous adipose tissue of pregnant women but 17BHSD2 was undetectable in both groups. PCOS subcutaneous AT showed significantly higher level of *CYP11A1*, *CYP17A1*, *CYP21A1*, *STAR* and *11BHSD1-2* mRNA when compared with the non-PCOS women ($P < 0.05$). There was no significant difference between *CYP19A1*,*3BHSD1-2. 17BHSD*1,3, 5.7.12. mRNA abundance between two group.

Limitations, reasons for caution: Although we collected 48 samples during one year, the small sample size is a limitation. Nevertheless, the strength of the observed differences in aged-matched and BMI-matched subjects suggests that power was not an important issue and that a larger study would be able to detect same findings.

Wider implications of the findings: This is the first report for gene expression profiles in AT of PCOS mothers which opens the road for exploration regarding gene expression related glucocorticoids and mineralocorticoids metabolism in AT for pregnant women suffering from PCOS.

[6]Skive Regional Hospital, Fertility Clinic, Skive, Denmark ;
[7]University of Naples Federico II, Department of Neuroscience- Reproductive Science and Odontostomatology, Naples, Italy

Study question: What is the cumulative live birth rate per started cycle (CLBR) in low prognosis women stratified according to the POSEIDON criteria?

Summary answer: CLBR varies in POSEIDON groups (48% in G1, 24% in G2, 29% in G3, 10% in G4), impacted by female age and number of oocytes.

What is known already: The POSEIDON criteria have been introduced as a new classification for low-prognosis women undergoing assisted reproductive technology (ART). The low prognosis patient is classified into four groups according to the results of ovarian reserve markers, female age, and the number of oocytes retrieved in previous IVF/ICSI cycles of conventional ovarian stimulation (OS). The low prognosis is supposedly caused by the impact of a decreased number of oocytes, which limits the number of embryos produced. This condition might be aggravated by advanced female age, thus negatively impacting the CLBR per started cycle.

Study design, size, duration: This study analyzed the data of 11,042 consecutive infertile couples who initiated IVF/ICSI treatment in three large Fertility Centers in Brazil, Turkey, and Vietnam between 2015 and 2017. Ovarian reserve was assessed before the cycle by either anti-Mullerian hormone (AMH) or antral follicle count (AFC), or both. The included patients were treated using conventional OS protocols.

Participants/materials, setting, methods: Patients were stratified into five groups based on female age, ovarian markers, and number of oocytes retrieved, including the previously described low prognosis POSEIDON groups (Groups 1-4), and a group of patients not fulfilling the criteria (Non-POSEIDON; NP). The primary outcome was the CLBR per started cycle, including all fresh and frozen-thawed embryo transfers. The secondary outcomes were the number of embryos per group and the prevalence of low prognosis patients in dataset.

Main results and the role of chance: The CLBR of patients fulfilling the POSEIDON criteria was, on average, ~30% lower than NP patients. Younger unexpected poor/suboptimal responders (G1; n=1,480) and expected poor responders (G3; n=852) had a CLBR of ~48% and ~29%, respectively ($p<0.0001$). The CLBRs of older unexpected poor/suboptimal responders (G2; n=1,726) and expected poor responders (G4; n=1,711) were ~24% and ~10%, respectively ($p=0.001$). Overall, the CLBR of NP patients (59.2%; n=5,273) was higher than POSEIDON patients ($p<0.0001$). Younger (G1b; n=1,214) and older

(G2b; n=1,301) unexpected suboptimal responder (4-9 oocytes) patients had a CLBR of ~54% and 28%, respectively, which were higher (p=0.0001) than that of unexpected poor responder (1-4 oocytes) patients (G1a: 23%, n=266; G2a: 12%, n=425). The number of embryos varied among the POSEIDON groups, impacted by the number of retrieved oocytes, and were overall lower than that of NP patients (p<0.0001). POSEIDON patients represented ~50% of all treated patients (Brazil: 64%; Turkey: 55%; Vietnam: 40%), with regional differences primarily owing to the average age of treated women.

Limitations, reasons for caution: Retrospective study design, with different practices in participating centers, might influence cycle cancellation, oocyte yield, number of embryos, and therefore, CLBR. However, our data provide the first multicenter real-world evidence to validate the concept of low prognosis –in terms of CLBR per started cycle– in POSEIDON patients.

Wider implications of the findings: The CLBR per cycle in POSEIDON patients is affected by both female age and number of oocytes retrieved. Thus, in addition to aid in patient counseling, the POSEIDON criteria may be used to guide clinical management with a specific focus on therapeutic strategies focused on optimizing the oocyte yield.

Trial registration number: NA

P-570 Levothyroxine and subclinical hypothyroidism in patients with recurrent pregnancy loss

H. Yoshihara[1], M. Sugiura-Ogasawara[1], S. Goto[1], K. Tamao[1]

[1]Nagoya City University Graduate School of Medical Sciences, Obstetrics and Gynecology, Nagoya, Japan

Study question: It was unclear whether subclinical hypothyroidism (SCH) affects subsequent live births and whether levothyroxine is effective in improving the live birth rate in patients with recurrent pregnancy loss (RPL).

Summary answer: SCH did not affect live births and levothyroxine did not improve the live birth rate.

What is known already: It has been reported that the frequency of miscarriage was significantly higher in women with SCH as compared with women on thyroid-stimulating hormone (TSH) ≦ 2.5 mIU/L and that intervention reduces the adverse pregnancy outcome in antithyroid peroxidase antibody (TPO)-positive women with SCH.

One study showed that out of 286 patients with two or more early losses, 19% had SCH, however, that there was no difference in the subsequent live birth rate between patients with SCH and euthyroidism (69% and 74%), either with or without treatment for SCH (71% and 67%).

Study design, size, duration: An observational cohort study was conducted at Nagoya City University Hospital between 2010 and 2019. The study included 1566 pregnancies of 1120 patients with a history of 2 or more pregnancy losses.

Participants/materials, setting, methods: 4D-Ultrasound, hysterosalpingography, chromosome analysis for both partners, antiphospholipid antibodies and blood tests for TSH, free thyroxine (FT4) and diabetes mellitus were performed before a subsequent pregnancy. SCH was defined as having a serum TSH > 2.5 mIU/L with a normal level of FT4. Live birth rates were compared between SCH and euthyroid patients treated with and without levothyroxine after excluding patients with an abnormal chromosome in either partner and those with a uterine anomaly.

Main results and the role of chance: The prevalence of SCH was 15.2 % (170/1120). Subsequent live birth rates were 79.2 % (42/53) for the levothyroxine group, 67.6 % (73/108) for the untreated SCH group and 69.6 % (606/871) for the euthyroid group. After excluding miscarriages with embryonic aneuploidy, chemical pregnancies and ectopic pregnancies, live birth rates were 91.3 % (42/46) for the levothyroxine group, 90.1 % (73/81) for the untreated SCH group and 90.9 % (606/667) for the euthyroid group. The live birth rates per pregnancy were 93.5% (58/62), 88.9% (96/108) and 90.3% (833/922), respectively. There was no significant difference in the live birth rate among the three groups.

Limitations, reasons for caution: The sample size of SCH patients was relatively small. Further RCT is necessary to confirm these results.

Wider implications of the findings: The measurement of TSH and FT4 might not be necessary for the screening of patients with RPL who have no features of hypothyroidism.

Trial registration number: not applicable

P-571 Is ovarian response related to adverse perinatal outcomes after fresh embryo transfer in GnRH antagonist downregulated IVF/ICSI treatment cycles?

E. Bardhi[1], C. Blockeel[1], W. Cools[2], S. Santos-Ribeiro[3], A. Racca[1], S. Mackens[1], M. De Vos[1], N. Polyzos[4], B. Popovic-Todorovic[1], M. De Brucker[1], H. Tournaye[1], P. Drakopoulos[1]

[1]Uz Brussel, Centrum voor Reproductieve Geneeskunde CRG, Avenue du Laerbeek 101- 1090 Jette, Belgium ;
[2]Uz Brussel, Interfaculty Center Data processing & Statistics ICDS, Avenue du Laerbeek 101- 1090 Jette, Belgium ;
[3]IVI-RMA Lisboa-, Instituto Valenciano de Infertilidade, Lisboa, Portugal ;
[4]Dexeus University Hospital- Salud de la Mujer Dexeus, Department of Reproductive Medicine, Barcelona-, Spain

Study question: Is there an association between ovarian response, as expressed by the number of oocytes retrieved, and adverse perinatal outcomes?

Summary answer: Ovarian response is not related to adverse perinatal outcomes.

What is known already: Several studies have found that singleton IVF pregnancies are at higher risk for adverse perinatal outcomes compared to naturally conceived ones. Possible explanations for this include infertility itself, embryo specific epigenetic modifications due to embryo culture and vascular endothelial dysfunction associated with ovarian ageing. However, one of the most accredited hypothesis for these findings, blames the altered endometrium function resulting from the non-physiological endocrine milieu that follows ovarian stimulation, which in turn can be related to ovarian response. Up to date, the safety of ART in terms of obstetrical and neonatal outcomes still remains under investigation.

Study design, size, duration: This was a retrospective, single-center cohort study including infertile women attending a tertiary university center from January 2009 to December 2015.

Participants/materials, setting, methods: All women who underwent their first ovarian stimulation cycle in a GnRH antagonist protocol, with a fresh embryo transfer that resulted in a singleton live birth, were eligible for this study. Patients were categorized into four ovarian response groups according to the number of retrieved oocytes: 1–3 (category I), 4–9 (category II), 10–15 (category III), or > 15 oocytes (category IV).

Main results and the role of chance: The overall number of patients analyzed was 964: 67 in category I, 450 in category II, 269 in category III and 178 in category IV.

Neonatal weight (in grams) was comparable between all groups (3222 ± 607g vs. 3254 ± 537g vs. 3235 ± 575g vs. 3200 ± 622g, *P*=0.85) as well as the term of delivery (38.4 ± 2.4 vs 39 ± 1.7 vs 39 ± 2.0 vs 38.6 ± 2.4 weeks, *P*=0.5). Birth weight z-scores and neonatal gender did not differ among the four oocyte categories (*P*=0.9 and *P*=0.17, respectively). The incidence of preterm birth and low birth weight was also comparable across the different oocyte categories (*P*=0.127 and *P*=0.19, respectively). Finally, gestational diabetes, hypertension disorders of pregnancy, placenta previa, intra-uterine growth restriction, premature rupture of membranes, hospitalization for threatened preterm labor, delivery mode, APGAR scores at 1, 5 and 10 minutes and major fetal malformations did not differ significantly among ovarian response categories either. Multivariate regression analysis (adjusting for female age, body mass index (BMI), initial stimulation dose, type of insemination procedure), number of embryos transferred and embryo stage at transfer, revealed that the number of oocytes was not associated with neonatal birth weight.

Limitations, reasons for caution: This is a large observational study based on retrospective data collection. Despite our robust methodological approach, the presence of biases related to retrospective design cannot be excluded.

Wider implications of the findings: The data of our study are reassuring and refute potential fears of a negative impact from enhanced ovarian response on neonatal outcomes. Future, larger investigations are needed to validate these results.

Trial registration number: not applicable

P-572 17β-oestradiol/nomegestrol pre-treatment for ovarian stimulation GnRH antagonist protocols do not affect clinical pregnancy rates.

M. Samama[1,2,3], R.C.P. Piscopo[4], F. Ikeda[2,3], V.H. Kussumoto[2], A. Sartor[3,5], L. Semião-Francisco[3], J. Ueno[2,3], Z. Jarmy_Di Bella[6]

[4]Gera Institute, Post Graduation, São Paulo, Brazil ;
[5]Gera Institute, Post-graduation, São Paulo, British Virgin Islands ;
[6]Escola Paulista de Medicina UNIFESP-EPM- Department of Gynecology- Sao Paulo- Brazil., Professor Head of the Division of Department of General Gynecology, São Paulo, Brazil

Study question: Whether pre-treatment with an oral contraceptive pill with natural oestrogen, 17β-oestradiol/nomegestrol, has effects on hormonal, embryological and clinical outcomes for women undergoing assisted reproductive techniques.
Summary answer: 17β-oestradiol/nomegestrol favor top quality embryo formation and was not associated with deleterious effects on biochemical and clinical pregnancy.
What is known already: Pre-treatments with combined oral contraceptive pill (COCP) suppress the woman's own hormones production and could improve ovarian response to the hormone therapy in *in vitro* fertilization cycles. In the GnRH antagonist protocols with synthetic oestrogen combined oral contraceptive pill pre-treatment, the rate of live birth/ongoing pregnancy was lower than with no pre-treatment.
Study design, size, duration: Cohort study in an assisted reproduction techniques (ART) post-graduation program setting and no pre-treatment patients set in an assisted reproductive center in Sao Paulo, Brazil, which ran from 2017 to 2019, with a total number of patients of 130.
Participants/materials, setting, methods: Three groups were analyzed: no pre-treatment patients were recruited from the ART center, patients from the post-graduation program received natural oestrogen combined oral contraceptive pill and were compared to a synthetic COCP group, whose data was analyzed retrospectively as a reference population. Patients underwent pre-treatment with COCP before GnRH antagonist ovarian stimulation protocol for *in vitro* fertilization (IVF). Statistical analysis was conducted using generalized linear models or binomial regression. Significance was defined if $p<0.05$.
Main results and the role of chance: Significant effects of treatment group were present in the number of embryos (no pre-treatment mean=2.3; 17β-oestradiol/nomegestrol group mean=3.41; p=0.006) and number of top-quality embryos (day 3) (no pre-treatment group mean=1.3; 17β-oestradiol/nomegestrol mean=2.64; p=0.031). The mean number of mature oocytes was significantly higher in natural oestrogen COCP compared to synthetic COCP, when the analysis was controlled for the duration of COCP treatment (17β-oestradiol/nomegestrol group mean=6.28 and ethinylestradiol/gestodene group mean=4.34; p=0.014). However, there were no significant differences in the mean number of mature oocytes between 17β-oestradiol/nomegestrol group and no pre-treatment group (means=6.284 and 5.56, respectively; p=1). 17β-oestradiol/nomegestrol was not statistically associated with deleterious effects on biochemical pregnancy (odds ratio=0.32, CI 95%=0.074–1.392; p=0.129). Ethinylestradiol/gestodene lowered chances of having positive biochemical pregnancy when compared to the no pre-treatment group (odds ratio=0.138, CI 95%=0.028–0.694; p=0.016). 17β-oestradiol/nomegestrol was not associated with negative clinical pregnancy outcome (odds ratio=1.714, CI 95%=0.339–8.676; p=0.515). Mean total dose of follicle stimulating hormone administered for each treatment group was 2349.02 in 17β-oestradiol/nomegestrol group, 2259.24 in no pre-tretment group and 2859.21 for ethinylestradiol/gestodene.
Limitations, reasons for caution: There might be a possible bias of unaccounted variables, such as the number of blastocysts transferred, considering that in the clinical setting in which the study took place, patients are preferentially programmed to transfer at day 3, and thus possibly altering the ratio of total blastocyts to embryos transferred.
Wider implications of the findings: Natural oestrogen COCP was not associated with deleterious embryological or clinical outcomes, and significantly improved the number of embryos and top-quality embryos. Therefore, 17β-oestradiol/nomegestrol prescription might benefit IVF cycle scheduling, and possibly better synchronized follicular growth and future positive clinical pregnancy with cryopreserved embryos obtained from 17β-oestradiol/nomegestrol patients.
Trial registration number: Not Applicable

P-573 Anti-Müllerian hormone (AMH) lower reference values observed in a population of Indian women compared to French women, using an automated AMH assay

B. Mougin[1], J. Kaur[2], P. Bourron[1], S. Bellvert[3], M. Loubet[3], N. Mahajan[2]

[1]Biomérieux SA, Medical Affairs, Marcy l'Etoile, France ;
[2]Mother & Child Hospital, Fertility Clinic, New Delhi, India ;
[3]Biomérieux SA, Clinical Affairs, Marcy l'Etoile, France

Study question: How much do reference VIDAS® AMH values differ for women between India and France?
Summary answer: Significantly lower serum AMH levels were observed for women aged 20 to 44 living in India compared to women living in France.
What is known already: Serum AMH testing is routinely performed in female patients for the assessment of the ovarian reserve. Several published studies have reported differences in age-specific AMH reference values in various countries. Reference intervals have been previously defined for VIDAS® AMH, in populations living in France and in India.
Study design, size, duration: This study compared the age-specific reference VIDAS® AMH values defined during dedicated studies performed in France and in India, for the 20-44 year age range.
Participants/materials, setting, methods: Healthy fertile women with no endocrine or gynaecological disorders were enrolled in the studies conducted in India and France. Serum AMH concentrations were measured using the bioMérieux VIDAS® AMH assay, and comparative analyses were done for the 20-44 year age range, for 748 Indian and 356 French women. Descriptive statistics and linear regression modelling after log transformation were used to estimate the differences.
Main results and the role of chance: Overall lower median AMH values were observed for India with calculated differences of 1.52, 0.50, 1.59, 0.54 and 0.19 ng/mL for the five age classes covering the 20-44 year age range, respectively. The equations for the linear regression models were the following: log(AMH)=-0.0358*(age)+1.4916 for France and log(AMH)=-0.0396*(age)+1.4006 for India. These results confirm previous data reporting lower serum AMH values in women living in India compared to women living in France.
Limitations, reasons for caution: This study focused on women within the 20-44 year age range. Despite selected inclusion criteria and quite large size of the two study populations, more studies are necessary to further characterize the lower serum AMH levels observed in Indian women, in populations representing the regional and ethnical diversity for India.
Wider implications of the findings: These results are in line with CLSI guideline recommendations to check local reference intervals, that particularly makes sense for AMH. They should also stimulate more studies to cover the population diversity worldwide, and to contribute to the adoption of the appropriate usage of this biomarker for management of infertile women.
Trial registration number: Not applicable

P-574 Influence of cross-sex hormone therapy in trans*persons on laboratory profile and BMI

K. Feil[1], A.L. Zippl[1], E. Bürstmayr[1], B. Böttcher[1], K. Winkler-Crepaz[2], B. Toth[1]

[1]Medical University of Innsbruck, Gynecological Endocrinology and Reproductive Medicine, Innsbruck, Austria ;
[2]Paracelsus Medical University Salzburg, Gynecology and Obstetrics, Salzburg, Austria

Study question: What influence has cross-sex hormone therapy (CHT) on concentration of gonadotropins, sex steroids, liver enzymes, triglyceride, hemoglobin and body mass index (BMI)?
Summary answer: Cross-sex hormone therapy seemed to be safe within the study population. Significant changes were present in trans*men for SHBG and hemoglobin.
What is known already: For many trans*persons CHT is the milestone of a life as a member of the desired sex. For this purpose, male and female sex steroids are applied, which can also lead to major side effects.
Study design, size, duration: This retrospective study was performed at our Department between 2005 and 2017. The concentration of gonadotropins

and sex steroids as well as liver enzymes, triglycerides, hemoglobin and body mass index were analysed before and three, six, twelve and twenty-four months after start of CHT. Demographic data were also evaluated.
Participants/materials, setting, methods: In total 84 patients (33 trans*-women and 51 trans*men) were included in the study. Endogenous hormone production was suppressed using GnRH agonists. Transdermal or oral Estradiol was administered to trans*women and transdermal or intramuscularly testosterone to trans*men.
Main results and the role of chance: The mean age at first visit was 20.9± 6,58 SD years in trans*men and 32.7 ± 15,90 SD years in trans*women. LH and FSH decreased in both sexes immediately after starting GnRHa, but not to levels below the detection limits. The sex steroids showed a rapid adaptation to the reference ranges of the desired sex. SHBG decreased significantly in trans*men, while hemoglobin increased significantly to the normal male ranges. There were no significant changes in BMI, but a trend towards weight gain in both sexes.
Limitations, reasons for caution: As the follow up period of 2 years is short, no long term safety assessments can be made so far.
Wider implications of the findings: CHT seemed safe in the study population. Since there were no significant differences and no pathological increase in liver enzymes, a routine check for liver enzymes does not appear to be necessary.
Trial registration number: Not applicable

P-575 Polycystic Ovarian Syndrome related hyperandrogenism and elite sport activity – a systematic review

C. Lamballk[1], E. Bos[1], M. Caanen[1]

[1]Amsterdam University Medical Centers Location VUMC, Reproductive Medicine, Amsterdam, The Netherlands

Study question: Is there a higher prevalence of PCOS among athletic women compared to the general population?
Summary answer: Based on the information of the current literature, no decisive evidence was found for a higher prevalence of PCOS among female elite athletes.
What is known already: The population of sporting women and physically active women at a high level of sport is increasing. This may lead to the Athlete Triad consisting of altered bone mineral density, low energy availability and menstrual dysfunction. It is suggested that Polycystic Ovarian Syndrome (PCOS) might be a cause for the menstrual disorders in female athletes. There is growing concern about androgen levels and top sports performance, doping control and fair play. The PCOS condition is positioned between two main issues in the field of female top sports as cause for menstrual irregularities related to higher endogenous testosterone levels.
Study design, size, duration: A systematic literature review was performed up to October 2019 in the following databases: PubMed, Cochrane, Embase and Sportdiscus. To be included in the review, papers had to include elite athletes women diagnosed with PCOS by the Rotterdam Criteria performing any type of sport at national or international level. Furthermore, the papers needed a focus on PCOS, hyperandrogenism, oligomenorrhea or amenorrhea prevalence outcomes and androgen measurement.
Participants/materials, setting, methods: Fourteen studies of an initial 536 were selected by two researchers independently. The included studies consisted of 10 observational cross-sectional studies, two case-control studies (observational and experimental) one prospective cohort and one retrospective cohort review of medical reports. The results are presented by outcome corresponding with the 3 hallmarks of PCOS and were plotted in forest plots.
Main results and the role of chance: PCOS and Hyperandrogenism showed a non significant and menstrual dysfunction a significant favoured prevalence in the athletes' group. The reported prevalence of PCOS diverged from 1.4% to 44%.
Limitations, reasons for caution: None of the studies primarily aimed at exploring the PCOS prevalence among elite athletes. Overall, the majority of the studies had a high risk of bias.
Wider implications of the findings: Exposure to higher androgen levels in female elite sport is currently a fierce matter of debate. This discussion requires higher quality data than currently available on prevalence of the most frequently occurring female natural condition of PCOS among top sport women. This merits well designed and powered prospective studies.
Trial registration number: not applicable

P-576 Cumulative Live birth rates in advanced maternal age (AMA) patients (40-43 years old) with autologous oocytes: the predictive factors

P. Oger[1], L. Delaroche[1], V. Barbet[2], X. Guettier[1], G. Kerbrat[1], V. Maget[1], G. Soudré[1], E. Genauzeau[1], P. Meicler[1], F. Lamazou[1]

[1]Ramsay santé Hôpital Privé de Parly 2, ART Center IFM P2, Le Chesnay, France ; [2]Capionis, biostatistics, Bordeaux, France

Study question: What are the predictive factors of the cumulative live birth rates (CLBR) in women aged between 40-43 years using their autologous oocytes?
Summary answer: In women aged between 40-43 years old, additional vitrified embryos is the only predictive factor to CLBR.
What is known already: In Vitro Fertilization (IVF) in AMA patients is becoming increasingly important. In this population, the low success rates and the high risks of miscarriages are mainly linked to the oocyte aneuploidy rates which increase with the maternal age. Several studies showed the probability of having a healthy baby in the AMA group of patients is less than 10% per cycle when using autologous oocytes and without any preimplantation genetic testing for aneuploidy (PGT-A). These low success rates question the management of AMA patients.
Study design, size, duration: This is a single-center retrospective study. The institutional review board approved this study and the patients'consent to the use of their data was prior obtained.
Participants/materials, setting, methods: All IVF cycles performed from November 2015 to December 2018 in women between 40-43 years old using their own oocytes were retrospectively analyzed. The main endpoint was the CLBR defined as a live-born delivery ≥28 weeks after the fresh or one of the subsequent frozen embryo transfers per pick-up. A multivariate logistic regression model was used to assess the influence of the clinically relevant factors. The p-values <0.05 were considered to be statistically significant.
Main results and the role of chance: A total of 569 IVF cycles in 316 couples were included. Mean female age was 41.4 ± 0.88 and mean AMH level was 2.0 ± 2.1 pg/mL. Using female age categories, the CLBR was 8.6% for 40-41 patients, 9.6% for 41-42 patients and 4.3% for 42-43 patients ; CLBR was improved in patients with supernumary vitrified embryos (OR [95%CI] = 2.78 [1.16-6.4] (p=0.02)). Multivariate logistic regression model did not highlight any other predictive factors on the CLBR: neither the maternal age (p=0.20), the etiology (p=0.80), the type of infertility (p=0.83), the smoking status (p=0.21), the AMH level (p=0.54) nor the number of mature oocytes (p=0.58) influenced individually the CLBR.
Limitations, reasons for caution: Although the main outcome was CLBR, the design was retrospective. The results of this study differed from those available in the current literature.
Wider implications of the findings: This study provides to AMA patients and clinicians a tool for building realistic expectations and providing accurate individual counselling. These preliminary results call for a prospective randomized controlled trial including higher number of cycles.
Trial registration number: IRB00010835

P-577 Late follicular phase ovarian stimulation protocol without exogenous pituitary modulators

Y. Fu[1], X. Zhu[1]

[1]Shanghai Ninth Hospital, Reproduction, Shanghai, China

Study question: Is it feasible to perform ovarian stimulation from late follicular phase without exogenous pituitary modulators during in-vitro fertilization (IVF)/ intracytoplasmic sperm injection (ICSI) treatments?
Summary answer: Late follicular phase ovarian stimulation could be performed without exogenous pituitary modulators.
What is known already: Gonadotropin-releasing hormone antagonist (GnRH-ant) was the most commonly-used modulator to prevent the premature luteinizing hormone (LH) surge when ovarian stimulation was initiated in the late follicular phase. Our team of researchers firstly introduced the usage of exogenous progestational agents as an alternative pituitary modulator to gonadotropin releasing hormone agonist (GnRH-a), and GnRH-ant for the prevention of premature LH surges in ovarian stimulation. Recently, we have documented

ovarian stimulation stared in late follicular phase with a dominant follicle diameter of ≥14mm before spontaneous ovulation could be performed without exogenous pituitary modulators.

Study design, size, duration: We retrospectively screened out the data of normal-ovulatory patients who performed ovarian stimulation in late-follicular phase with a dominant follicle diameter of ≥10 mm in the absence of exogenous pituitary modulators (namely late stimulation (LS) protocol) from women who treated with IVF/ICSI for the first time with the "freeze-all" strategy from May 2016 to December 2018, in our setting, and compared the reproductive results with early-follicular phase started ovarian stimulation using progesterone protocol.

Participants/materials, setting, methods: 404 participants were included: 116 subjects for the study group and 288 subjects for the control group. In the study group, only gonadotropin (Gn) was injected from the start of ovarian stimulation till the trigger day. In the control group, Gn and micronized progesterone soft capsule were added from menstrual cycle day 3. The primary outcome was the number of mature oocytes.

Main results and the role of chance: The number of mature oocytes was 9.67±5.33 in the study group and 9.38±5.15 in the control group (*P*=0.693). Total Gn dose (1962.28 ±517.06 versus 1626.04 ±311.75 IU) was greater and mean Gn duration (10.48±2.44 versus 8.78±1.53) was longer in the study group than in the control group (*P*<0.001). The number of follicles with diameter >14 mm was similar between the two groups, while number of follicles with diameter >10 mm in the study group was greater than that in the control group (13.33±6.67 versus 11.87±6.02, p=0.02). Additionally, there was no statistic difference in the number of mature oocytes between the two groups (9.67±5.33 in the study group versus 9.38±5.15 in the control group, P=0.693). Similarly, the two groups were comparable regarding number of oocytes retrieved, fertilized oocytes, cleaved embryos and good-quality embryos. No secondary premature LH surges were detected in all the participants. The clinical pregnancy rate was comparable in the two groups (54.55% versus 56.48%, P = 0.718). The implantation rate was similar in the two groups(36.94% vs. 37.77%, P=0.829). No differences were found in the rate of biochemical pregnancy, multiple pregnancy, ectopic pregnancy and early miscarriage (P > 0.05).

Limitations, reasons for caution: The limited cases and retrospective design resulted in the bias of our study. Further studies in a large sample size and continuous follow-up are still needed to determine the long-term safety of for children conceived with this novel protocol.

Wider implications of the findings: Our data suggest late follicular phase ovarian stimulation without exogenous pituitary modulators was a feasible protocol when performing random-start ovarian stimulation. In addition, it may be provided as an effective alternative for patients who choose frozen-embryo transfer (FET) during infertility treatment or fertility preservation.

Trial registration number: not applicable

P-578 Development of a new infertility treatment for resistant ovary syndrome through autoimmune suppression

Y. Tanaka[1], **K. Kawamura**[1]

[1]*International University of Health and Welfare school of medicine, Department of obstetrics and gynecology, Chiba, Japan*

Study question: Can suppression of autoimmune status using corticosteroid hormone induce follicle growth in patients with resistant ovary syndrome (ROS)?

Summary answer: Treatment of corticosteroid hormone, predonisolone (PSL) was effective for induction of follicle growth in ROS patients.

What is known already: ROS shows hyper gonadotropin and low estrogen, similar to premature ovarian insufficiency (POI). Infertility is the common complaint with ROS and POI. Although no follicle is found in ovaries of POI under ultrasound, ROS patients have normal number of antral follicles which are unresponsive to endogenous and exogenous FSH. Presence of genetic mutation or autoimmune antibodies to FSH or FSH receptor was found in some ROS patients, majority of causes are still unknown. So far only two case reports of live birth in ROS patients have been published by using an approach of in vitro maturation of oocytes .

Study design, size, duration: Case series study. From, April 2018 to Dec 2019, we enrolled four ROS patients with written informed consent after permission of this procedure from the ethical committee of the hospital.

Participants/materials, setting, methods: After diagnosis of ROS, the participants received 15-20mg/day PSL for 4weeks before starting ovarian stimulation. With continuous PSL treatment, we administrated estrogen plus progesterone for 10-14days to induce withdrawal bleeding. At initiation of bleeding, we started ovarian stimulation using 100mg clomiphene. The clomiphene treatment was continued up to 4weeks until their follicles reaching to 14-18mm in diameter. Then, 15,000-20,000IU hCG was injected. Oocyte retrieval was performed at 36hours after hCG.

Main results and the role of chance: The median age of participants was 37 years-old (range 26-41) with normal serum AMH (median 5.58 ng/ml, range 3.00-6.46) levels and normal antral count (range 7-15). However, they had increased serum FSH (median 44.6mIU/ml, range 19-95) and LH (median 31.4mIU/ml, range 8.2-51.4) levels as well as low estrogen levels (median 27.6 mIU/ml, range 0-52.6). Those patients showed no recent spontaneous follicle growth and long term amenorrhea (median 18.5 years, range 11-22 years). They also did not respond ovarian stimulation before this procedure. Among 4 patients, we succeeded follicle growth in two cases. In case 1, the follicle started to growth after 22−25 days of clomiphene treatment, whereas follicle growth could induced by15-19 days of clomiphene treatment in case 2. Total of 16 and 20 preovulatory follicles (range 3-5 and 2-7 per stimulation) were found and total 10 and 11 of mature oocytes were obtained in case 1 and 2, respectively. Seven out of 10 and 7 out of 11 oocytes were fertilized and all embryos developed to high-quality embryos (grade 1-3) based on Veeck criteria in case 1 and 2, respectively. All high-quality embryos were cryopreserved for future transfer under hormone replacement cycles.

Limitations, reasons for caution: The prevalence of ROS is extremely rare, the number of participants is small. We need to complete the procedure to check if the pregnancy and live birth will be achieved.

Wider implications of the findings: We developed a new approach for successful follicle growth to allow oocytes retrieval in ROS patients by autoimmune suppression using PSL. If we can detect the autoimmune antibodies responsible for ROS, this procedure could be a more useful method for groups of ROS patients hard to be treated.

Trial registration number: UMIN000034464

P-579 Peroxiredoxin 4 protects against ovarian ageing by ameliorating D-galactose induced oxidative damage in Mice

Y. Meng[1], **X.R. Liang**[1]

[1]*The First Affiliated Hospital of Nanjing Medical University, State Key Laboratory of Reproductive Medicine, The Center for Clinical Reproductive Medicine*

Study question: What the effect and underlying molecular mechanism dose Prdx4 protein play in D-galactose induced ovarian ageing?

Summary answer: D-galactose induced ovarian ageing is accelerated in Prdx4$^{-/-}$ mice, which results from accelerated apoptosis in granulosa cell via oxidative stress and ER stress-related pathways.

What is known already: Prdx4, a member of the Prdx family, is an important ER-resident antioxidant in cells. As revealed by our previous study, the expression of Prdx4 was detected in ovarian granulosa cells and closely related to ovarian function. We also discovered that it was located in ER of granular cell and involved in regulating the ER stress. D-galactose induced ovarian aging in mice has been extensively used to study mechanisms of diminished ovarian reserve (DOR).

Study design, size, duration: In this study, we established mice model with gene prdx4 knock out (Prdx4$^{-/-}$) by the CRISPR/Cas9 technology. Adult (5 months) wild-type and Prdx4$^{-/-}$ mice were both intraperitoneally injected with D-galactose (150 mg/kg/day) daily for 6 weeks. Ovarian function, oxidative damage, ER stress and granulosa cell apoptosis in the ovaries were evaluated in the two groups.

Participants/materials, setting, methods: We detected the representative estrous cyclicity during 12 consecutive days. Secondly, we calculated ovary-to-body weight ratio and detected the level of E_2. Thirdly, the number of different types of follicles were counted by hematoxylin and eosin (H&E) staining, and apoptosis in granulosa cells were tested by TUNEL. In addition, we observed the expression of senescence-associated protein and oxidative stress related factors via immunohistochemistry. Eventually, three ER stress pathways related markers were examined by western blot.

Main results and the role of chance: The HPG axis was more disrupted (*P*<0.01), and ovarian weight was relatively lower in the Prdx4$^{-/-}$ mice. The numbers of atretic follicles and apoptotic granulosa cells were significantly

increased in Prdx4$^{-/-}$ mice (P<0.05). In addition, the Prdx4$^{-/-}$ mice showed increased expression of oxidative damage-related factors (8-OhDG, 4-HNE, and NTY) and ovarian senescence-associated protein P16 (P<0.05). Moreover, levels of the proapoptotic factors CHOP and activated caspase-12 protein (P<0.01), which are involved in the endoplasmic reticulum stress pathway and level of cell apoptosis-related BAX protein were elevated in the ovaries of the Prdx4$^{-/-}$ mice.

Limitations, reasons for caution: This is a descriptive study in mice. More further experiments are necessary to explore the molecular mechanism for Prdx4 on ovarian function protection.

Wider implications of the findings: This study suggests that Prdx4 shows protective effect on ovarian function by reducing apoptosis of ovarian granulosa cell via downregulating oxidative stress and ER stress-related pathways.

Trial registration number: not applicable

P-580 GnRH agonist as an adjuvant to hCG for final oocyte maturation

I. Park[1], H. Sun[1], J. Kim[1], J. Lee[1], S. Shim[1], K. Lee[2], G. Jeon[3]

[1]Liora Fertility Center, Obstetrica & Gynecology, Busan, Korea- South ;
[2]Mamapapa& baby OBGY, Obstetrics and Gynecology, Ulsan, Korea- South ;
[3]Haeundae paik Hospital, Obstetrics and gynecology, Busan, Korea- South

Study question: Does triggering final oocyte maturation with standard dosage of hCG and additional GnRH agonist make better IVF outcomes?

Summary answer: GnRH agonist as an adjuvant to hCG for final oocyte maturation increases the number of mature oocytes and improves embryos quality.

What is known already: A single bolus of hCG has been the gold standard for triggering final oocyte maturation in ART cycles. GnRH agonist trigger has been utilized in GnRH-antagonist cycles for inducing final oocyte maturation while reducing the risk of ovarian hyperstimulation syndrome (OHSS). GnRH agonist trigger could help retrieving more mature oocyte. However, after GnRH agonist trigger, luteal phase defect results in lower pregnancy rate in fresh transfer cycle. Final oocyte maturation triggering with both standard dosage of hCG and GnRH agonist could help getting better IVF outcomes in GnRH antagonist cycles.

Study design, size, duration: This retrospective study included women undergoing IVF cycles using GnRH antagonist protocol between January 2013 and December 2017. A total of 4335 low and normo-responders were assessed.

Participants/materials, setting, methods: When at least 2 follicles reached 18 mm in diameter, final oocyte maturation was triggered by hCG 10000 IU alone or hCG 10000 IU plus GnRH agonist (leuprolide 1.0mg). And oocyte aspiration was done after 36 to 38 hours later. We divided the patients into two groups by triggering method. Group A (n=3776): trigger by hCG 10000 IU. Group B (n=559): trigger by hCG 10000 IU + GnRH agonist (leuprolide 1.0 mg)

Main results and the role of chance: In each group, age (36.3 vs. 36.4), endometrial thickness (10.1 mm vs. 9.9 mm) and the number of transferred embryos (1.9 vs. 1.9) did not show significant differences. There was no significant difference between two groups in total number of oocytes [9.9 vs. 10.4, P=0.054]. Oocyte recovery rate (total number of oocytes/ follicles>11mm) [118.7% vs. 131.0%, P<0.01], the number of mature oocytes [6.1 vs. 6.4, P=0.032] and the number of 2PN [6.7 vs. 7.1, P=0.029] were significantly higher in Group B than in Group A. Group B had higher embryo quality score [75.6 vs. 85.0, P<0.01] than Group A. Ongoing pregnancy rates were similar between two groups [43.9% (1535/3494) vs. 44.3% (203/458), P=0.190]. In both group, there was no case of severe OHSS.

Limitations, reasons for caution: This is retrospective study. The sample size of each group shows difference between two groups. Randomized control study will be needed to confirm our conclusions.

Wider implications of the findings: Triggering final oocyte maturation with standard dosage of hCG and additional GnRH-agonist increases the number of mature oocyte and 2PN. It also improves embryo quality. Routine use of dual trigger with hCG and GnRH agonist could be a good option to improve IVF outcomes without increasing OHSS or treatment burden.

Trial registration number: not applicable

P-581 Negative short-term effect of hysterectomy and bilateral salpingectomy on sex steroids, gonadotropins and AMH

J. Hutmacher[1], V. Uerlings[2], A. Günthert[3], J.M. Weiss[4]

[1]Cantonal Hospital of Frauenfeld, Obstetrics and Gynecology, Frauenfeld, Switzerland ;
[2]Cantonal Hospital of Lucerne, Obstetrics and Gynecology, Lucerne, Switzerland ;
[3]gyn-zentrum, Gynecology, Lucerne, Switzerland ;
[4]VivaNeo, Reproductive Medicine, Berlin, Germany

Study question: What is the course of sex steroids, gonadotropins and AMH after hysterectomy and bilateral salpingectomy?

Summary answer: DHEA-S, testosterone, androstenedione, estradiol, progesterone, LH, FSH, SHBG and AMH showed significantly decreased blood levels at the morning after surgery compared to preoperative/long-term samples

What is known already: Bilateral salpingectomy in benign conditions is widely performed to prevent ovarian cancer. Recent Meta-Analyses demonstrate no impairment of ovarian function of this procedure, even though an impaired postoperative ovarian stromal blood flow was described. Whether a hysterectomy and bilateral salpingectomy negatively affects sex steroids, gonadotropins and AMH remains to be determined.

Study design, size, duration: Prospective cohort study (February 2013 – January 2015) of 40 premenopausal women with ovary-sparing elective hysterectomy and bilateral salpingectomy for benign uterine conditions or premalignant high-grade cervical pathologies.

Participants/materials, setting, methods: Serum concentrations of DHEA-S, testosterone, androstenedione, estradiol, progesterone LH, FSH, SHBG, and AMH were assessed one day before, one day after and 4-6 weeks after surgery in a public hospital. Postoperative sampling was performed strictly at 07.30 a.m. (±1 hour).

Patients with presurgical evidence of malignancies, suspect ovarian morphology in transvaginal ultrasound, menopausal symptoms, menopausal hormone treatment, baseline FSH values >25 IU/L or baseline AMH values <0,6 pmol/l were excluded.

Main results and the role of chance: Mean age and BMI were: 44,83 years and 24,53 kg/m^2, respectively. At the day after surgery all hormones decreased significantly: DHEA-S ($p < 0.002$ mean: 4.10/2.37/3.69 mmol/L); testosterone ($p < 0.001$ mean: 0.95/0.49/0.86); androstenedione ($p < 0.24$ mean: 4.87/4.18/4.26 nmol/l); estradiol ($p < 0.05$ mean: 553.73/309.84/475.72 pmol/L); progesterone ($p < 0.13$ mean: 1.96/0.98/3.41 ng/ml); LH ($p < 0.3$ mean: 10.58/9.17/12.98 IU/L); FSH ($p < 0.46$ mean: 11.15/10.79/16.54 IU/L); SHBG ($p < 0.22$ mean: 74.64/67.13/73.65 nmol/L); and AMH ($p < 0.46$ mean: 5.23/4.99/7.12 pmol/l). There was no statistically significant correlation between hormone levels and operation time, blood loss or any further variable. Serum hormone changes did not correlate with age or BMI. However, by 4-6 weeks after surgery, circulating hormone values had returned to preoperative levels. We conclude that this hormonal decrease reflects an impaired hormonal regulation after surgery. These hormonal changes are transient, lasting no longer than 4-6 weeks.

Limitations, reasons for caution: These findings are based on a small sample size. The results need to be confirmed in larger patients groups and should include cortisol serum levels to depict stress levels.

Wider implications of the findings: These data reveal a postoperative dysregulation of the pituitary-gonad axis. It should be further explored how long these changes last and what kind of surgeries are involved. This might be important knowledge for the initiation of hormonal therapies after surgery.

Trial registration number: Switzerland: EKNZ

P-582 Recombinant-FSH or human-menopausal-gonadotrophin during ovarian stimulation resulted in similar mean euploid blastocyst rates per cohort of inseminated oocytes: an observational study on 961 patients.

S. Colamaria[1], D. Cimadomo[1], A. Vaiarelli[1], M. Giuliani[1], C. Argento[1], G. Bruno[1], S. Ferrero[1], G. Fabozzi[1], R. Mazzilli[1], A. Conforti[2], C. Alviggi[2], M. Schimberni[3], N. Ubaldi[4], L. Rienzi[1], F.M. Ubaldi[1]

[1]Clinica Valle Giulia, Genera centers for reproductive medicine, Rome, Italy ;
[2]University of Naples- Federico II, Department of Neuroscience- Reproductive Science and Odontostomatology, Naples, Italy ;
[3]Clinica Valle Giulia, Bioroma, Rome, Italy ;
[4]Catholic University of the Sacred Heart, Obstetrics and Gynecology, Rome, Italy

Study question: Do the type (recombinant-FSH or human-menopausal-gonadotrophin [hMG]) and dose of gonadotrophin adopted for controlled-ovarian-stimulation affect the euploid-blastocyst-rate per cohort of metaphase-II oocytes (m-EBR per MII)?
Summary answer: The type and total dose of gonadotrophins do not affect the m-EBR per MII.
What is known already: Controlled-ovarian-stimulation (COS) is one of the cornerstones of IVF. Its purpose is to obtain an adequate response in terms of oocytes' number and quality to improve treatments' efficacy and efficiency by obtaining several competent embryos. Although some data suggested that recombinant-FSH and hMG for COS in long agonist protocols perform similarly, the evidence is limited in antagonist protocols, i.e. the most commonly used at present. Therefore, the decision on which gonadotrophins should be used for COS is still uncertain, especially in patients at their first COS (naïve) and/or in freeze-all strategies.
Study design, size, duration: Observational study including all naïve patients (n=961, mean-maternal-age:39.2±3.5yr, mean-AMH:2.2±1.7ng/ml, mean-BMI:21.5±2.5) indicated for trophectoderm biopsy-based preimplantation-genetic-testing-for-aneuploidies (PGT-A) in the period 2013-2018. All patients underwent a GnRH-antagonist protocol. The kind of gonadotrophin was chosen depending on patients' compliance to the type of administration (pen for recombinant-FSH versus syringe for hMG) and gynecologists' judgment. The dose was established according to patients' characteristics. The primary outcome was the m-EBR per MII in the two groups.
Participants/materials, setting, methods: To achieve 80% power (α=0.05) to rule-out a 5%-difference in the primary outcome we required 792 and 158 naïve patients in the recombinant-FSH and hMG groups, respectively, assuming that 1/5 would use hMG. Only completed PGT-A cycles (live-birth achieved or no euploid embryos produced/left) with all MII-oocytes undergoing ICSI were included. Secondary outcomes were: mean number of oocytes, blastocysts and euploid blastocysts, maturation and blastocyst rates, and cumulative-live-birth-delivery-rate (CLBdR) per cycle.
Main results and the role of chance: 773(80.4%) and 188(19.6%) patients used recombinant-FSH and hMG, respectively. The groups were similar for maternal/paternal age, AMH, BMI, sperm factor, cause of infertility, and trigger of ovulation. The dose and duration of COS were lower with recombinant-FSH (2447±813IU versus 2672±871IU,p<0.01;9.7±1.7days versus 10.0±1.7day,p=0.02), nevertheless the number of cumulus-oocytes-complexes (COCs) was higher (n=8185,10.6±6.5 versus n=1709,9.1±5.7,p<0.01). The maturation rates per COCs (MII/COC) were similar (74%±19% versus 72%±21%,p=0.3), therefore also the number of MII was higher with recombinant-FSH (n=5827,7.5±4.4 versus n=1213,6.4±4.3,p<0.01). More blastocysts were biopsied with recombinant-FSH (n=1926,2.5±2.2 versus n=402,2.1±2.1,p=0.02), although the blastulation rate per MII was similar (33%±25% versus 33%±28%;p=0.5). The number of euploid blastocysts was slightly higher with recombinant-FSH (n=897,1.2±1.5 versus n=186, 1.0±1.5,p=0.05), while the m-EBR per blastocysts were comparable (34%±37% versus 30%±37%,p=0.1). Lastly, both the m-EBR per MII (15%±20% versus 14%±20%,p=0.14) and the CLBdR (n=251/773,32.5% versus n=50/188,26.6%;p=0.1) were similar. Once corrected for maternal age, AMH and sperm factor, neither the kind nor the dose of gonadotrophins was associated with the m-EBR per MII in a generalized-linear-model (p=0.2 and p=0.5). Once corrected for maternal age, number of oocytes and sperm factor, neither the kind nor the dose of gonadotrophins was associated with the CLBdR in a multivariate logistic-regression-analysis (p=0.2 and p=0.7).
Limitations, reasons for caution: The study was powered to exclude a 5%-difference in the primary outcome, therefore secondary outcomes are observational. A cost-effectiveness analysis is required. The choice of the gonadotrophin was based on patients' compliance with the administration method and gynecologist's judgment, thus randomized-controlled-trials investigating the CLBdR per cycle are still required.
Wider implications of the findings: Recombinant-FSH in naïve patients undergoing blastocyst culture, PGT-A and vitrified-warmed euploid embryo transfer(s) is suitable as first-line COS approach. Indeed, it may result in larger cohorts of oocytes of a similar competence as hMG, but involving a higher patients' compliance (lower dose, shorter COS and a well-accepted type of administration).
Trial registration number: None

P-583 GnRH-agonist and urinary-human-chorionic-gonadotrophin trigger of final oocytes' maturation result in similar oocytes' competence: an observational study on 2725 cycles with aneuploidy testing

C. Petriglia[1], D. Cimadomo[1], A. Vaiarelli[1], S. Colamaria[1], M. Giuliani[1], G. Bruno[1], R. Maggiulli[1], D. Soscia[1], M.G. Amendola[1], G. Nastri[1], F. Innocenti[1], G. Fabozzi[1], N. Ubaldi[1], F.M. Ubaldi[1], L. Rienzi[1]

[1]Clinica Valle Glulia, Genera center for reproductive medicine, Rome, Italy

Study question: Does the trigger of final oocytes' maturation (GnRH-agonist versus urinary-human-chorionic-gonadotrophin [u-hCG]) affect their competence during IVF cycles with preimplantation-genetic-testing-for-aneuploidies (PGT-A)?
Summary answer: GnRH-agonist and u-hCG involve similar maturation rates per oocyte-pick-up (OPU) and mean euploid blastocyst rates per cohort of metaphase-II oocytes (m-EBR per MII).
What is known already: The conventional trigger of final oocytes' maturation after controlled ovarian stimulation (COS) is hCG. Nevertheless, standing the growing application of GnRH antagonist protocols for COS, GnRH-agonist trigger has been introduced to almost eradicate the incidence of ovarian hyperstimulation syndrome (OHSS) in patients at high risk. While it is clear that this strategy affects the window of implantation when conventional luteal phase support is used, no evidence has been instead produced regarding its effect on oocytes' competence. Lastly, it is still uncertain whether GnRH-agonist trigger might be efficiently adopted in an unselected population of patients candidate to freeze-all.
Study design, size, duration: Observational study including 2725 OPU for PGT-A performed between 2013 and 2018 at a private IVF center (maternal age:39.5±3.3yr, AMH:2.1±1.8ng/ml, BMI:21.7±2.7). Also cycles without MII, zygotes or blastocysts were included. The primary outcome was the m-EBR per MII in the cycles adopting GnRH-agonist (n=1294) versus u-hCG (n=1431). The main secondary outcome was the mean maturation rate per OPU (MII/COCs). All outcomes were adjusted for patients'/cycles' putative confounders in generalized-linear-models and multivariate logistic-regression-analyses
Participants/materials, setting, methods: All patients had regular menstrual cycles. Different gonadotrophins and doses were used in antagonist COS protocols (recombinant-FSH,n=1048, 38.5%; recombinant-FSH+LH-activity,n=1065, 39.1%; hMG,n=282, 10.3%; biosimilar-FSH,n=90, 3.3%; corifollitropin-alpha+recombinant-FSH/hMG,n=240, 8.8%) according to patients' characteristics and gynaecologists' judgement. When ≥2 follicles reached a diameter ≥17–18mm, the trigger was performed 35hr before OPU with a subcutaneous bolus of GnRH-agonist (Buserelin:0.5ml) or intramuscular injection of u-hCG (10,000IU). Denudation, ICSI, blastocyst biopsy, comprehensive-chromosome-testing, and vitrified-warmed euploid blastocyst transfers were conducted after OPU.
Main results and the role of chance: The adoption of the GnRH-agonist trigger increased during the observational period (~10% to ~60%), especially in patients collecting >10 cumulus-oocyte-complexes (COCs) (~30% to ~80%). This reduced the incidence of patients referring symptoms of a moderate-severe OHSS from ~2% to none, with no impact on the competence of the retrieved oocytes. Overall, GnRH-agonist trigger was adopted in younger patients (38.8±3.4yr) who collected more COCs (n=17593, 13.6±7.4 per OPU) than u-hCG (40.2±3.1yr; n=10552 COCs, 7.4±4.6 per OPU). Nevertheless, the trigger adopted, also when adjusted per maternal age and number of COCs in a generalized-linear-model, did not associate with the mean maturation rate per OPU (p=0.1). A similar statistical approach outlined that the mean fertilization rate per MII, the mean blastulation rate per cohort of zygotes, and the mean-EBR per cohort of biopsied blastocysts were also independent of the trigger adopted (p=0.5, p=1.0, and p=0.3, respectively). Not even the primary outcome under investigation (i.e. m-EBR per MII) was affected by the trigger used (p=0.83). At last, the cumulative-live-birth-delivery-rate (CLBdR) per completed cycle (i.e. ≥1 live-birth achieved or no euploid embryos left/produced) was independent from the trigger adopted (Odds-Ratio: 1.0,95%CI 0.85-1.31, adjusted-p=0.6) in a multivariate-logistic-regression-analyses corrected for confounders.
Limitations, reasons for caution: This is a retrospective study. No cost-effectiveness analysis was conducted. GnRH-agonist trigger was performed independently from LH levels, although this might identify specific subpopulations of patients with a suboptimal response. Lastly, properly-conducted

Randomized-Controlled-Trials are still eagerly requested, especially in antagonist COS protocols.
Wider implications of the findings: Throughout the years the adoption of GnRH-agonist trigger after antagonist COS protocols has sharply increased for cycles planned for PGT-A with blastocyst culture, biopsy, and freeze-all. This did not impact oocytes' competence, while almost eradicating OHSS. U-hCG trigger is still used in ~50% of the patients collecting ≤10 COCs.
Trial registration number: None

P-584 Role of Homeostasis model assessment (HOMA2-IR), Quantitative insulin sensitivity check index (QUICKI) and Irisin in diagnosing insulin resistance among young girls with Polycystic ovarian syndrome

H. Sagili[1], B. Sharan[1]

[1]JIPMER, Obstetrics and Gynaecology, Puducherry, India

Study question: Do HOMA2-IR, QUICKI and Irisin diagnose additional cases of insulin resistance in young girls with Polycystic ovarian syndrome (PCOS) in comparison with 75 gm OGTT?
Summary answer: HOMA2-IR, QUICKI and Irisin appear to detect additional cases of insulin resistance in young girls with PCOS in comparison with 75 gm OGTT.
What is known already: Young girls with PCOS have a predilection to become insulin resistant with an increased risk of impaired glucose tolerance (IGT) and type 2 Diabetes Mellitus (DM). Because impaired glucose tolerance is often asymptomatic, screening for insulin resistance (IR) is recommended. The gold standard method of assessing Insulin resistance namely Euglycemic hyper-Insulinemic clamp technique is expensive and not practical. Currently 75 gm oral Glucose tolerance test (OGTT) is being offered as a screening method for insulin resistance but might not identify all cases of IR. The role of other surrogate markers for diagnosis of IR is not yet established.
Study design, size, duration: This cross sectional study was carried out over a period of two years.82 young girls aged 15-19 years -41 young girls with PCOS were compared to 41 age matched controls who had presented with minor gynaecological complaints such as dysmenorrhea, white discharge per vaginum, lower abdominal pain etc. Excusion criteria were thyroid dysfunction,hyperprolactinaemia and treatment with Insulin sensitizers. Consecutive sampling was carried out.
Participants/materials, setting, methods: Girls recruited from Gynaecology outpatient department of a tertiary care hospital underwent testing for Fasting- Serum Irisin, Insulin; Blood Glucose and second hour Serum Insulin; Blood glucose after 75 gm glucose. HOMA 2-IR and QUICKI were calculated using computer software and Serum Irisin was measured by ELISA. Cut offs for HOMA2-IR, QUICKI and Irisin were defined based on population based studies as >2.5, 0.383+0.007 for nonobese / 0.331+ 0.010 for obese and 15.43 ng/ml respectively.
Main results and the role of chance: Almost half the cases were obese, another 22% were overweight in our study and the body mass index between cases and controls was statistically significant (p<0.0001).78% of the cases had all three features of PCOS according to Rotterdam's criteria. Infrequent menstrual cycles and clinical and/or biochemical signs of hyperandrogenism were seen in 14.7% and infrequent cycles and polycystic ovaries were present in 7.3%. 51% of cases had impaired glucose tolerance on 75 gm OGTT and there were no cases of overt diabetes. 43.9% cases had IR based on HOMA2-IR compared to 21% controls (p=0.03). 34% cases compared to 17% controls had IR based on QUICKI (p=0.038).19% cases compared to 9.7% controls had IR based on fasting serum Irisin (p=0.211). Overall 21 cases were diagnosed to be insulin resistant based on 75 gm OGTT ; 18 additional cases (43.9%) were diagnosed as insulin resistant based on a panel of markers (HOMA2-IR ,QUICKI and fasting serum Irisin). 11 and 8 cases (26.8% and 19.5%) were diagnosed based on only high HOMA2-IR and QUICKI values respectively. Similarly, 3 cases (7.3%) were diagnosed as insulin resistant based on only high fasting serum Irisin values .
Limitations, reasons for caution: The study was done on a small sample and as a case-control study for the findings to be applicable to a larger population. Further, follow up of these subjects may yield additional insight into the progression of insulin resistance and type 2 DM in young girls with PCOS.
Wider implications of the findings: As young girls with PCOS are at high risk of developing IGT, early identification of IR by a panel of HOMA2-IR, QUICKI and Irisin in addition to GTT may play a pivotal role in institution of lifestyle changes that may help in delaying the progression to type 2 DM.
Trial registration number: not applicable

P-585 Prokineticin receptor 2 (PROKR2) mutations in functional hypothalamic amenorrhoea

A. Tranoulis[1], D. Mavrogianni[2], A. Soldatou[3], A. Pampanos[2], T. Leoutsakou[4], P. Drakakis[5], D. Loutradis[6], L. Michala[7]

[4]Alexandra Hospital- National and Kapodistrian University of Athens, Department of Molecular Biology, Athens, Greece ;
[5]Alexandra Hospital-Athens University Medical School, Division of Human Reproduction- IVF Unit- First Department of Obstetrics and Gynaecology, Athens, Greece ;
[6]Alexandra Hospital- Athens University Medical School, Division of Human Reproduction- IVF Unit- First Depertment of Obstetrics and Gynaecology, Athens, Greece ;
[7]Alexandra Hospital- National and Kapodistrian University of Athens- School of Medicine, First Deparment of Obstetrics and Gynaecology, Athens, Greece

Study question: To identify any possible mutations in prokineticin recptor 2 (PROKR2) gene in subjects with functional hypothalamic amenorrhoea (FHA).
Summary answer: PROKR2 mutation screening in 41 women with FHA resulted in the identification of eight novel different mutations in five patients.
What is known already: Although the proximate cause of FHA is the abnormal gonadotropic-releasing hormone (GnRH) secretion, it is seemingly more than an isolated desynchronisation of the GnRH axis. There is fair evidence to support the association of FHA with behavioural, emotional, cognitive and psychological factors. However, it remains uncertain, whether this variability is also attributable to a genetic predisposition. The PROK2 and PROKR2 singling pathway is implicated in the cause of idiopatic hypogonadotropic hypogonadism (IHH) and Kallmann's syndrome. Two heterozygous PROKR2 mutations (c.254 G>A and c.518 T>G) have also been identified amongst patients with FHA. The latter were found to be loss-of-function mutations.
Study design, size, duration: This is a prospective, single-centre study carried out at a tertiary referral clinic for gynaecological endocrinology and paediatric & adolescent gynaecology, spanning the period January 2016 to June 2019. We analysed the coding sequence of PROKR2 in 84 women: 41 with FHA, 23 with IHH, and 20 healthy controls respectively.
Participants/materials, setting, methods: Genomic DNA was extracted from peripheral blood samples using PureLink Genomic DNA Kits for purification of genomic DNA. PCR was performed using primers designed to amplify the two coding exons and the exon-intron boundaries. The amplified PCR products were sequenced using the ABI Prism 3130 Genetic Analyzer, Applied Biosystems. Variants were validated using the sequencing Analysis v 5.2 software.
Main results and the role of chance: Eight novel PROKR2 mutations were identified in five of the 41 women with FHA, either in heterozygous state (two cases) or in homozygous or compound heterozygous state (three cases)**:** 241 c.G>C, c.296 G>T, c.375 A>G, c.404 A>G, c.404 C>G, c.410 C>A, c.421 G>A, and c.475 G>T. Furthermore, three novel PROKR2 heterozygous mutations were identified in three of 23 women with IHH: c.246 C>T, c.252 C>T and c.259 G>C. Reproductive phenotypes ranged from absent to partial puberty to complete reversal of gonadotropin-releasing hormone deficiency following discontinuation of treatment.No mutations were found in the cohort of 20 controls with normal menstrual cycles.
Limitations, reasons for caution: Further research to ascertain the functional impact of these variants is warranted. Differences in the genetic backgrounds of various ethnic populations should also be considered.
Wider implications of the findings: Identification of gene mutations underlying FHA may lead to new pathophysiology insights, improved diagnostics, and novel treatment approaches.
Trial registration number: not applicable

P-586 Impact of gonadotropin genetics profile and ovarian reserve on controlled ovarian stimulation outcomes

A. Rebecchi[1], E. Papaleo[1], M. Mignini Renzini[2], C. Alviggi[3], A. Marino, Alessandro[4], C. Brigante[5], A. Conforti[3], M. Molgora[1], R. Iemmello[6], I. Carbone[7], L. Quaranta[1], A. Allegra[4]

[6]Ospedale Maggiore Policlinico- Mangiagalli and Regina Elena, Infertility Unit, Milan, Italy ;
[7]Ospedale Maggiore Policlinico- Mangiagalli and Regina Elena, Obstetrics and Gynecology, Milan, Italy

Study question: o assess the difference between expected, through standardized-3D AFC, and retrieved oocytes in relation to gonadotropin genetic profile after standard COS with 150 UI/day r-FSH.
Summary answer: In good prognosis women, specific genetic variants seem to partially influence ovarian stimulation, despite no relevant impact on pregnancy rates was observed.
What is known already: Among fertility treatment, controlled ovarian stimulation represents the key step, with the main aim to obtain a certain number of competent oocytes that will enable the best probability of achieving a live birth. The ovarian response to FSH in individuals is difficult to predict. Indeed, women with similar demographic, anthropometric and gonadotropin profiles may have different response to r-FSH due to the "sensitivity" of follicles to exogenous FSH itself. Several studies demonstrated that such "sensitivity" could be influenced by specific genotype characteristics. However, the evidence in this sense seems to be controversial and inconclusive.
Study design, size, duration: We performed a multicenter, longitudinal, prospective, interventional, cohort pilot-study, enrolling 119 women attending four clinical Centers of medically assisted reproduction from August 2016 to November 2018.
Participants/materials, setting, methods: Infertile normo-gonadotropin patients, aged between 34 and 39, at their first COS, with normal ovarian reserve (AFC between 8 and 16) measured with 3D automated ultrasonography. Blood samples were collected for gonadotropin genetic polymorphisms assessment and hormone assay. Stimulation protocol consisted of standard 150 IU/day r-FSH for the whole stimulation period starting from basal assessment, GnRH antagonist starting from day 5-6 of stimulation, and trigger when at least two follicles reached >16 mm diameter.
Main results and the role of chance: 106 patients completed the stimulation protocol. The mean basal 3D follicular count was 13.4, the mean of follicles > 16 mm at induction was 5.8 and the mean number of retrieved oocytes was 8.4. No significant correlation was found between the number of retrieved oocytes and different genotypes for each polymorphism. However, after 5 days of stimulation, we observed a significant impact of AG genotype for FSHR p.N0680S on the percentage of observed follicles ≥10 mm compared with genotypes AA (p = 0.04) and GG (p = 0.005). Nonetheless, at day of trigger, no significant differences were found in the number of follicles ≥16 mm. This may be due to a fastest development of follicles in the first part of stimulation for women carrying AG genotype. LHCGR2 GG genotype leads to a shorter stimulation compared with genotypes AA (p = 0.008) and GA (p = 0.006). The same result was obtained for homozygous GG genotype for the FSHB-211 polymorphism compared to the genotype GT (p = 0.04). Significant correlation was found between BMI and heterozygous genotype of the FSHR p.N0680S (OR= 1.28 [1.09-1.52] p=0.004). We obtained 36.8% of ongoing pregnancies per started cycle.
Limitations, reasons for caution: Strict inclusion criteria limited the enrolment of subjects planned before the study. Thus, the main findings of our study could be underpowered. However, this is the first prospective study in which polymorphisms were associated to AFC assessed by a reliable, standardized automated method together with centralized AMH assessment.
Wider implications of the findings: In normo-responder patients, the impact of pharmacogenomics in the personalization of treatment protocol is far from clearly correlating with IVF-ICSI pregnancies. On the other hand, a marginal effect on ovarian stimulation and anthropometric characteristics of women seems to emerge. Further biggest studies are needed.
Trial registration number: not applicable

P-587 Body Mass Index stratified Anti-Müllerian hormone thresholds for diagnosing Polycystic Ovary Syndrome

X. Liu[1], Y. Guo[1]

[1]The First Affiliated Hospital of Zhengzhou University, Reproductive Medicine Center, Zhengzhou, China

Study question: Should Anti-Müllerian hormone (AMH) threshold for diagnosing Polycystic Ovary Syndrome (PCOS) be stratified according to different Body Mass Index (BMI)?
Summary answer: PCOS patients with lower BMI had higher serum AMH levels and AMHR mRNA expression in granulosa cells and we proposed BMI stratified AMH thresholds.
What is known already: Serum AMH levels are higher among patients with PCOS than healthy women and PCOM (Polycystic Ovary Morphology) women with normal ovulation. While AMH has been reported to be positively or non-significantly related to BMI in infertile women without PCOS, in women with PCOS, AMH appears to be negatively correlated with BMI levels. AMH is believed to be a surrogate indicator of the antral follicle count (AFC) for diagnosing PCOS. However, the heterogeneity of PCOS patients has seldom been considered when calculating cut-off values.
Study design, size, duration: This was a retrospective cohort study based on 4347 infertile women under 35 years old treated in a reproductive medicine centre of a university-affiliated hospital from February 2016 to May 2018. Granulosa cells(GCs) were collected from 22 patients undergoing transvaginal oocyte retrieval after controlled ovarian hyperstimulation with agonist protocol from December 2019 to January 2020.
Participants/materials, setting, methods: The study population included 1220 patients with PCOS, 1386 patients with PCOM and 1741 normal controls. We divided them into normal-weight groups and overweight groups separately based on a BMI threshold of 24 kg/m^2 according to a guideline based on the Chinese population. RNA samples were extracted from GCs from 13 PCOS patients and 9 normal controls. Expression of AMHR mRNA were evaluated by RT-qPCR.
Main results and the role of chance: Regardless of normal weight or overweight, PCOS patients tend to have higher AMH levels (P<0.001) and slightly higher AMHR expression in GCs (Normal weight: 2.69±2.59 vs 1.04±1.01, P=0.088; Overweight: 1.78±1.22 vs 0.82±0.42, P=0.116) than control groups. In the PCOS group, normal-weight women had higher serum AMH levels than overweight women (P<0.001) and slightly higher AMHR expression(P=0.133,0.180, respectively), while in the control groups, there was no such difference. The cut-off level for AMH for diagnosing PCOS was 4.77 ng/ml in the normal weight group and 4.15 ng/ml in the overweight group with sensitivity of 81.8% and 85.8%, specificity of 90.5% and 84.2%, respectively.
Limitations, reasons for caution: The current GC samples collected from patients were limited and the expression pattern of AMHR may be affected by the medication used during COH, thus, further experiments including larger sample size and validation with the animal model are needed.
Wider implications of the findings: This study agreed with the former study that AMH levels of patients with PCOS were affected by their BMI. Our study suggested that BMI should be taken into consideration when assessing endocrine indicators of women with PCOS, such as AMH, in both clinical practice and basic research.
Trial registration number: 81571409

P-588 The activated mTOR-S6K signaling pathway increases DNA damage in follicles of women with polycystic ovary syndrome

G. Jing[1], S. Cai[2], G. Lin[3]

[1]Reproductive and Genetic Hospital of CITIC-Xiangya, Reproduction Medicine Center, Changsha, China ;
[2]Reproductive and Genetic Hospital of CITIC-Xiangya, Reproductive Medicine Center, Changsha, China ;
[3]Central South University, School of Basic Medical Science, Changsha, China

Study question: Does the follicular microenvironment of polycystic ovary syndrome (PCOS) change by regulating the expression of mammalian rapamycin (mTOR) pathway targets?
Summary answer: The mTOR-S6K signaling, by controlling DNA damage response and genome stability of granulosa cells and oocytes, maintains follicular microenvironment of female ovarian.
What is known already: Recent researches suggest that mTOR pathway, which was found to be especially active in PCOS, is considered to have close relationship with the pathogenesis of PCOS. In previous studies, we determined the role of mTOR by use of conditional knockout mice model. mTOR-dependent pathways in primordial or growing oocytes differentially affected downstream processes including follicular development, sex-specific identity of early granulosa cells, maintenance of oocyte genome integrity, oocyte gene expression, meiosis, and preimplantation developmental competence. However, the underlying mechanism between mTOR pathway and pathophysiological changes of PCOS remains largely undetermined.
Study design, size, duration: In this study, patients with PCOS (n = 4) diagnosed according to the 2003 Rotterdam standard underwent partial or wedge resection of the ovary. The ovarian tissues used as control were obtained from female (n=3) who underwent ovariectomy for fertility preservation. Samples were fixed and analysed by immunohistochemistry to determine mTOR pathway activation and expression of markers reflecting DNA damage, cell apoptosis and proliferation. Mtor-conditional knockout mice was performed to examine the underlying molecular mechanism.
Participants/materials, setting, methods: Ovarian tissues of PCOS patients and Mtor- GcKO mice were used as study models. Ovarian tissues were fixed and analysed histologically. Immunostaining for: 1) the expression of MTOR and the activated form of its major downstream effectors—phosphorylated RPS6KB1, phosphorylated ribosomal protein S6 (pRPS6), phosphorylated EIF4EBP1. 2) γH2AX as a marker of DNA damage; 3) CASPASE3 as a marker of cells apoptosis; 4) KI67 as a marker of cells proliferation;
Main results and the role of chance: We found that nuclear expression of p-RPS6 level was increased in oocytes of primary and secondary follicles in PCOS patients compared with control group. In the PCOS group, γH2AX expression in oocytes and its surrounding granulosa cells of non-growing and primary follicles significantly increased ($p<0.05$). Expression of KI67 in granulosa cells of growing follicles showed no significant differences between any groups ($p>0.05$). The results of immunohistochemistry analysis showed that the levels of the active forms of phosphorylated MTOR (p-MTOR) and its downstream effectors were regularly expressed in oocytes and granulosa cells at different stages of folliculogenesis in mice. A major downstream effector of MTOR activation, p-RPS6, was gradually increased in different stages of oocyte as follicle development and strongly expressed in cumulus cells and pre-antral granulosa cells but barely detectable in mural granulosa cells. The results of Western blot showed that BMP15 was significantly decreased in oocytes collected from secondary follicles in Mtor- GcKO mice. Immunofluorescence staining of γH2AX revealed more DNA double-strand breaks (DSBs) in Mtor-GcKO oocytes of the early- stage growing follicles.
Limitations, reasons for caution: Due to the limitation by PCOS female tissue acquisition, the ovarian tissue detected in this study was obtained from the patients who need to perform ovarian wedge resection. Additionally, the underlying molecular link between mTOR pathway and DNA damage repair should be further evaluated.
Wider implications of the findings: These results reveal an important function of the mTOR-S6K signaling in DNA damage response and suggest a mechanism related to genome stability in the follicular microenvironment of PCOS patients. Our findings may subsequently provide valuable resources for developing targeted interventions aimed at improving follicle recruitment in vivo for PCOS patients.
Trial registration number: NA

P-589 True Natural Cycle outweighs Hormone Replacement Therapy in euploid frozen embryo transfer

A. Bayram[1], N. De Munck[1], I. El Khatib[1], A. Arnanz[1], A. Abdala[1], A. El Damen[1], L. Melado[1], B. Lawrenz[1], H. Fatemi[1]

[1]IVIRMA Middle East Fertility Clinic LLC, IVF Lab, Abu Dhabi, United Arab Emirates

Study question: Does the cycle regimen used for endometrial preparation affects the outcomes in euploid frozen embryo transfer (FET) cycles?
Summary answer: Clinical pregnancy and implantation rates were significantly increased in natural cycle (NC) as compared to hormone replacement therapy (HRT).
What is known already: The gold standard protocols in FET cycles are HRT, true or modified NC. When comparing live birth and clinical pregnancy rates (CPR), the superiority of one regimen over another has not been demonstrated. NC can only be performed in women with regular ovulatory menstrual cycles, while HRT cycles can be used in women with regular and irregular menstrual cycles. An increased early pregnancy loss has been reported in previous studies in HRT compared to NC, which could be related to the higher proportion of patients with polycystic ovary syndrome (PCOS) or the presence of bias linked to possible embryo aneuploidy.
Study design, size, duration: This single center retrospective cohort study included a total of 802 single/double euploid FET cycles between March 2017 and October 2019. Trophectoderm biopsy samples were subjected to Next Generation Sequencing to test the ploidy state. Vitrification and warming were performed using the Cryotop method (Kitazato, Biopharma). The CPR, implantation rate (IR) and early pregnancy loss (EPL) were evaluated in euploid frozen embryo transfers between true NC and HRT.
Participants/materials, setting, methods: The following patient characteristics were analyzed: age, Anti Müllerian hormone (AMH), body mass index (BMI), primary or secondary infertility, duration of infertility, uterine abnormalities (diagnosed by ultrasound), endometrial thickness, quality of the transferred embryo/s, difficulty of the transfer (requirement of additional instrumentation), day of biopsy and single (SET) or double (DET) embryo transfer. PCOS patients were excluded. The primary aim was to evaluate whether the clinical pregnancy and implantation were affected by the cycle regimen.
Main results and the role of chance: The mean patient age was 34.02±5.10 vs 33.34±5.52 years in NC and HRT. The FET was performed in a NC (n=294, 36.6%) or HRT cycle (n=508, 63.4%). Clinical pregnancy rate was significantly higher in NC; 66.3% vs 57.1% in HRT ($p=0.029$) while EPL rate was significantly lower in NC; 1.26% vs 5.05% ($p=0.025$), respectively. Also, the implantation rate was significantly higher in NC as compared to HRT (64.6%±46.81 vs 57.6%±47.93; $p=0.046$).
Patient characteristics (age, AMH, BMI, duration of infertility, uterine abnormalities, endometrial thickness, embryo quality, embryo transfer difficulty, biopsy day and SET/DET) were similar between both groups compared.

Multivariate logistic regression model was performed with all significant values of the univariate model ($p<0.20$), to check the factors predicting the clinical pregnancy outcome. Following characteristics showed a significant ($p<0.05$) effect on CPR: AMH: OR: 0.889 [0.795-0.995], $p=0.039$, age: OR: 1.36 [1.001-1.071], $p=0.04$, transfer of a top-quality blastocyst: OR: 7.445 [3.552-15.604], $p=0.001$, ET difficulty [Difficult vs Easy]: OR: 0.575 [0.347-0.954], $p=0.032$ and cycle regimen [NC vs HRT]: OR: 1.482 [1.035-2.121], $p=0.031$.
Limitations, reasons for caution: A prospective randomized study with large sample size would have minimized potential limitations as compared to this retrospective design.
Wider implications of the findings: Patients with regular menstrual cycles should be offered a natural FET cycle to achieve better outcomes in terms of clinical pregnancy and implantation rates.
Trial registration number: NA

P-590 Should we measure serum LH levels at the initiation of ovarian stimulation in a GnRH antagonist downregulated IVF/ICSI cycle?

F. Di Guardo[1], A. Racca[1], B. Popovic-Todorovic[1], S. De Rijdt[1], G. Verheyen[1], H. Tournaye[1], M. De Vos[1], C. Blockeel[1]

[1]Universitair Ziekenhuis Brussel- Vrije Universiteit Brussel, Centre for Reproductive Medicine, Brussels, Belgium

Study question: Does the serum LH level at the onset of ovarian stimulation (OS) in a GnRH antagonist cycle have an impact on reproductive outcomes?
Summary answer: The serum LH level at the start of GnRH antagonist cycles has no impact on live birth rates (LBRs) nor cumulative live birth rates (CLBRs).
What is known already: Previous studies suggested that elevated LH levels in the early follicular phase could be associated with lower pregnancy rate. Introducing a GnRH antagonist from Day1 onwards instead of Day 6, has been shown to suppress high LH levels at the start of OS for intrauterine insemination

in polycystic ovarian syndrome (PCOS) patients. A comparison between the administration of GnRH antagonist on Day 1 versus Day 6 of stimulation in regular IVF cycles has also been performed, which demonstrated no significant differences neither in follicular development nor in the oocytes maturity, however, so far, the effect on reproductive outcomes remains unknown.
Study design, size, duration: This was a retrospective, single-centre cohort study including all women (aged 18-43 years) undergoing their first ovarian stimulation for IVF/ICSI in a tertiary referral university hospital between 2009 and 2018. A total of 8329 hCG-triggered GnRH antagonist cycles were included. Cycles with hormonal pre-treatment, IVM, managed natural cycles, oocyte donation, and PGT were excluded from the analysis.
Participants/materials, setting, methods: LH serum levels at the initiation of the cycle were studied in all included patients. Cycles were divided into two groups based on a LH threshold level of 10 UI/L. The LH grouping was repeated using a LH threshold level of 15 UI/L in order to obtain cycles with very-high basal LH level. The primary outcome was CLBR. The secondary outcome was LBR.
Main results and the role of chance: General population baseline characteristics were average female age (33.6 ± 5 years), average basal LH (5.6 ± 3.1 UI/L) and mean number of oocytes retrieved (9 ± 6.1). The population was divided into a group of 7758 cycles with basal LH<10 IU/L and a group of 571 cycles with basal LH ≥10 IU/L. The multivariate analysis adjusting for potential confounders did not show any difference between the two groups in terms of CLBR (31.8% vs. 30.9%, p value=0.678) nor LBR (23.1% vs. 21.4%, p value=0.339). The analysis was repeated with the basal LH threshold level set at 15 IU/L, resulting in a group of 8216 cycles (LH<15 IU/L) and 113 cycles (LH ≥ 15 IU/L). Although LBR was comparable (23% vs. 23%, p value=0.997), CLBR in cycles with basal LH ≥ 15 IU/L was significantly higher compared to those in cycles with LH<15 IU/L (31,7% vs. 41,7%, p=0.05). Multivariable regression analysis showed that lower age, a diagnosis of Rotterdam PCOS and higher number of cryopreserved embryos were significantly associated with CLBR (adjusted OR = 0.94, 95% CI=0.92-0.94, p value <0.001; 1.25, 95% CI=1.08-1.46, p value=0.02; 1.29, 95% CI=1.26-1.32, p value <0.001 respectively).
Limitations, reasons for caution: In spite of the large dataset and the rigorous methodological approach, the presence of biases related to the retrospective design of the study cannot be excluded.
Wider implications of the findings: Based on our data, the assessment of basal LH levels at the initiation of an hCG-triggered GnRH antagonist cycle could be omitted.
Trial registration number: not applicable

P-591 The relation of eating disorder and polycystic ovarian syndrome in female

M. Bazrafkan[1], M. Amiri[2], A. Nadjarzadeh[3]

[1]Reproductive Biotechnology Research Center- ACECR, Avicenna Research Institute, tehran, Iran ;
[2]Shahid Sadoughi University of Medical Sciences- Faculty of Health, Nutrition, Yazd, Iran ;
[3]Shahid Sadoughi University of Medical Sciences-Faculty of Health, Nutrition, Yazd, Iran

Study question: The aim of this study was to clarify the prevalence of eating disorder and relation with BMI and quality of life in women with PCOS.
Summary answer: Women with PCOS had a higher BMI and eating disorder. Quality of life scores decrease by the eating disorder and body mass index increase.
What is known already: Polycystic ovary syndrome(PCOS) is an endocrine disorder in women, that can lead to infertility. Eating disorder has been suggested as one of the leading causes of obesity that is a main risk factor to PCOS. Also, women with PCOS had lower quality of life due to obesity and overweight that are the largest contributor to poor quality of life. On the other hand, obesity and weight loss is major concern in this women that lead to depression and lower quality of life.
Study design, size, duration: This cross sectional study was conducted in Avicenna Research Institute by 150 participants with polycystic ovary syndrome. The data collection was performed by using of the three structural questionnaire including demographic questionnaire, Eating Disorder Questioner(EDE-Q) and Health-Related Quality of Life Questionnaire (PCOSQ).
Participants/materials, setting, methods: 150 participants with polycystic ovary syndrome conducted in this study,The data collection was performed by using of the three structural questionnaire including demographic questionnaire, Eating Disorder Questioner(EDE-Q) and Health-Related Quality of Life Questionnaire (PCOSQ).
Main results and the role of chance: Prevalence of eating disorder was 26.3%. Body mass index(BMI) was higher in women with eating disorder(P=0.001). Also results showed significant correlation between EDE-Q score and BMI(P=0.000). Regarding to the relationship between EDE-Q score and quality of life, the results indicated that the quality of life decreased as the EDE-Q score increased(P=0.000). On the other hand, BMI and quality of life were also inversely correlated(P=.033).
Limitations, reasons for caution: no limitation
Wider implications of the findings: Clinicians should be aware of diagnosis and management of eating disorder in infertile women specially PCOS patients to prevent its complications.
Trial registration number: IR.SSU.SPH.REC.1397.149

P-592 Ovulatory women with polycystic ovaries and their clinical outcome following individualised ovarian stimulation based on AMH and body weight.

H. Visnova[1], E. Papaleo[2], F. Sánchez Martin[3], K. Koziol[4], B. Klein[5], B. Mannaerts[6]

[1]IVF CUBE, Reproductive Medicine, Prague 6, Czech Republic ;
[2]San Raffaele hospital, Obstetrics and Gynaecology Dept, Milan, Italy ;
[3]Ginemed, Fertility Clinic, Sevilla, Spain ;
[4]Novum Warsaw, Fertility Clinic, Warsaw, Poland ;
[5]Ferring Pharmaceuticals, Global Biometrics, Copenhagen, Denmark ;
[6]Ferring Pharmaceuticals, Reproductive Medicine and Maternal Health, Copenhagen, Denmark

Study question: How does the efficacy and safety of individualised fixed dosing regimen compare to conventional dosing for ovarian stimulation in patients with polycystic ovaries?
Summary answer: The ongoing pregnancy rates were similar but the incidence of early moderate/severe OHSS and/or preventive interventions for OHSS was three times lower following individualised stimulation.
What is known already: Individualised dosing of follitropin delta targets a mean of 11 oocytes (range 8-14 oocytes) and has proven to optimize ovarian response resulting in similar efficacy and improved safety compared to conventional ovarian stimulation. The safety improvement is positively associated with serum AMH levels, which is a biomarker of polycystic ovarian morphology.
Study design, size, duration: Retrospective comparative analysis of a subset of 153 women with polycystic ovaries with AMH > 35 pmol/l. Following ovarian stimulation, women with <25 follicles ≥12 mm were triggered using recombinant hCG and were eligible for fresh blastocyst transfer. Women with ≥25 follicles ≥12 mm were either triggered with GnRHa for subsequent frozen embryo transfer or had their cycle cancelled. Frozen embryo transfers up to one year after the stimulation cycle were included in the analysis.
Participants/materials, setting, methods: Women aged 18-40 years were randomised for ovarian stimulation to either an individualised fixed-dose of follitropin delta based on AMH and body weight (n=78) or to 150 IU follitropin alfa (n=75) which daily dose could be adjusted after 5 days of stimulation. Only single blastocyst transfers were performed with the exception of one double blastocyst transfer in the follitropin alfa group. Continuous endpoints were evaluated using t-tests. Binary endpoints were evaluated using chi-square tests.
Main results and the role of chance: Women with polycystic ovaries had the same characteristics in both treatment groups with an overall age of 31.8 years, body weight of 62.8 kg, and AMH of 49.2 pmol/l. At the end of stimulation the number of follicles (≥12 mm) was 12.1 ±7.0 and 18.3 ±7.0 with increased progesterone (>3.18 nmol/l) in 27% and 67% in women treated with individualised follitropin delta and conventional follitropin alfa, respectively. The overall mean (SD) number of oocytes was 9.3 ±6.7 and 17.9 ±8.7 respectively and there were slightly more women with blastocyst transfer (74.4% vs. 68.0%) and slightly less women with at least one cryopreserved blastocyst (61.5% vs 76.0%) in the follitropin delta group. The ongoing pregnancy rate per started stimulation cycle following fresh blastocyst transfer was 28.2% and 24.0%, respectively. The incidence of all cases of OHSS was three times higher in the follotropin

alfa group i.e. 5.1% vs 16.0% (P=0.025) as well as the combined early moderate/severe OHSS and/or preventive interventions for early OHSS i.e. 7.7% with individualised follitropin delta and 26.7% with conventional follitropin alfa (P=0.001).
Limitations, reasons for caution: This retrospective analysis includes ovulatory women with polycystic ovaries defined as serum AMH > 35 pmol/l. Anovulatory women may have different efficacy and safety profiles and should be studied separately.
Wider implications of the findings: The results demonstrate that individualised follitropin delta treatment provides an improved balance between efficacy and safety in potential high responders, as it normalizes the ovarian response and decreases the incidence of OHSS and preventive interventions of OHSS, with less embryo transfer cancellations.
Trial registration number: NCT01956110

P-593 Effect of AMH, age and history of previous pregnancy on the number of total and mature oocytes obtained in a donation programme

V. Pataia[1], M. Wolska[1], J. Wang[2], N. Macklon[2], K. Ahuja[2]

[1]London Egg Bank, London Egg Bank, London, United Kingdom ;
[2]London Women's Clinic, London Women's Clinic, London, United Kingdom

Study question: In an oocyte donation programme, does Anti-Mullerian hormone (AMH), age and/or history of previous pregnancy predict the number of total and mature oocytes obtained?
Summary answer: AMH correlated to the number of total and mature oocytes obtained from oocyte donors, but age and history of previous pregnancy did not.
What is known already: A relationship between age, AMH and ovarian stimulation response is well established in the subfertile population. However, the value of these markers in healthy oocyte donors remains to be clarified. Additionally, the effect of previous donor pregnancy on oocyte donation outcomes remains largely unexplored.
Study design, size, duration: Retrospective cohort analysis of 223 oocyte donors. Donors were aged 18-35, registered in accordance with the Human Fertilisation and Embryology Authority (HFEA) guidance, and underwent their first donation cycle between January 2018 and May 2019. Donors were divided into 6 age groups: 18-20 (n=28), 21-23 (n=60), 24-26 (n=39), 27-29 (n=45), 30-32 (n=27), 33-35 (n=24). Donors were also divided according to their reproductive history as previously pregnant (n=65) or never pregnant (n=158).
Participants/materials, setting, methods: Kruskal-Wallis test was applied to compare the relationship between study parameters and outcomes between age groups. The respective associations within each age group were investigated using Spearman's rank correlation. Mann-Whitney U test was performed to assess the effect of previous pregnancy on study parameters and outcomes.
Main results and the role of chance: No significant differences were obtained in mean AMH levels, total oocytes or total mature oocytes between donor age groups (p>0.05). Moreover, a history of previous pregnancy had no significant impact on study parameters (p>0.05). AMH was however positively correlated with the number of mature oocytes obtained (p≤0.05), and the strength of association increased with age. Similar findings applied to the total number of oocytes obtained, particularly in donors ≥27 years old.
Limitations, reasons for caution: This is a small study and a higher number of donors included would allow clinical outcomes to be assessed. All donors accepted on the donation programme had a minimum AMH level of 12pmol/L and/or antral follicle count of 12. Thus, our results may not be replicated in the general population.
Wider implications of the findings: In a cohort of healthy oocyte donors under 35 years-old meeting standard ovarian reserve criteria for acceptance, a similar number of total/mature oocytes is likely to be obtained irrespective of age or history of previous pregnancy.
Trial registration number: not applicable

P-594 Prediction of oocyte maturation rate in antagonist flexible IVF protocol using a novel machine learning algorithm

O. Houri[1], A. Wertheimer[1], Y. Gil[2], S. Danieli-Gruber[1], G. Oron[1], O. Sapir[1], S. Yoel[1], A. Ben Haroush[1]

[1]Rabin Medical Center-Beilinson Hospital, IVF and Infertility Unit, Petach Tikva, Israel ;
[2]Tel Aviv University, Electrical engineering, tel aviv, Israel

Study question: Is there a machine learning algorithm that can predict oocyte maturation rate in GnRH antagonist cycles using baseline and treatment characteristics
Summary answer: Machine learning algorithms can predict oocyte maturation rate using simple parameters. We demonstrated an accuracy rate of 75% in predicting high oocyte maturation rate
What is known already: GnRH antagonist cycles may be associated with heterogeneous follicular development that may result in lower oocyte maturation rate. Oocyte maturation is affected by different baseline and treatment parameters, and has a key effect on treatment outcome. As far as we know, a prediction model for oocyte maturation rate made by machine learning and neural network algorithms was not described yet.
Study design, size, duration: A retrospective cohort study of 462 women aged ≤ 38 who underwent their first IVF treatment using a GnRH antagonist protocol in one tertiary hospital. All were treated with a flexible antagonist protocol. Median maturation rate was approximately 80%,. Treatment parameters of cycles with high oocyte maturation rate (≥80%, n=236) were compared to cycles with low oocyte maturation rate (<80%, n=226). Patients that their oocytes were fertilized by insemination only without ICSI were excluded.
Participants/materials, setting, methods: We used XGBoost algorithm that fits the training data using decision trees, and can also rate the factors according to their influence on the prediction. We assigned a weight to each class (positive/negative), to overcome potential biases due to the unbalanced nature of data. For the machine learning training phase, 80% of the cohort was randomly selected. We have then used the rest of the samples as a test-set, to evaluate our model's accuracy.
Main results and the role of chance: The following data was retrieved from medical records: patient's age, gravity, parity, BMI, Infertility cause and duration, gonadotropins doses number of oocyte retrieved, treatment parameters on the day of GnRH antagonist initiation including estradiol and progesterone levels, maximal follicle diameter and number of follicles, GnRH antagonist treatment duration, and treatment parameters on trigger day including number of follicles, estradiol and progesterone levels.
The test-set samples' parameters were fed into the trained model and the predicted outcome was compared to the actual outcome. On the randomly picked samples used to evaluate our model, we demonstrated an accuracy rate of 75% in predicting oocyte maturation rate in GnRH antagonist cycles. The most predictive parameters arranged by descending importance order were: estradiol level on trigger day, estradiol level on antagonist initiation day, average gonadotropins units per day, progesterone level on trigger day, patients' weight, number of oocytes retrieved, patients' height, number of follicles on GnRH antagonist initiation day, patients' age and infertility duration.
Limitations, reasons for caution: Retrospective design and lack of information regarding follicle synchronization.
Wider implications of the findings: A state-of-the-art machine learning algorithm presented promising ability to predict oocyte maturation rate using simple parameters**.** We now plan to expand the cohort and evaluate the model in larger numbers
Trial registration number: not applicable

P-595 Progestin Primed Ovarian Stimulation is an effective oral alternative for Antagonist Protocol in patients undergoing assisted reproductive techniques: a retrospective study.

J.P. Caetano[1], L. Calazans[1], L. Amorim[1], E. Xavier[1], A.L. Campos[2], B. Coimbra[3], R. Marinho[1]

[1]Pro-Criar Medicina Reprodutiva, Medical, Belo Horizonte, Brazil ;
[2]Pro-Criar Medicina Reprodutiva, Embriology, Belo Horizonte, Brazil ;
[3]Hospital das Clíncias - Universidade Federal de Minas Gerais, Medical Residency, Belo Horizonte, Brazil

Study question: Are Clinical Pregnancy Rates in Progestin Primed Ovarian Stimulation noninferior to Antagonist Protocol in patients undergoing assisted reproductive techniques (ART)?
Summary answer: Our results showed noninferiority of Clinical Pregnancy Rates in Progestin Primed Ovarian Stimulation compared to Antagonist Protocol with blastocyst transfer and freeze-all strategy.

What is known already: The blockade exerted by progestin in ovulation induction involves blocking the hypothalamic-pituitary-ovary axis, changing the frequency and amplitude of GnRH pulses (La Marca et al., 2019). Early LH peak suppression occurs despite high oestradiol concentration (Kuang et al., 2015). In the current stage of ART development, in which embryo freezing is an increasingly common practice and provides good results, new options for controlling the LH peak can be considered (Kuang et al., 2015). The use of progestins has aroused interest in this regard, and the possible negative effect on the endometrium is no longer a concern (Yu et al., 2018).

Study design, size, duration: A retrospective study included all ovarian punctures performed at Pró-Criar Medicina Reprodutiva, Belo Horizonte, Minas Gerais, Brazil, between May 2018 and May 2019 using a GnRH antagonist analogue or oral progestins to block the LH peak in IVF/intra-cytoplasmic sperm injection (ICSI) cycles for infertility treatment. A total of 266 IVF/ICSI cycles performed were analysed and 222 cycles (83.5%) were included in the study, 112 in the Progestin group and 110 in the Antagonist Group.

Participants/materials, setting, methods: Exclusion criteria were age older than 42 years, fresh embryo transfer, transfer at the cleavage stage (D2/D3), preimplantation genetic screening, cryopreservation of oocytes, shared donation and cycles without embryo transfer at the time of analysis. The primary outcome evaluated was the clinical pregnancy rate at the first embryo transfer. The secondary outcomes were the mean MII oocytes retrieved, fertilization rate, blastocyst formation rate, mean duration of stimulation and mean dose of gonadotropins.

Main results and the role of chance: The primary outcome of our study, Clinical Pregnancy Rate at the first embryo (Blastocyst) transfer, was 58.4% in the progestin group and 54.9% in the antagonist group (P = 0,735), a finding consistent with most studies published to date using different progestins. The mean number of retrieved oocytes was 11 in the antagonist group and 9 oocytes in the progestin group (P = 0.009). The fertilization rate was 80% for both groups (P=0.935). The rate of blastocyst formation per cycle was 50% in the antagonist group and 55.6% in the progestin group (P = 0.106). Stimulation lasted a mean of 10 days in the two analysed groups and did not vary with patient age in either group. The gonadotropin dose used was higher in the antagonist group (2025 IU) than in the progestin group (1950 IU) (P = 0.057). In addition, the blockade was effective: there was only one case of spontaneous ovulation, which corresponded to less than 1% of the cycles, an incidence compatible with the 0.34 to 8% risk described in the literature for failure to control the LH peak in antagonist protocol cycles.

Limitations, reasons for caution: This was not a randomized controlled trial, and the choice of protocol depended on the attending physician, yet statistical analysis showed that the studied populations were similar, with similar mean age, BMI, duration of infertility and distribution of causes of infertility between the groups.

Wider implications of the findings: The use of progestins to block the LH peak has the advantages of ease of oral administration and lower cost compared to GnRH antagonists. It allows flexible ovulation monitoring, therefore more comfortable for the patient. The freeze-all strategy allows the embryos to be transferred into a more physiological uterine environment.

Trial registration number: not applicable

P-596 Salivary progesterone - a new diagnostic tool for luteal phase monitoring in Assisted Reproductive Technology (ART)

B. Alsbjerg[1], D. Sakkas[2], B. French[2], H.O. Elbaek[1], B.B. Povlsen[1], R.J. Laursen[1], M. Alper[2], P. Humaidan[1]

[1]Regional Hospital Viborg - Skive Sundhedshus, The Fertility Clinic- Skive Regional Hospital, Skive, Denmark ;
[2]Boston IVF, Boston IVF, Waltham MA, U.S.A.

Study question: Can salivary progesterone (P4) measurement be used as an alternative and more patient-friendly diagnostic tool for luteal phase monitoring during ART?

Summary answer: Luteal phase deficiency was detected by constant low salivary P4 in IVF.

What is known already: The reproductive outcome of ART depends on P4 levels during the luteal phase. Traditionally, P4 levels are measured in serum, which is cumbersome for patients due to constant venopunctures. Furthermore, when P4 level is measured in serum it is total P4; meaning, both the part tightly bound to proteins and the free bioactive portion. Free P4 is the active part accounting for only 2 % of total serum P4. Importantly, salivary P4 contains free progesterone, only.

Moreover, salivary P4 fluctuates during the natural cycle, whether this is the case in different ART cycles is unknown until now.

Study design, size, duration: An observational study including 20 patients. Ten IVF patients treated with GnRH-antagonist protocol and 10 patients undergoing Hormone Replacement Therapy Frozen Embryo Transfer (HRT-FET) were included from October 2018 to April 2019. Salivary P4 was measured over a 12-hour period from 7 a.m. to 7 p.m. on blastocyst transfer day and in HRT-FET patients on 6th day of vaginal progesterone treatment. Furthermore, serum P4 was measured the same day between 11 a.m. and 1 p.m.

Participants/materials, setting, methods: Patients were included from a Danish public fertility clinic. Saliva samples were frozen upon collection and P4 levels were measured using enzyme immunoassay kits (Salimetrics™) at a separate clinic. Immunoassay measurements were conducted precisely according to assay specifications. Reactions were conducted in hormonespecific antibody-coated microtitre plates. Samples and controls were incubated simultaneously with competitive horseradish-peroxidase-bound P4. Competitive reactions were detected using the peroxidase substrate tetramethylbenzidine (TMB) via optical density readings at 450 nm.

Main results and the role of chance: The 12-hour salivary P4 profiles in IVF patients showed substantial fluctuations on the blastocyst transfer day; however, no time related pattern was discovered. The percentage variation in IVF cycles ranged from 49 to 351%, with levels ranging from 202 pg/ml to 23953 pg/ml. One IVF patient had a mean salivary P4 level of 355 ±97 pg/ml which correlated to a low mean serum P4 level of 8.5 ng/ml. The corpus luteum (CL) deficiency was found despite the fact that the patient had 19 follicles and 12 oocytes retrieved; this patient did not conceive.

In HRT-FET cycles, similar fluctuations of salivary P4 levels were seen despite the absence of a CL and the fact that P4 derived from vaginal P4 application, only. The percentage variation ranged from 99 to 395 %, and salivary P4 levels from 8 to 21044 pg/ml. In contrast, the percentage variation in serum P4 ranged from 11 to 47 %, only.

In IVF as well as in HRT-FET cycles the ratio of salivary P4 to serum P4 varied significantly between patients. This individual variation was also previously described during natural cycle.

Limitations, reasons for caution: This study included a limited number of patients, and seven out of 160 salivary P4 levels were very high. Until now it is unclear whether these high measurements are caused by contamination of the saliva samples, due to non-compliance with collection instructions, or a true high salivary P4.

Wider implications of the findings: The analysis of salivary P4 may be a new patient friendly alternative to serum sampling for luteal phase monitoring in ART. However, future studies should explore optimal cut-off levels of salivary P4 levels during luteal phase in ART. In the long term a home test could be developed.

Trial registration number: ClinicalTrial.gov no.: NCT03725904

P-597 Cumulative live birth rate with recombinant follicle stimulating hormone biosimilar: a multicenter study with over than 7,000 cycles.

Study question: In routine clinical practice, is the cumulative live birth rate (cLBR) followed by IVF/ICSI using Bemfola®, a biosimilar of follitropin alfa, comparable to the originator?
Summary answer: This real-world data confirms the clinical effectiveness of Bemfola® for controlled ovarian stimulation (COS) for IVF/ICSI.
What is known already: Although randomised controlled phase 3 clinical trials on selected populations demonstrate the efficacy of new drugs to allow approval for routine use, once drugs have been introduced into clinical practice, real world data (RWD) may assess their actual effectiveness. As in the case of Bemfola®, a follitropin alfa biosimilar approved on the basis or its proven efficacy related to the number of oocytes retrieved, RWD may assess additional parameters of clinical interest such as live birth rates following IVF/ICSI. Indeed, RWD reflect the actual effectiveness in an unselected infertile population across multiple indications, protocols and clinical strategies.
Study design, size, duration: National, multicenter, retrospective, cohort study conducted in 17 public and private ART centers. Data from all cycles of women who underwent COS with a follitropin alfa, between January 2016 and February 2017 including follow-up period up to December 2017 were collected. The main assessment criterion was cumulative live birth rate (cLBR) including fresh and frozen-thawed embryo transfers per initiated cycle.
Participants/materials, setting, methods: Data from 9,162 COS cycles were extracted. The present descriptive analysis includes 7,448 cycles for which COS was performed with a follitropin alfa without any association with other gonadotropin. From these, 2,478 cycles were performed with Bemfola® and 4,970 with another follitropin alfa (90% corresponding to the originator Gonal-f®). cLBR in both groups are displayed with their 95% confidence interval (95%CI).
Main results and the role of chance: Mean female age were 34.1±4.7 and 33.9±4.7 years and mean BMI were 23.9±4.7 and 23.8±4.6 kg/m² in the Bemfola® and other follitropin alfa groups, respectively. The medians of AMH serum levels were 2.3 ng/mL (interquartile interval:1.3-3.8) and 2.6 ng/mL (interquartile interval: 1.4-4.7) and the proportion of women presenting an AMH serum level > 5.2 ng/mL were 14.8% and 21.5%, in the Bemfola® and other follitropin alfa groups. The most prescribed starting dose of follitropin alfa were between 150-225 IU in both groups. Oocyte retrieval resulted in 7.1±5.7 and 7.9±5.5 mature oocytes in the Bemfola® and in the other follitropin alfa groups, respectively. cLBR per cycle were 20.0% (95% CI: 18.4%-21.5%) in the Bemfola® group and 20.8% (95% CI: 19.7%-21.9%) in the other follitropin alfa group. cLBR in the COS cycles that were followed by at least one embryo transfer during the follow-up period were 21.2% (95% CI:19.5-22.8) in the Bemfola® group and 21.6% (95% CI:20.5-22.8) in the other follitropin alfa group.
Limitations, reasons for caution: Although systematic biases cannot be excluded, detailed analyses revealed that the apparent biases seem to favor the originator follitropin alpha, suggesting that Bemfola® had been preferentially prescribed to poorer prognosis patients. The comparator follitropin alpha group included another follitropin alpha biosimilar, but too few cases to impact results (10%).
Wider implications of the findings: This is the largest multicentric cohort describing cLBR with the use of a follitropin alfa biosimilar in a non-selected population. This real-world evidence demonstrates that the use of Bemfola® is an effective option for COS, with clinical results comparable with other follitropin alfa.
Trial registration number: NA

P-598 The Effects of Lipid Metabolism and Obesity on the Number of Retrieved Oocytes in Polycystic Ovary Syndrome Undergoing Natural Cycles

T. Liu[1], J. Yan[1]

[1]Beijing University Third Hospital, Center for Reproductive Medicine, Beijing, China

Study question: To assess the effects of lipid metabolism and body mass index (BMI) on the number of retrieved oocytes (no.RO) in polycystic ovary syndrome (PCOS) undergoing natural cycles.
Summary answer: The increase of serum low density lipoprotein cholesterol (LDL-C) can improve anti-Mullerian hormone (AMH) level, antral follicle counts (AFC) and no.RO when BMI is normal.
What is known already: The no.RO can be affected by various factors in controlled ovarian hyperstimulation (COH) cycles, in which BMI and lipid metabolism are very important to predict ovarian response.
Study design, size, duration: This is a retrospective cohort study. None interventions were applied to the patients. The main outcome measures are as followed: Lipid metabolic index, including total cholesterol (TCHO), triglycerides (TG), high density lipoprotein cholesterol (HDL-C) and LDL-C. Basal sex hormone, including follicle stimulation hormone (FSH), luteinizing hormone (LH), progesterone(P), estradiol (E2) and AMH. IVF index, including AFC, no.RO, maturation rate (MR), fertilization rate (FR) and embryo formation rate (EFR).
Participants/materials, setting, methods: The participants were PCOS patients with clomiphene resistance undergoing natural cycles from January 1, 2015 to November 30, 2019. All the data were from clinical records.
Main results and the role of chance: 219 patients were eventually included in this study. Scatter plots and fitting curves showed that TCHO and LDL-C had a tendency to increase first and then decrease with no.RO, while HDL-C had a tendency to decrease first and then increase with no.RO. The correlation between BMI, TG and no. RO was not statistically significant. Cutoff values of TCHO (5.89mmol/L), HDL-C (1.71mmol/L) and LDL-C (4.09mmol/L) were identified through fitting curves. Among four BMI groups (low: <18.5Kg/m2, normal: 18.5~24Kg/m2, overweight: 24~28Kg/m2 and obesity: ≥28Kg/m2), only AMH and four lipid metabolic index showed statistically significant differences, while all IVF index and other basal sex hormone did not. Next, cutoff values were used separately to divide each BMI group into two subgroups. The results showed that significant differences were found in AMH, AFC and no.RO between LDL-C subgroups (BMI: normal), P and AFC between TCHO subgroups (BMI: normal), E2 between LDL-C subgroups (BMI: overweight) and P between LDL-C subgroups (BMI: obesity). No statistically significant differences in MR, FR and EFR were observed in all subgroups comparisons.
Limitations, reasons for caution: The sample size of subgroups higher than TCHO, HDL-C and LDL-C cutoff values is still limited, and this part of the sample size should be further expanded.
Wider implications of the findings: LDL-C may be a better predictor of no.RO than BMI in natural cycles.
Trial registration number: ChiCTR-ONC-17011861

P-599 Replacing antagonist by clomiphene citrate to prevent premature ovulation in IVF-ET: is it possible?

S. Ekmekjian[2], H. Maroun[1], C. Boyadjian[1], T. Tadros[1], I. Aboujaoude[1]

[1]Aboujaoude Hospital-, Center for Reproductive Medicine-, jaleldib, Lebanon ; [2]Lebanese University faculty of sciences II, Reproduction biology lab, Fanar, Lebanon

Study question: Do 150 mg of clomiphene citrate (CC) capable of replacing the classical antagonists in controlled ovarian stimulation (COS) to prevent premature ovulation (PO)?
Summary answer: Our data indicated that CC is as efficient as antagonist in IVF-ET.
What is known already: Since the introduction of antagonists in the 90th, the antagonist protocol is becoming the most used protocol in COS for IVF-ET patients. However, due to their relatively high cost, infertility specialists in developing countries try to find a more affordable molecule to avoid premature the ovulation during COS. New larges studies showed that CC could be used to prevent PO in mild stimulation using 50 mg daily. No studies to our knowledge used CC in standard IVF-ET protocols. Therefore, we decided to do a pilot study in order to replace antagonists with CC 150 mg per day until triggering.
Study design, size, duration: We studied 161 patients who entered our IVF-ET program. All patients started COS on day 3 of the menstrual cycle using HMG or recombinant FSH.
Participants/materials, setting, methods: Patients were sorted as follows: group 1 Ganirelix (n=73) underwent the classic antagonist protocol where Ganirelix was introduced at day 6 of the COS; group 2: CC (n=88) where we replaced the antagonist by CC 150 mg. Single or double triggering for final oocyte maturation was performed using HCG 5000 IU and/or Decapeptyl 0.3 mg when at least 3 follicles reached 17mm in diameter. Oocyte retrieval was conducted 35 to 37 hours after triggering.
Main results and the role of chance: As shown in the Table1, whereas patients and COS characteristics were similar in both groups, we observed no statistical differences in terms of number of oocytes retrieved, empty follicles cases and pregnancy rates.

		ANT CC(n=73)	ANT Org(n=88)	P
Ages (years)		28.1 ± 4.71	30.3 ± 4.39 (19-35)	0.0032*
Duration of infertility (years)		7.3 ± 4.034 (0.5-19)	6.8 ± 4.348	NS
IVF-ET Indications	• **Male (%)**	68.5	65.5	NS
	• **IUI failure (%)**	12	13.5	NS
	• **Tubal (%)**	11.5	11	NS
	• **Endometriosis (%)**	8	9	NS
Duration of COS (days)		8.4 ± 1.44	8.6 ± 1.89	NS
E2 day of trigger (pg/ml)		2825.5 ± 2065	1870.4 ± 1414.60	0.01
Progesterone day of trigger >1.5 ng/ml (%)		21.1	16.7	NS
Total dose of Gonadotropins (IU)		2108.6 ± 988.15	1954.5 ± 737.72	NS
No. of total oocytes		9.8	11.3	NS
MII oocytes (%)		69.3	77	NS
Empty follicles (%)		4.1	2.3	NS
No. of embryos transferred		2.7	2.5	NS
Clinical pregnancy rate / transfer (%)		38.8	24.7	NS
Ongoing pregnancy / transfer (%)		31.3	23.5	NS
Miscarriage rate (%)		19.2	5	NS

38.831.319.2

Limitations, reasons for caution: The present study could not address the exact mechanism of action of the CC on the hypothalamic-pituitary axis to prevent PO neither discriminating possible outcome differences using lower dose of CC due to limited sample size. Moreover, potential side effects of CC where not taken into consideration in this study.

Wider implications of the findings: Our data indicate that clomiphene seems to be as efficient as the antagonists, cheaper, and easier to use in order to prevent premature ovulation in IVF-ET. Further randomized controlled studies, including larger populations, are needed to confirm and expand present findings**.**

Trial registration number: not applicable

P-600 Transdermal testosterone vs. oral dehydroepiandrosterone (DHEA) pre-treatment in improving IVF outcomes in diminished ovarian reserve patients (POSEIDON group 3 and 4): a randomised controlled trial

N. Sharma[1], K.D. Nayar[1], S. Gupta[2], M. Singh[1], R. Bhattacharya[1], G. Kant[1], R. Gahlot[1], K.D. Nayar[1]

[1]Akanksha IVF Centre- Mata Chanan Devi Hospital, Reproductive Medicine, New Delhi, India ;

[2]Akanksha IVF Centre- Mata Chanan Devi Hospital, Reproductive Medicine, New Delhi, India

Study question: To compare the efficacy of transdermal testosterone with oral dehydroepiandrosterone in improving IVF outcomes using GnRH antagonist protocol in POSEIDON group 3 and 4 patients.

Summary answer: Patients receiving pre-treatment with testosterone gel had higher mean number of oocytes retrieved and grade A embryos as compared to the patients receiving oral DHEA

What is known already: Diminished ovarian reserve (DOR) is associated with suboptimal ovarian response, higher cycle cancellation rate and lower clinical pregnancy rate following IVF cycles. Various treatment regimens have been devised for management of such patients and use of adjuvants in the form of oral or transdermal androgen is one of them. Androgens improves follicular response to gonadotropin stimulation as well as increase FSH receptor expression in granulosa cells, in turn leading to better oocyte yield and pregnancy rate. Aim was to compare the effect of transdermal testosterone gel with oral DHEA on the ART outcome in DOR patients(POSEIDON Group 3 and 4)

Study design, size, duration: A prospective, randomised controlled trial was carried out from 1st January 2019 to 31st October 2019 at a tertiary infertility centre in India. 50 patients fulfilling the criteria of Group 3 and Group 4 of POSEIDON classification were included in the study. Patients with endocrine disorders (thyroid, prolactin), endometrioma, history of surgery on the ovaries, sensitivity to testosterone gel, male factor infertility and deranged liver and renal function tests were excluded.

Participants/materials, setting, methods: Enrolled patients were randomised into two groups of 25 patients each, one group was pretreated (TTG group) with transdermal testosterone gel ,12.5 mg/day from day 6th of previous cycle to day 2nd of stimulation cycle while patients in other group took DHEA tablet,75 mg/day for a total duration of three months (DHEA group) before stimulation with GnRH antagonist fixed protocol followed by fresh Day 3 transfer

Main results and the role of chance: The baseline characteristics of the two groups were comparable. The primary outcome measures were the number of oocytes retrieved and number of grade A embryos formed (according to Istanbul consensus). The secondary outcome measures were implantation rate, clinical pregnancy rate, miscarriage rate and ongoing pregnancy rate. The mean number of oocytes retrieved in TTG group was 5±1.4 which was significantly higher than DHEA group-3.3±1.7, ($p<0.001$). The mean number of Grade A embryos were also significantly higher (4.28±0.88 vs 2.85±0.63, $p<0.001$) in TTG group. The TTG group had higher implantation rate (28% vs 20%, $p= 0.49$), clinical pregnancy rate (32% vs 20%, $p = 0.41$), ongoing pregnancy rate (32% vs 16 %, $p= 0.38$) and lower miscarriage rate (0% vs 20%, $p=0.38$), however, these differences were not statistically significant.

Limitations, reasons for caution: The study was done at a single centre with small sample size, replication with more subjects and in different centers is needed. Also, cost effectiveness of either drug was not assessed.

Wider implications of the findings: Pre-treatment with testosterone gel in DOR patients improves ovarian response to stimulation and results in higher number of oocytes retrieved and good quality embryos resulting in improved clinical pregnancy rates. Transdermal testosterone is advantageous because of better bioavailability, easy application, patient friendly and less adverse effects.

Trial registration number: MCDH/2019/28

P-601 The role of midkine, a heparin-binding growth factor, in human follicle development and oocyte maturation

S.E. Pors[1], S.G. Kristensen[1], D. Nikiforov[1], L. La Cour Poulsen[2], A. Sanchez[3], I. Pla Parda[3], C. Yding Andersen[1]

[1]Rigshospitalet, Laboratory of Reproductive Biology, Copenhagen, Denmark ;
[2]Zealand University Hospital, Zealand Fertility Clinic-, Køge, Denmark ;
[3]Lund University, Department of Translational Medicine, Lund, Sweden

Study question: Does midkine, a heparin-binding growth factor found in follicle fluid, affect human follicle development and oocyte maturation?
Summary answer: Midkine affect human follicle development by augmenting oocyte maturation *in vitro* and its concentration increases in intrafollicular fluid during the mid-cycle surge of gonadotropins.
What is known already: In vitro maturation (IVM) of immature oocytes without exogenous FSH stimulation has attracted much interest in recent years and immature oocytes from small antral follicles (SAF) is a new way of augmenting the fertility potential of women undergoing fertility treatment by having ovarian tissue cryopreserved. However, regulation of human oocyte maturation is highly complex and dynamic and far from fully elucidated. The growth factor midkine, acting via the NOTCH signalling pathway, has recently been identified in human follicular fluid (FF) and may represent an important factor for follicle and oocyte development.
Study design, size, duration: Follicle fluid (n=50) from SAF, immature oocytes (n=891) and tissue were obtained from ovaries from women undergoing ovarian tissue cryopreservation for fertility preservation. Small antral follicles with different diameters were isolated from surplus medulla tissue (n=183). In addition, FF from preovulatory follicles were aspirated from women undergoing fertility treatment at different time points after final follicle maturation was induced (n=25). All women had given written consent for use of the material for research purposes.
Participants/materials, setting, methods: Concentration of midkine in FF was analysed by proteomics and ELISA. Microarray data on gene expression from SAF were obtained and analysed. Immunohistochemistry using antibodies against midkine and Notch2 were performed. Immature oocytes, collected after ovarian tissue cryopreservation, were randomly allocated for IVM with or without midkine in the media (1 ug/ml). From the same patient, two FF containing immature oocytes from SAF were obtained. FF levels of midkine were associated to the IVM outcome.
Main results and the role of chance: FF samples from preovulatory follicles were collected at five time points after ovulation trigger: 0, 12, 17, 32 and 36 h, respectively. Expression of midkine protein was significantly higher at 0,12 and 17 h compared to 32 and 36 after the ovulation trigger. When measuring the midkine content with ELISA the concentration of midkine was high at all timepoints measured after administration of the ovulation trigger and only decreased significantly at 32 h. In SAF midkine was also present in concentration ranging from 190-2300 ng/ml. The highest levels of gene expression of midkine was present in SAF (<9 mm) compared to larger follicles (>9 mm). Preliminary results of the immunohistochemical investigations indicate that midkine and its potential receptor, NOTCH2, both are present in granulosa and cumulus. In addition, midkine significantly increased the maturation rate of immature oocytes (without midkine: 27%; with midkine: 34%, p=0.04). The concentration of midkine was compared using ELISA between FF from SAF from the same patient. Follicles that contained an oocyte that matured contained higher concentration of midkine as compared to the follicle in which the oocyte failed to mature (n=16 follicles from 8 patients).
Limitations, reasons for caution: The dynamics in the preovulatory follicles were investigated in FF from follicles obtained in stimulated cycles and the use of ovulation trigger may have affected results.
Wider implications of the findings: These results indicate that midkine is a new growth factor, important for human follicular development both during ovulation and in folliculogenesis. Further investigations on the processes taking place in the ovary, will increase the possibility for optimizing and developing future treatments especially for women with a low ovarian reserve.
Trial registration number: Not applicable

P-602 Comparison of letrozole versus clomiphene citrate (CC) for ovulation induction in infertile women with polycystic ovary syndrome (PCOS) in Indian population: A prospective clinical trial

E. Gupta[1], K.D. Nayar[1], S. Gupta[1], M. Singh[1], R. Bhattacharya[1], R. Gahlot[1], G. Kant[1], K.D. Nayar[1]

[1]Akanksha IVF Centre- Mata Chanan Devi Hospital, Reproductive Medicine, New Delhi, India

Study question: To compare the efficacy of letrozole and clomiphene citrate for ovulation induction in infertile women with PCOS for IUI cycles in Indian population
Summary answer: Letrozole favors monofollicular development and has a better endometrial response when compared to CC though no difference in the clinical pregnancy and multiple pregnancy rate
What is known already: Clomiphene citrate is used for ovulation induction in PCOS. Clomiphene resistance occurs in 15-20% of the patients. PCOS women in India have a higher prevalence of insulin resistance(~75%) and are more likely to have CC resistance. CC also has a negative effect on the cervical mucus and endometrium. Treatment with CC is thus associated with a discrepancy between ovulation and conception rates. Letrozole, an aromatase inhibitor used for ovulation induction has no adverse effects on the endometrium and the cervical mucus. It can thus act as an effective alternative to CC in Indian women with PCOS
Study design, size, duration: A prospective clinical trial on 120 infertile patients with PCOS diagnosed according to Rotterdam criteria was carried out at a tertiary care infertility centre in India from January 2019 – October 2019.
Participants/materials, setting, methods: One hundred and twenty women with PCOS were divided into two groups-61patients with Letrozole, 2.5 mg/day and 59 patients with clomiphene citrate 100 mg/day from day 3-7 of the menstrual cycle. Follicular monitoring was done and 10,000 IU of HCG was administered when the largest follicle was ≥18 mm. Intra-uterine insemination was done 36-40 hours after HCG administration. 400mg micronized progesterone was given intra-vaginally for 15 days as luteal phase support.
Main results and the role of chance: Baseline characteristics in both letrozole and CC group were comparable. Mean number of follicles ≥ 18mm on the day of hCG administration was 1.13±0.53 in letrozole group and 2.6±1.15 in the CC group (p <0.0001). Mean endometrial thickness on the day of hCG administration was 8.21±0.86 in letrozole group and 7.35±0.99 in CC group (p <0.0001). Ovulation rate in letrozole group was 77.04% and in CC group was 59.32%, which was not statistically significant (p= 0.05). Clinical pregnancy rate was 14.75%(9/61) with letrozole group and 13.56%(8/59)with CC group, however this difference was not statistically significant (p>0.05). Mutiple pregnancy rate was higher with CC group (2.5% (2/8)vs. 1.11%(1/9) , p=0.57) but not statistically significant
Limitations, reasons for caution: The study was done at a single centre with small sample size. Replication with more subjects and multiple centres is needed
Wider implications of the findings: Letrozole leads to more monofollicular development and better endometrial response compared to CC. Hyperinsulinemia, which is frequently associated with PCOS, is one of the causes for CC resistance. The prevalence of insulin resistance in PCOS is approximately 75%.Thus, letrozole has an important role as first line treatment for PCOS patients.
Trial registration number: MCDH/2019/45

P-603 Drug free In Vitro Activation for woman with very advanced maternal age

L. Valkova[1], N. Magunska[2], B. Petkova[3], T. Milachich[3], K. Kawamura[4], A. Shterev[2]

[1]SAGBAL Dr Shterev EOOD, IVF Unit, Sofia, Bulgaria ;
[2]SAGBAL Dr Shterev EOOD, Department of Obstetrics and Gynecology- IVF Unit, Sofia, Bulgaria ;
[3]SAGBAL Dr Shterev EOOD, IVF Unit, Sofia, Bulgaria ;
[4]Advanced Reproductive Medicine Research Center- International University of Health and Welfare School of Medicine, Department of Obstetrics and Gynecology, Narita, Japan

Study question: What is the effect of drug-free In Vitro Activation (IVA) for woman with very advanced maternal age (vAMA)?
Summary answer: Drug free IVA had positive effect through decreasing the levels of FSH, LH, E2. Good quality oocytes were retrieved and top quality embryos were obtained.
What is known already: There are studies demonstrating good results in patients with premature ovarian insufficiency (POI) using drug- free IVA. The mechanism involves suppression of Hippo signaling pathway leading to secondary follicle growth. Women with diminished ovarian reserve (DOR) as well as patients with AMA and vAMA have very low number of follicles and oocytes

even after applying of ovarian hyperstimulation. Their chance for pregnancy and live birth is minimal but number of patients with AMA or vAMA who wish to have children with autologous oocytes increases constantly.
Study design, size, duration: Case report. From March to November 2019, after refusing the use of donor oocytes to patients with vAMA were proposed application of drug-free IVA. Detailed information for risks and chances were provided to the women and one woman signed necessary informed consents. The procedure was performed after permission of the Ethics Research Committee of the hospital.
Participants/materials, setting, methods: To a 48 years-old woman with primary infertility drug-free IVA was performed by taking pieces from both ovaries under laparoscopic surgery. The cortices were dissected into small cubes (2x2x2 mm) that were auto-transplanted at the same surgery. The ovarian pieces were placed into peritoneal pockets of the mesosalpinx and of the remaining ovaries followed by closure using sutures. Ovarian stimulation and fertilization with donor sperm of the retrieved oocytes were performed after manipulation.
Main results and the role of chance: The hormone levels before and after drug-free IVA were compared. They were: FSH – 50.8 vs 8.3 IU/L, LH - 38.1 vs 6.1 IU/L and E2 – 79.4 vs 56.9 pg/ml, respectively. Before manipulation the hormonal ovarian stimulation was impossible because of high levels of gonadotropins. After surgery, we succeeded to make hormonal stimulation three times. In each cycle we achieved: follicle growth, high quality oocytes and embryos using donor sperm. After these three stimulations, we obtained six oocytes and five embryos. Embryo transfer (ET) was performed two times: the first one on day 2 with two embryos and second one on day 3 with one embryo. All embryos were with top quality for the corresponding day, but pregnancy was not achieved. One of possible reasons for the negative result could be obstruction of the implantation by 3 myomas in the uterus of the patient. Laparoscopy for elimination of the myomas is forthcoming. Until the appropriate moment for the ET we decided to generate embryos in different stimulation cycles with subsequent cryopreservation by vitrification. We have already vitrified on day 3 two top quality embryos from the third stimulation.
Limitations, reasons for caution: The procedure has to be finished and is important if the pregnancy and live birth will be achieved. In contrast to positive effect of drug-free IVA on improvement of oocyte quality, it cannot fix the issue of aneuploidy. Additional genetic tests before implantation or after pregnancy could be performed.
Wider implications of the findings: There are data about children born after drug-free IVA in young patients. If the results are good also for patient with AMA and vAMA this could be approved as useful method for this hard for treatment steadily growing groups of patients.
Trial registration number: NA

P-604 Does the Freeze-all strategy improves the cumulative live birth rate and the time to become pregnant in IVF cycles?

A. Delvigne[1], J. Vandromme[2], A. Larbuisson[1], S. Johnson[1]

[1]CHC Montlégia, ART center, Liège, Belgium ;
[2]CHU Saint-Pierre, Gynecology, Brussels, Belgium

Study question: Does the Freeze-all strategy improves the cumulative live birth rate in IVF cycles?
Summary answer: The CLBR is significantly lower in the FA group. Nevertheless, the CLBR in the FA group remains superior to that observed in previous studies.
What is known already: Elective freezing of all good quality embryos and transfer in subsequent cycles, named as the freeze-all strategy (FAS) is widely used for ovarian hyperstimulation syndrome (OHSS) prevention. The benefits of the FAS on live birth rates among high responders have been shown by many studies. Similarly, the benefits of frozen embryo transfer (FRET) compared to fresh embryo transfer (FET) has been demonstrated to prevent preterm birth and small for gestational age. Consequently, why should we limit the FAS to high responders rather than extend it to all?
Study design, size, duration: A retrospective and monocentric study was conducted between January 2008 and January 2018 comparing the cumulative live birth rates (CLBR) of patients having undergone FAS to those using FET and having at least one frozen embryo during the same period.
Participants/materials, setting, methods: Logistic regression (LR) was used to identify confounding variables. Analysis were made for the entire cohort and also for different subgroups according to the BELRAP (Belgian Register for Assisted Procreation) criteria and to confounding factors selected by the LR.
Main results and the role of chance: 2216 patients were studied in all. 233 patients constituted the freeze all (FA) group and 1983 the control (C) group (population 1). Patients selected according to BELRAP criteria (less than 36 years old and first IVF trial) were divided as follows: 124 patients in the FA group with 1241 in the C group (population 2). For these two groups, the CLBR was respectively 50.2% vs 58.1% P=0.021 for population 1 and 53.2% vs 63.3% P=0.023 for population 2. LR revealed the following confounding variables: age, rank of the attempt, tobacco, number of oocytes retrieved, number of embryos obtained, and the date of oocytes retrieval before 2011 and after 2011. Once these confounding variables were excluded, the FA and the C group were restricted to respectively 109 and 770 patients. The CLBR stays in favour of the control group: 70.1% vs 55.9% P=0.03. The time to become pregnant is equally in favour of the C group with a median of 5 days against 61 days for the FA group.
Limitations, reasons for caution: Its a retrospective study carried over a long Long period of time with changes in the freezing techniques and in our transfer politics during the study. We also have an heterogeneous FA group with mostly hy- responders (75%).
Wider implications of the findings: The CLBR is significantly lower in the FA group compared to the control group (excellent rate of 70.1%) witch is the contrary of what is found in recent studies.
But CLBR of 55.9% is still a very good rate for the FA population as its the best found in the littérature.
Trial registration number: not appilcable

P-605 Letrozole did not improve endometrium receptivity in non-ovulation PCOS women, one RCT study for endometrium preparation before thawed embryo transfer in non-ovulation PCOS women.

C. Wang[1], Q. Mai[1], C. Zhou[1]

[1]the first affiliated hospital of Sun Yat-sen University, repeoductive medical center, Guangzhou, China

Study question: Does letrozole can improve the endometrium receptivity in women with PCOS who underwent thawed embryo transfer (TET)?
Summary answer: Letrozole did not improve endometrium receptivity and clinical pregnancy rate in non-ovulation PCOS women.
What is known already: Polycystic Ovarian Syndrome (PCOS) is the most common endocrine disorder in infertile women. For non-ovulation PCOS women, hormone replace treatments (HRT) are always used for the endometrium preparation before thawed embryo transfer. In international PCOS guideline, Letrozole has been advised as the first line controlled ovarian stimulation medicine. Letrozole is not only be used as COH medicine but also could be used as endometrium reparation before thawed embryo transfer in non-ovulation PCOS women. However, there is no evidence show the effect of letrozole on endometrium receptivity and clinical pregnancy rate in women with PCOS who undergoing TET.
Study design, size, duration: One RCT study (ChiCTR1800014746) involved PCOS women undergoing TET at Reproductive Medicine Center of The First Affiliated Hospital of Sun Yat-sen University from 2017 to 2019. The sample size was calculated based on previous pregnancy rate of letrozole COH and HRT endometrium preparation in PCOS women underwent TET. Considering the mean pregnancy, 5% type I error and 20% type II error, 130 patients were required in each group and 150 patients were studied in each group.
Participants/materials, setting, methods: 296 non-ovulation PCOS women were involved in our RCT. 148 women were randomized selected into HRT endometrium preparation group and 148 women were radonmized selected into letrozole COH endometrium preparation group.In letrozole COH endometrium preparation group,10 cycles were canceled. In HRT endometrium preparation group, 7 cycles were canceled. SPSS ver. 20 was used for dada analysis. P value of less than 0.05 was considered statistically significant with Fisher corrections.
Main results and the role of chance: Total 283 TET cycles were evaluated, 140 for letrozole COH endometrium preparation group (group A) and 143 for HRT endometrium preparation group (group B). The mean age in group A and group B were 30.09 and 29.61 years (p=0.853). The base line of basic FSH, BMI, the number of oocytes and embryo transfer number were no significant

difference between two groups. The endometrium thickness on the day endometrium transformation was significant higher in Group A.(10.28±1.94mm VS 9.21±1.59mm; P<0.001) The E2 level on embryo transfer day were significantly lower in Group A (88.6pg/ml VS 181pg/ml; P<0.01). The progesterone level on embryo transfer day were significantly higher in Group A . (23.22±12.39 VS 12.59±6.53; P<0.001) The average number of clinical visiting times was 3.1±0.89 in Group A and 2.2±0.8 in Group B. (P<0.05) Clinical pregnancy rate were 54.7% in Group A and 60.3% in Group B. (P=0.63) The endometrium grew more slowly in Group A. In Group A, the average day for endometrium thickness reaching 7mm and above was about 4.5 days before the day of endometrium transformation. However, the endometrium thickness in Group B can reach 7mm before 7 days before the day of endometrium transformation.

Limitations, reasons for caution: It is a single center RCT study and the life birth rate of two groups are not available right now. Our research did not evaluate the mechanism according to the endometrium receptivity in Letrozole COH endometrium preparation group.

Wider implications of the findings: For non-ovulation PCOS women, Letrozole COH endometrium preparation protocol can provide comparable clinical pregnancy rate. However, HRT endometrium preparation protocol could be more convenient due to less number of clinical visiting times and stable high clinical pregnancy rate. It is still beyond studies about endometrium receptivity in Letrozole COH patients.

Trial registration number: ChiCTR1800014746

P-606 Effect of body mass index on cumulative live birth rate following in vitro fertilization

L. Zhou[1]

[1]*Shenzhen Zhongshan Urology Hospital, Fertility Center, Shenzhen-Guangdong, China*

Study question: Is it beneficial to the cumulative live birth rate of in vitro fertilization by achieving a particular body mass index prior to infertility treatment?

Summary answer: BMI does not affect the cumulative live birth rate of IVF, but it does elevate the miscarriage rate in the fresh cycles.

What is known already: It is critical to evaluate the impact of body mass index on the cumulative live birth rate following in vitro fertilization, as achieving a lower BMI prior to infertility treatment is often recommended for women with overweight and obesity. It is important to extrapolate the true benefits of weight loss on CLBR from this study.

Study design, size, duration: This is a retrospective cohort study. A total of 4166 women aged 20-40 years old with first conventional stimulation across different BMIs at our institution from 2012 to 2016 were stratifified into cohorts. BMI was defifined according to World Health Organization guidelines.

Participants/materials, setting, methods: The primary outcome was live birth as measured by cumulative live birth rate per initiated cycle. Secondary outcomes included clinical pregnancy rate, miscarriage rate and live birth rate independent in fresh and cryopreserved cycles.

Main results and the role of chance: There were 3384 first fresh cycles and 1929 subsequent frozen embryo transfer cycles. There were 3645 live births, for an overall cumulative live birth rate of 87.49% per initiated cycle. The clinical pregnancy rate and cumulative live birth rate decreased with increasing BMI, but there was no statistical significance. The miscarriage rate was lower in underweight (BMI < 18.5 kg/m2) and normal weight cohorts (18.5 <BMI < 24.9 kg/m2, over weight cohort (BMI>25 kg/m2) of patients had a relatively higher rate in fresh cycles(P=0.041), but there was no statistical significance in all linked cryopreserved cycles.

Limitations, reasons for caution: Our conclusions are limited by the retrospective nature of the study, and the single-center design also weakens the universality of our observations. It is possible that patients with a failed initial transfer and subsequent weight loss, followed by a successful transfer, were not captured within this study's time frame.

Wider implications of the findings: BMI does not affect the cumulative live birth rate of IVF, but it does elevate the miscarriage rate in the fresh cycle. Therefore, it is recommended to delay embryo transfer to achieve a lower BMI may be beneficial to assisted reproductive outcomes.

Trial registration number: no

P-607 Factors in first complete in vitro fertilisation cycle which predict success in second complete cycle

X. Zhang[1], **T. Dineen**[1], **A. Kovacs**[1], **R. Mihart**[1], **J. O'Callaghan**[1], **J. Culligan**[1], **A. Tocado**[1], **N. Daly**[1], **M. Walsh**[1], **D. Florio**[1], **D. McAuliffe**[1], **J. Waterstone**[2]

[1]*Waterstone Clinic, Laboratory, Cork, Ireland ;*
[2]*Waterstone Clinic, Clinic, Cork, Ireland*

Study question: To determine the factors in first complete in vitro fertilisation (IVF) cycle which predict live birth (LB) in second complete IVF cycle.

Summary answer: The patients that had LB, miscarriage or had frozen embryos from first complete IVF cycle had a greater likelihood of achieving LB in second cycle.

What is known already: Individualised prognostics are valuable for both patients and practitioners. A better understanding of the factors that determine the chance of success in IVF can help patients choose the correct fertility treatment options.

Studies have shown that treatment response in the first cycle is reproducible. The number of aspirated oocytes is a predictor for subsequent treatment outcome. However, the majority of studies have considered only the outcome of the fresh IVF transfer without the inclusion of frozen embryo transfer results.

Study design, size, duration: This cohort study includes all women (Median age = 36.0, 19.6% ≥ 40years) undergoing IVF treatment with homologous oocytes in a single IVF unit who had a first (n= 4180) and a second (n=1838) egg collection between 2008 and 2017. The outcome of all embryo transfers (fresh and frozen) from both egg collections was analysed.

Participants/materials, setting, methods: A complete cycle is defined as all fresh and frozen/thawed embryo transfers derived from the same oocyte aspiration. LB rates of the 1st and 2nd complete cycles were calculated. Multivariate logistic regression was used to identify prognostic factors in the first complete cycle with regard to the outcome of the second complete cycle, such as the number of retrieved oocytes, number of good quality embryos, blastocyst cryopreservation and pregnancy outcome.

Main results and the role of chance: In all women LB rate was 38.0% (n=4180) for the first complete cycle, significantly higher than for the second complete cycle 34.0% (n=1838, p=0.003).

In the second complete cycle LB rate was 30.1% (364/1202) in women that did not achieve any pregnancy in the first complete cycle in comparison with 44.2% (156/353, OR=1.5) in women with LB and 37.1% (105/283, OR=1.3) in women with miscarriage. Moreover, embryo development patterns in the first complete cycle demonstrated a significant association with LB rate in the second complete cycle. A significantly higher LB rate in the second complete cycle was found for women who had frozen blastocyst(s) in the previous cycle (OR=1.4, P=0.019) compared to those who had not.

The LB rate of the 2nd complete cycle significantly increased with the number of oocytes retrieved in the first complete cycle. However, this association was only significant in the poor ovarian response group (number of oocytes less than 4) after adjusting for the factors of womens' ages and of having frozen blastocyst(s).

Limitations, reasons for caution: This is a cohort analysis based on retrospective data collection. A significant number of patients did not undergo a second cycle, which may potentially bias the results.

Wider implications of the findings: These results allow us to provide patients with more accurate advice when they have a consultation after their first complete cycle.

Trial registration number: not applicable

P-608 Optimization of oocyte retrieval rate in women undergoing ovarian stimulation for in-vitro fertilization using hCG or GnRH agonist for triggering final oocyte maturation

[2]*Eugonia, Assisted Reproduction Unit, Athens, Greece*

Study question: At which follicular diameter is the ratio of oocytes retrieved to the number of follicles > certain diameter on the day of triggering final oocyte maturation (oocyte retrieval rate) optimised?
Summary answer: The smallest mean follicular diameter, leading to a lower 95% confidence-interval(CI) of oocyte retrieval rate ≥100%, is 15mm for hCG and 16mm for GnRH-agonist triggering.
What is known already: Oocyte retrieval rate is calculated by dividing the number of oocytes retrieved to the number of follicles equal or greater than a specific mean follicular diameter (i.e. ≥11mm, ≥12mm, etc.), assessed in two perpendicular planes on the day of triggering. Ideally, the smallest mean follicular diameter leading to a lower 95%CI of oocyte retrieval rate ≥100% should be used for this purpose. In this case, the number of oocytes retrieved would be expected to be ≥ to the number of follicles above this follicular diameter. Although this is an essential information for patient consultation, no such data is currently available.
Study design, size, duration: A retrospective study was performed between 01/2018 and 12/2019, including 413 in-vitro fertilization (IVF) cycles (306 women). Ovarian stimulation was performed with a fixed dose of recombinant gonadotrophin and gonadotrophin releasing hormone (GnRH) antagonist, while triggering was carried out with human-chorionic-gonadotrophin(hCG) or GnRH-agonist, when ≥14 follicles ≥11mm in diameter were present. Thirty-six hours following final oocyte maturation, oocyte pick-up(OPU) was carried out by puncturing all follicles that could be aspirated. Follicular flushing was not performed.
Participants/materials, setting, methods: Follicular development was assessed by recording the mean diameter of each follicle ≥10mm by 2-dimensional ultrasound. On the day of triggering, the number of follicles ≥ to a specific diameter was calculated for all diameters recorded, leading to multiple oocyte retrieval rates for each cycle. The primary outcome measure was the identification of the smallest follicular diameter on the day of triggering, with which the lower 95%CI of the calculated oocyte retrieval rate is ≥100%.
Main results and the role of chance: The mean ± standard deviation (SD) age of the patients included was 38.7 (±5.2) years, the mean BMI was 25.8 (±5.5) kg/m^2, the mean basal FSH levels were 7.8 (±3.1) IU, the mean AMH levels were 4.5 (±6.1) ng/mL and the mean number of antral follicle count was 11.8 (±9.5). At OPU, the mean number (95% CI) of oocytes retrieved was 6.8 (6.1-7.5). In 299 out of 413 cycles (72.4%), hCG was used for triggering final oocyte maturation, whereas in 114 cycles (27.6%), this was performed with GnRH agonist. The smallest follicular diameter on the day of triggering final oocyte maturation with hCG, at which the lower 95% CI of oocyte retrieval rate was ≥100%, was 15 mm (mean oocyte retrieval rate: 133.7%, 95% CI: 109.8%-157.6%). The smallest follicular diameter on the day of triggering final oocyte maturation with GnRH agonist, at which the lower 95% CI of oocyte retrieval rate was ≥100%, was 16 mm (mean oocyte retrieval rate: 144.2%, 95% CI: 107.6%-180.8%).
Limitations, reasons for caution: The results obtained can be generalized only if similar practices to the current study are used for evaluating follicular development and performing oocyte retrieval. For instance, whether the results of the current study are also valid for cycles in which follicular flushing is performed needs to be assessed.
Wider implications of the findings: The findings of the present study allow for precise prediction of the number of oocyte retrieved depending on the triggering signal. In this way, patient consultation can be facilitated, especially in cases where an oocyte target has been set, such as preimplantation genetic testing or oocyte donation cycles.
Trial registration number: not required

P-609 Predictor for supraphysiologic serum estradiol elevation on hCG day of controlled ovarian stimulation (COS) using letrozole and gonadotropins in women with estrogen-dependent cancer

S.J. Han[1], M. Lee[1], S.W. Kim[1], H. Kim[1], J.Y. Lee[2], S.Y. Ku[1], C.S. Suh[1], S.H. Kim[1]

[1]Seoul National University Hospital, Obstetrics and Gynecology, Seoul, Korea- South ; [2]Hamchoon Women's Clinic, Obstetrics and gynecology, Seoul, Korea- South

Study question: Are there predicting factors for supraphysiologic estrogen elevation during COS with administration of letrozole in patients with estrogen-dependent cancer?
Summary answer: In the COS cycles using letrozole, early monitoring serum estradiol (E2) is an independent predicting factor for supraphysiologic level of serum E2 on hCG day.
What is known already: Supraphysiologic serum E2 levels (≥400 pg/ml) as a consequence of ovarian stimulation may promote the estrogen-dependent tumor growth or recurrence. Therefore, use of aromatase inhibitors is recommended to reduce the potential effects of elevated serum E2 levels in patients with estrogen-dependent cancers during ovarian stimulation. Previous studies that have shown an effective lowering of peak estrogen levels and feasible results of COS using the letrozole protocol have used a fixed dose of letrozole (5 mg/ day). However, a part of patients has supraphysiologic levels of estrogen associated with ovarian stimulation despite the administration of letrozole.
Study design, size, duration: From January 2009 to December 2019, patients with estrogen-dependent cancer who underwent COS with antagonist protocol using a fixed dose of letrozole (5 mg/ day) to keep estrogen levels low were included in this study. Cycles for fertility preservation and general in vitro fertilization cycles were all included. Subjects are consisted of 74 breast cancer patients, 5 endometrial cancer patients and 2 other estrogen-dependent cancer patients. A total of 94 COS cycles were retrospectively analyzed.
Participants/materials, setting, methods: Administration of letrozole was started on the second or third day of the menstrual cycle. Ovarian stimulation began with a dose of 150-450 IU/day on the same day or third day of letrozole administration and was continued until the hCG day. Dose of FSH was adjusted according to the patient's age, anti-Mullerian hormone (AMH), and body mass index (BMI). Early monitoring serum E2 was measured in all patients on the 4-6th day of stimulation.
Main results and the role of chance: Supraphysiologic levels of serum E2 was found in 20.2% of the patients who underwent COS with a fixed dose of letrozole (5 mg/ day) administration. Subjects were classified into two groups according to the serum E2 level on hCG day, physiologic E2 group (≤400 pg/ml) and supraphysiologic E2 group (>400 pg/ml). Mean age, BMI, AMH, basal serum LH/ FSH/ E2, total dose and duration of letrozole administered, duration of stimulation, total dose of gonadotropins administered were not different between the two groups. However, early monitoring serum E2 level was significantly higher in the supraphysiologic E2 group (68.9±49.3 vs. 119.8±78.1, p=0.001). Early monitoring serum E2 is associated with the occurrence of supraphysiologic elevation of serum E2 on hCG day (adjusted odds ratio [aOR] = 1.013; 95% confidence interval [CI], 1.003-1.022). The best cut-off for early monitoring serum E2 to predict the occurrence of supraphysiologic estrogen levels was 86.5 pg/ml (sensitivity was 73.7% and specificity was 73.3%). The mean area under a receiver operating characteristic (ROC) curve (AUC) was 0.731 (p=0.002 compared with 0.5).
Limitations, reasons for caution: Limitations of this study included the retrospective design and the small sample size. Prospective study will be needed to confirm that uptitration of letrozole is effective to prevent supraphysiologic levels of estrogen.
Wider implications of the findings: To prevent supraphysiologic elevation of serum E2, uptitration of letrozole should be considered when early monitoring serum E2 level is more than 86.5 pg/ml during COS with letrozole in patient with estrogen-dependent cancer.
Trial registration number: Not applicable

P-610 Severe OHSS after GnRH-agonist triggering is not eliminated if hCG is co-administered at triggering and/or during the luteal phase: a systematic review and meta-analysis

P. Ioannidou[1], J. Bosdou[1], G. Lainas[2], T. Lainas[2], N. Michaleli[1], G. Grimbizis[1], E. Kolibianakis[1]

[1]Aristotle University of Thessaloniki- Medical School, 1st Dept. of Ob/Gyn- Unit for Human Reproduction, Thessaloniki, Greece ; [2]Eugonia, Assisted Reproduction Unit, Athens, Greece

Study question: Is severe ovarian-hyperstimulation-syndrome (OHSS) after triggering with gonadotrophin-releasing-hormone agonist (GnRH-agonist) eliminated if human chorionic gonadotropin (hCG) is co-administered at triggering and/or during the luteal phase?
Summary answer: Severe OHSS, although low in incidence, is not eliminated, when hCG is administered either concomitantly with GnRH-agonist (dual-triggering) and/or during the luteal phase.

What is known already: Replacement of hCG by GnRH-agonist has decreased or even eliminated the incidence of severe OHSS. Concomitantly, however, the probability of pregnancy after fresh transfer and standard luteal phase support is decreased. This has been managed by freezing all embryos and deferring transfer to a future replacement cycle. Alternatively, in an effort to perform a fresh transfer, support of the luteal phase with hCG administered either concomitantly with GnRH-agonist (dual-triggering) and/or during the luteal phase has been advocated. The potential of both strategies, however, in eliminating severe OHSS has not been yet systematically assessed.
Study design, size, duration: Literature search was performed in MEDLINE and CENTRAL until 12/2019, in order to identify studies evaluating the incidence of severe OHSS following GnRH-agonist triggering in high-risk women. The incidence of severe OHSS was assessed separately for studies in which hCG was administered either concomitantly with GnRH-agonist(dual-triggering) and/or during the luteal phase, aiming to perform a fresh transfer and for studies in which no support was administered during the luteal phase and all embryos were frozen.
Participants/materials, setting, methods: Twenty-nine studies (n=2269 patients), published between 2000 and 2019, were included in this systematic review and meta-analysis. Pooling of severe OHSS incidence in the included studies is reported as a weighted average, by fitting the logistic regression model without covariate but an intercept, or by fitting the logistic-normal random-effects model without covariates but random intercepts. The confidence intervals are based on score (Wilson) or exact binomial (Clopper-Pearson) procedures.
Main results and the role of chance: Triggering of final oocyte maturation was performed with GnRH-agonist alone in 24 studies, whereas in five studies a combination of GnRH-agonist and hCG was used for this purpose.
The pooled mean number of oocytes retrieved in the high-risk for OHSS women included in these studies was 18.2 (95% CI: 15.0-21.5).

The pooled incidence of severe OHSS in high risk women triggered by GnRH-agonist who did not receive any form of luteal phase support was 0% (95% CI: 0.0-0.0, 15 studies, 1327 women).

The pooled incidence of severe OHSS in high risk women triggered by GnRH-agonist in whom hCG was added to standard luteal phase support was 0% (95% CI: 0.0-1.0, eight studies, 557 women).

The pooled incidence of severe OHSS in high risk women triggered by a combination of GnRH agonist and hCG (dual triggering), who received only estradiol and progesterone was 1% (95% CI: 0.0-3.0, three studies, 282 women).

The pooled incidence of severe OHSS in high risk women triggered by a combination of GnRH agonist and hCG (dual triggering) in whom hCG was in addition administered to standard luteal phase support was 1% (95% CI: 0.0-5.0, two studies, 103 women).
Limitations, reasons for caution: Despite the absence of statistical heterogeneity, clinical heterogeneity was present among studies regarding ovarian stimulation protocol, triggering signal, severe OHSS definition as well as the criteria used to define high risk probability for OHSS. Moreover, the number of patients/studies analysed in certain groups was limited.
Wider implications of the findings: Although the incidence of severe OHSS after GnRH-agonist triggering in high-risk women was low in all strategies examined, its elimination (upper 95% CI = 0) was only present in studies where no hCG was added. Thus, for elimination of severe OHSS, following GnRH-agonist triggering, addition of hCG is not recommended.
Trial registration number: not required

P-611 Cumulative live birth rates of oocyte in-vitro maturation and controlled ovarian stimulation in infertile patients with polycystic ovary syndrome

I. Segers[1], S. Santos-Ribeiro[1,2], L. Mostinckx[1], H. Tournaye[1], G. Verheyen[1], M. De Vos[1,3]

[1]UZ Brussel, Centre for Reproductive Medicine CRG, Jette- Brussels, Belgium ;
[2]IVI-RMA Lisboa, Reproductive medicine, Lisbon, Portugal ;
[3]Vrije Universiteit Brussel, Follicle Biology Laboratory, Jette-Brussels, Belgium

Study question: What is the clinical outcome of in-vitro maturation of oocytes (IVM) compared with controlled ovarian stimulation (COS) in polycystic ovary syndrome (PCOS) patients undergoing ICSI?
Summary answer: Overall, cumulative live birth rate (CLBR) was lower after IVM. However, in patients with hyperandrogenic PCOS phenotype A, CLBR after IVM and COS was similar.
What is known already: Published evidence suggests that embryo development and LBR are inferior following IVM compared to COS in patients with and without PCOS. Although PCOS phenotype has emerged as an important factor influencing COS and IVM treatment outcomes, assignment of PCOS phenotypes is lacking in patients enrolled in previous studies. PCOS women can be categorized into the following phenotypes: A= hyperandrogenism + ovulatory dysfunction + polycystic ovaries, B= hyperandrogenism + ovulatory dysfunction, C= hyperandrogenism + polycystic ovaries and D= ovulatory dysfunction + polycystic ovaries. Clinical outcomes of non-hCG triggered IVM and COS have not previously been compared among similar patient phenotypes.
Study design, size, duration: This was a retrospective, single-centre cohort study including 716 cycles in unique patients between 18 and 36 years of age who underwent either non-hCG triggered IVM (30h) after a short HP-hMG course (189 patients) or COS (527 patients) followed by ICSI and fresh or frozen embryo transfer between January 2010 and December 2016. First rank of trial were included.
Participants/materials, setting, methods: Predicted high responders with PCO-like morphology (PCOM) and/or levels of AMH ≥3.5 µg/l, or PCOS according to 2003 extended Rotterdam criteria, ≤37 years of age and scheduled for ICSI were included. Patient characteristics and IVM or COS treatment cycle data were collected. The primary objective was CLBR, defined as the rate of liveborns resulting from the transfer of all fresh and cryopreserved embryos from the same cycle. Secondary outcome was embryo quality.
Main results and the role of chance: IVM patients had higher BMI (24.8 vs 24.0 kg/m^2, p=0.03), higher basal antral follicle count (AFC (42.6 vs 26.6, p<0.001)), higher AMH (10.0 vs 6.4 µg/l, p<0.001) and were younger (28.3 vs 29.7y, p<0.001). Patients undergoing IVM had more often PCOS-A (19.7% vs 8.3%) and PCOS-D (65.4% vs 24.3%), a similar incidence of PCOS-C (4.3% vs 7.6%) and less often PCOM (10.3% vs 59.8%, overall p<0.001). IVM cycles yielded more oocytes (17.8 vs 13.9, p<0.001), lower maturation rates (51,7% vs 77.8%, p<0.001) and lower utilization rate per fertilized oocyte (51.0% vs 54.9%, p<0.05). After IVM, patients had more often transfer of vitrified/warmed cleavage stage embryos, whereas fresh transfer of blastocysts was more often performed following COS. Overall, CLBR was 40% after IVM and 59% after COS (p<0.001). There was no difference in CLBR between IVM and COS in patients with PCOS-A (43% vs 33%, p=0.45) whereas CLBR was higher (p<0.05) following COS compared to IVM in patients with PCOS-D (65% vs 41%) and PCOM (59% vs 30%).
Limitations, reasons for caution: This is a large observational study based on retrospective data collection. Despite our robust methodological approach, the presence of bias related to the retrospective design cannot be excluded. The low number of patients with PCOS-C impedes the validity of results in women with PCOS-C.
Wider implications of the findings: The current non-hCG triggered IVM system is an equally efficient mild-approach alternative for COS in patients with PCOS phenotype A. Further development of IVM systems could enhance the potential of IVM in a broader patient population.
Trial registration number: not applicable

P-612 The impact of endometrial thickness change between the day of ovum pick and embryo transfer on pregnancy outcome during in vitro fertilization cycle

M. Jeong[1], M.K. Chung[2], G.K. Lee[2], H.J. Jeong[1], H.S. Lee[1], M.H. Kim[1], J.W. Kim[1], E.B. Noe[1]

[1]Seoul Rachel Fertility Center, Medical Department, Seoul, Korea- South ;
[2]Seoul Rachel Fertility Center, Laboratory, Seoul, Korea- South

Study question: Is there any difference in pregnancy outcome according to the change of endometrial thickness in the patients undergoing in vitro fertilization-embryo transfer (IVF-ET) cycle?
Summary answer: Clinical and ongoing pregnancy rates were significantly higher when endometrial thickness did not increase on embryo transfer (ET) day compared with ovum pickup (OPU) day.
What is known already: Many studies have reported the importance of endometrial thickness on pregnancy outcome during in-vitro fertilization (IVF) cycle, most of them discovered that thin endometrium adversely affects pregnancy outcome. Previous studies have mostly measured the endometrial thickness on the human chorionic gonadotropin (hCG) trigger day in fresh IVF cycle

and examined its effect on pregnancy outcome. It is known that the endometrial condition is changeable not only in natural menstrual cycle but also in IVF cycle, yet few studies have examined the impact of endometrial thickness change within the IVF cycle.

Study design, size, duration: A retrospective study was conducted using data from a total of 397 fresh IVF cycles undertaken at a single fertility center. The study period went from January 2017 to November 2018. Only cases in which endometrial thickness on hCG trigger day, OPU day, ET day were all measured were included. Pre-implantation genetic test cycles or oocyte donation cycles were excluded.

Participants/materials, setting, methods: Each endometrial thickness of hCG trigger day, OPU day, and ET day were examined and its impact on pregnancy outcome was analyzed. Subsequently, endometrial changing pattern such as increase or decrease between the days were individually examined. Clinical and cycle characteristics, and pregnancy outcomes were compared according to the endometrial thickness change around OPU day.

Main results and the role of chance: The endometrial thickness of hCG trigger day or ET day was not significantly related to the pregnancy outcome. The endometrial thickness of OPU day was significantly higher in the implanted cycles than in the non-implanted cycles (9.29mm vs. 8.76mm, p <0.001), and showed the same tendency for cases with clinical pregnancy (9.28mm vs. 8.84mm, p=0.002) and ongoing pregnancy (9.40mm vs. 8.82mm, p <0.001). When analyzing the relationship between endometrial thickness changes and pregnancy outcome, only the impact of change between OPU and ET day on pregnancy outcome was identified. Baseline and cycle characteristics were not significantly different according to the changing pattern of endometrial thickness between OPU and ET day. Interestingly, the rate of implantation, clinical pregnancy and ongoing pregnancy were all significantly higher in the 'non-increased' group in which endometrial thickness were equal or decreased from OPU to ET day, compared with 'increased' group where endometrial thickness were thicker on ET day. After adjusting the transferred number of good quality embryos, clinical pregnancy (aOR=1.583, 95% CI: 1.018-2.464) and ongoing pregnancy (aOR=1.734, 95% CI: 1.101-2.728) rates were still significantly higher in the 'non-increased' group than in the 'increased' group.

Limitations, reasons for caution: Limitations of this study included the retrospective design and the heterogeneity of the subjects, including such as infertility diagnosis or ovarian stimulation method which may affect the pregnancy outcome in IVF cycle. Therefore, prospective studies are needed before generalizing the results.

Wider implications of the findings: Though we have generally measured endometrial thickness on hCG day and considered that thickness to be crucial factor for IVF outcome, this study result suggest that endometrial thickness on OPU day and its change until ET day may be more important clues for predicting pregnancy outcome.

Trial registration number: not applicable

P-613 Genomics analysis of maternal exomes reveals new candidate genes and pathways for the diagnosis and prediction of recurrent preimplantation embryo arrest in IVF cycles

S. Kahraman[1], F. Sagir[1], B. Yuksel[1], M. Cetinkaya[1], M. Gavaz[1], B. Kara[1], M. Yesil[1], G. Akar[1], S. Buonaiuto[2], G. Damaggio[2], M. Fabiani[3], A. De Marino[4], V. Colonna[2], C. Simon[5], A. Capalbo[4]

[1]Istanbul Memorial Hospital-, ART and Reproductive Genetics Center, Istanbul, Turkey ;
[2]National Research Council CNR, Institute of Genetics and Biophysics, Naples, Italy ;
[3]Igenomix Italy, Genetics and Biophysic, Marostica, Italy ;
[4]Igenomix Italy, Genetics and Biophysics, Marostica, Italy ;
[5]Valencia University and INCLIVA, Department of Obstetrics and Gynecology, Valencia, Spain

Study question: Is genomic analysis of maternal exomes capable of identifying new target genes to improve infertility diagnosis and support the development of new treatment strategies?

Summary answer: Exome analysis of woman with recurrent embryo arrest successfully identify genomic variants lethal at the embryonic stage increasing diagnostic yield toward unexplained infertility

What is known already: In IVF cycles, it is estimated that about 40% of the human oocytes are capable of growing to the blastocyst stage, whereas others arrest at different early stages of development. It is commonly thought that much of human embryonic developmental potential is determined before fertilization by the content of the oocyte (maternal-effect genes). Infertile patients commonly show individual variability in embryo developmental rate, ranging from high to total developmental failure in multiple treatment cycles. The genetic determinant of this phenotype is unknown and this study aims at exploring the genetic aetiology of extreme phenotypes of preimplantation embryonic arrest

Study design, size, duration: Ten women (five with consanguinity history, four being the offspring of first-cousin marriage) with a history of recurrent embryo developmental failure in multiple IVF cycles were recruited at Istanbul Memorial Hospital (Dec 2018-Nov 2019). These were all young women (average age 32.3 y), with good ovarian reserve (average AMH 3.6) and with several failed IVF cycles (average 4.4, range 3-8), following the retrieval of high number of mature oocytes per procedure (average 11.2).

Participants/materials, setting, methods: Whole-exome sequence was performed by Agilent SureSelect whole-exome capture and Illumina sequencing technology. Variant calling against the reference genome GRCh38 was done using Freebayes. Variants were annotated with a custom script that integrates information from Ensembl99 with publicly available manually curated lists of genes associated with embryonic development, miscarriages, lethality, cell cycle. The code is available on gitHub. The Hospital Ethical Committee approved the study and data were treated anonymously.

Main results and the role of chance: Variant calling identified on average 436k high quality variants per samples. According to Ensembl classification 2.8% are expected to have high (0.25%) or moderate (2.56%) disruptive impact in the gene product. Variants were filtered on a per-individual base using three criteria. First, alleles with frequency >0.05% in the 1000 Genomes and gnomeAD reference populations were filtered out. Second, variants were ranked by severity (as estimated by Ensembl) according to their Sequence Ontology classification, and only variant in the last percentile were retained. Finally, variants were assigned a score that correlates with the gene relevance in early embryonic development and only variants in the last fifth percentile were retained.

Overall, 62 unique variants in 54 genes were retained after filtering, all involved in lethal embryonic pathways. All retained variants have high impact and half of them is a stop gain. Each sample carry on average 8.6 (2.7 s.d.) potentially detrimental variants. Of particular relevance seven samples share stop gain and splice donor mutations at four sites in three exones of the MTCH2 gene, a nuclear-encoded transporters localized in the inner mitochondrial membrane, involved in the energy and lipid metabolism, never reported associated to preimplantation embryo arrest.

Limitations, reasons for caution: Functional genomics studies and validation in an independent cohort of patients with preimplantation embryo arrest phenotype and of different ethnicity is required to corroborate these findings. The generation of polygenic models will also further contribute increasing discovery rate and to develop more general and powerful predictive models for this phenotype.

Wider implications of the findings: We have identified MTCH2 and several new candidate genes as the plausible cause of female infertility characterized by early embryonic arrest. Such discoveries not only contribute to the recognition of novel gene function/pathways in reproduction but also help the development of genetic diagnosis and suggest possible therapeutic targets for infertility.

Trial registration number: 25

P-614 NLRP3 inflammasome analysis in grannulose-cumulus cells from low ovarian reserve patients

C. Andres[1], L. Rancan[2], C. Cordero[1], R. Pandolfi[3], M. Saladino[3], C. Rodriguez[1], B. Linillos[4], V. Elena[2], J. Tresguerres[4], C. Susana[1]

[1]Clinica tambre, IVF Laboratory, Madrid, Spain ;
[2]Complutense University, Biochemistry and molecular biology, Madrid, Spain ;
[3]Clinica tambre, Andrology Laboratory, Madrid, Spain ;
[4]Complutense University, Physiology Department, Madrid, Spain

Study question: Is the inflammasome NLRP3, together with other inflammatory markers, activated on low ovarian reserve patients and is this correlated with the number of follicles retrieved?

Summary answer: Inflammasome activation was observed in patients with low ovarian reserve (LOR) in comparison to donors with normal response. It is not correlated with follicle number.

What is known already: LOR patients are women, within the reproductive age group, which are characterized by having a decreased ovarian follicular pool. They present abnormal but not post-menopausal ovarian reserve test results. There is a wide-range of origins that can lead to this pathology.

Oxidative stress associated with chronic low-grade inflammation has emerged as a plausible key contributor to the pathogenesis. The NLRP3 inflammasome can start an inflammatory form of cell death and trigger the release of proinflammatory cytokines through caspase activation. Although it has been associated to different diseases, an association with low ovarian reserve has not been described to date.

Study design, size, duration: Prospective clinical observational study conducted at Clinica Tambre in collaboration with the University Complutense of Madrid. A total of 16 donors and 9 patients participated in the study. Stimulation protocols were the same for all patients (FSHr and triggering with GnRH analogues). Collection of oocyte-granulose complexes (GCs) was performed during oocyte retrieval. GCs were processed according to the procedure described by Ferrero F, et al. 2012 throughout 2019. All patients signed the specific informed constent.

Participants/materials, setting, methods: mRNA expression of NLRP3, IL-1β, IL-1 receptor, caspase 1, 12 and 18, and serpin were analyzed in the CGs complexes as well as the number of follicles retrieved to evaluate correlation with gene expression. mRNA was measured by qRT-PCR. The 2-ΔΔCT method was used for relative gene expression changes calculation. Non parametric tests were used to identify significant differences between groups and spearmen correlation to asses correlation.

Main results and the role of chance: Increased mRNA expression was observed in LOR patients compared to donors (p=0.022). Accordingly, LOR patients had increased expression of IL-1B and its corresponding receptor in comparison to donors (p=0.0003 and p=0.0001 respectively). In the same manner, caspase 1, 12 and 18 were also significantly increased in our group of patients in comparison to the donor expression (p<0.0001, p=0.0008 and p=0.0003 respectively). Finally, pathway's inhibitor expression: SERPIN B9 was significantly higher in donors (p=0.0002).

When analyzing the correlation with the oocytes retrieved, we observed no significant correlation between the number of oocytes obtained with the expression of NLRP3 and Serpin (p= 0.2977 and p=0.7158, respectively). In contrast, we did observe a negative significant strong correlation in inflammation markers IL-18 (p=0,0069, r -0,6583) , IL-1B (p=0,0009, r-0,8244) and IL-1R (p=0,0009, r-0,824) and a significant negative mild correlation in caspase 1 (p=0,0102, r-0,5357) and 12 (p=0,0488, r-0,5616).

Our results show higher NLRP3 expression in patients with low ovarian reserve compared to donors suggesting an activation of the pathway and its possible involvement in the pathogenesis. Additionally, there seems to be a negative correlation in between the number of oocytes retrieved and inflammatory markers.

Limitations, reasons for caution: Due to the low number of patients who participated in our study, in order to confirm our results, further analysis is required.

Wider implications of the findings: Finding out the causes behind idiopathic LOR will give us a hint for a better approach to the treatment or ways to improve IVF outcomes.

Trial registration number: Not aplicable

P-615 Diabetic but not women with normal metabolic phenotype with unexplained infertility are in risk for decreased ovarian response : A prospesctive population based cohort study

S. Kalapahar[1], S. Sharma[1], R. Chattopadhyay[1], S. Parvin[1], S. Behera[1], S. Ghosh[1], P. Chakraborty[1], B. Chakravorty[1]

[1]Institute of Reproductive Medicine, Assisted Reproductive Medicine, KOLKATA, India

Study question: Does diabetes confer a differential ovarian response and IVF outcome through diminished connexin-43 expression in women with unexplained infertility(UI) undergoing ovarian stimulation?

Summary answer: Ovarian reserve and ovarian response to stimulation is lower in diabetic patient along with decreased connexin-43 expressions in comparison to non-diabetic women with unexplained infertility.

What is known already: Recent studies cue at the association of diminished ovarian reserve with diabetes mellitus. Reduced ovarian reserve in diabetes might be associated with decreased oocyte developmental competence leading to poor IVF outcome. Attenuation of ovarian gap junction protein (connexin-43) involves decreased follicular development and oocyte growth retardation. However, there is little information whether diabetes targets connexin-43 to alter follicular growth. Anti –mullerian hormone(AMH) and Antral follicular count(AFC) are the most important factors predicting ovarian stimulation response based on retrieved oocyte number. Hence, we have tried to find out the effect of diabetes on ovarian stimulation response in these women undergoing IVF.

Study design, size, duration: This is a prospective cohort study in women (n=415) with UI in age group between 25 and 35 years, conducted between August 2017 and December 2019 at Institute of Reproductive Medicine,Kolkata. Patients have been divided to diabetic(n=216) controlled with either tablet Metformin or insulin and non-diabetic based on ADA guidelines. All patients are stimulated using recombinant FSH with individualized dosing and GnRH antagonist (flexible)protocol .Fresh or frozen embryo transfer has been done within 1 year.

Participants/materials, setting, methods: All patients have been evaluated for HbA1C, AMH & AFC. All diabetic patient either taking tablet Metformin and/or insulin with HbA1C <7 have been included in the study group. After ovum pickup, follicular fluid of each patient has been evaluated by immunoblotting for connexin-43 expression in between granulosa cells. Routinely 2 blastocyst have been transferred.

Two tailed Student's *t*- test is used to evaluate significance of differences.p value <0.05 is considered to be significant.

Main results and the role of chance: Baseline parameters (Age,obesity) are comparable between two groups .AMH (1.69 ± 0.9 vs 2.97±0.3, p<0.05) & AFC (8±1.9 vs 10.4±2, p<0.05) are significantly less in diabetic patient than non-diabetic group indicating low ovarian reserve.Total gonadotropin dose requirement is significantly higher in diabetic group (2873±75.08 vs 2497±80.15, p<0.05). Oocyte recovery /patient is also lower, but not significant (7±1.5 vs 9±1.7). M II oocyte percentage is significantly lower in diabetic group (73±2.1 vs 80±1.5, p<0.05). Connexin-43 expression is also significantly lower in diabetic group obtained by immunoblot technique. Fertilization rate (62.16±5.7 vs 73.5±2.9), cleavage rate (87.7±6.1 vs 91.8±5.3) and blastocyst development rates (58.6±3.9 vs 65.9±6.2) are non-significantly less in diabetic group. But clinical pregnancy rate is significantly low (56.7 vs 64.1, p<0.05) in diabetic group after blastocyst transfer either in fresh or frozen cycle. Duration of diabetes has negative correlation (- 0.403) with number of M II oocyte retieved.

Limitations, reasons for caution: It is an observational study with limited number of patients. Exact cause or mechanism of decreased response is not revealed by this study. Before wide application of this observation, other undetected cause of diminished ovarian response should be searched for and study with larger sample size is warranted.

Wider implications of the findings: Diabetic women with infertility should be counseled regarding low ovarian reserve and decreased ovarian response irrespective of age. Diabetic women are associated with increased gonadotropin requirement and poor IVF outcome.

Trial registration number: not applicable

P-616 Can we detect a biologically relevant quantity of Anti-Mullerian Hormone (AMH) in human hair samples?

S. Sawarkar[1], M.Á. Rodríguez[2], L. Garcia-Calvo[2], A. Carbajal[2], B. Ring[1], Y.C. Vives[3], M.H. Duvison[4], A. Crisci[1], C.O. Marieta[5], M. Jimenez[6], S. Munne[1], M. Bejar[2]

[1]MedAnswers Inc., Research Development & Analytics, San Pedro, U.S.A. ;
[2]Universitat Autònoma de Barcelona, Dpt. Animal Health and Anatomy Veterinary Faculty, Barcelona, Spain ;
[3]Complejo hospitalario Ruber Juan Bravo, Unidad de Reproducción Asistida, Madrid, Spain ;
[4]Ginemed, Reproduccion asistida en Clinicas, Seville, Spain ;
[5]CER Santander, Medicina de la reproducción, Cantabria, Spain ;
[6]Sinae, Research, Seville, Spain

Study question: Can we detect a biologically relevant quantity of **Anti-Mullerian Hormone (AMH)** in human hair samples?

Summary answer: AMH can be detected in human hair samples, and levels of AMH in hair are correlative to maternal age.
What is known already: AMH is a product of granulosa cells of the preantral and small antral follicles in women. Hence, AMH is often used as a biomarker in assessing fertility. Typically, circulating levels of AMH are tested using blood samples obtained invasively through median cubital vein punctures. Hormone concentrations in hair may serve as a comparable and possibly superior means of assaying hormone levels accrued over longer periods of time. Detection of steroid hormones in hair has been used in psychoneuroendocrinological studies in human and companion, farm and wild animals. This study represents the first quantification of AMH levels in hair in humans.
Study design, size, duration: The study design was prospective in nature. A total of **(n=152)** human female participants between the ages of **18-65 years** were included in the study over a period of 10 months (recruitment ongoing).
Participants/materials, setting, methods: Sample collection was performed in a clinical setting. Blood and hair samples were collected from patients by nurses. Hair follicles are not required. A doctor or a clinical technician performed the ultrasound for measuring the antral follicle count (AFC). Biologically active AMH was extracted from hair using a proprietary method. AMH presence in hair extract was confirmed using Western Blotting. AMH was measured in plasma and serum by ELISA.
Main results and the role of chance: AMH was successfully detected in samples (n=152) via western blots on denatured gel with bands at 70kDa. An average level of **9.37 pg/ml (95%CI 6.77-12)** was detected in hair and **3.68 ng/ml (95%CI 2.79-4.56)** in serum in **age-group <25 yrs.** This is in contrast to the age group **>39 years**, within which a mean of **3.02 pg/ml (95%CI 2.19-3.85)** AMH detected in hair and **0.92 ng/ml (95%CI 0.43-1.41)** in serum samples. AMH measured in hair correlated with age more strongly than plasma AMH **(p-value =1.26 x10-5 (hair), p-value 0.088 (serum)**). AMH levels in hair also strongly correlated with antral follicle count (AFC).
Limitations, reasons for caution: Hair is a medium that can accumulate biomarkers over several weeks, while serum is an acute matrix representing only current levels. Range of detection of AMH in hair was wide within individuals from a similar age cohort. AFC testing was included in the study laterally and has limited data points.
Wider implications of the findings: We have a novel method of detecting AMH in a longitudinal matrix (hair) that could be a more appropriate representation of hormone levels compared to acute matrices like serum or saliva. Moreover, our method is also the only truly non-invasive method for testing fertility hormones.
Trial registration number: Not Applicable

P-617 Endocrine disruptors in the serum and follicular fluid of a cohort of Italian women undergoing Assisted Reproduction Techniques

Study question: Are human oocytes exposed to common plastic Endocrine Disruptors (EDs) present in the follicular fluid (FF) and blood serum (BS) before retrieval?
Summary answer: Monobutyl-phthalate (MBP), monoethylhexyl-phthalate (MEHP) and Bisphenol A (BPA) were detected in FF and BS and associated to geographical area, source of exposure and clinical features.
What is known already: Folliculogenesis is a strictly regulated process, requiring interactions of androgenic, estrogenic and gonadotropin signalling. EDs can affect this process and, thus, reproduction by creating hormonal imbalances through different and sometimes not well-established molecular mechanisms. Few *in vitro* evidences have associated several phthalates esters and BPA to antral follicle growth inhibition. Urinary EDs are generally considered markers of exposure, but they may not reflect accurately in vivo exposure of oocytes.
Study design, size, duration: A multicentre study involving six fertility centres across Italy (Milan, Turin, Rome, Naples, Bari, Catania) was conducted between 2018 and 2019, aiming to prospectively recruit at least 120 women attending fertility treatments. EDs testing was carried out in a centralised Laboratory (Seminology Laboratory "*Loredana Gandini*"- "Sapienza", University of Rome) with a standardized collection protocol and a unique disposable material provider.
Participants/materials, setting, methods: The designated sites recruited 122 women undergoing ART living in their respective geographical area for at least 3 years, aged ≤42 years, with normal ovarian reserve (AMH≥1 ng/ml and FSH≤12 IU/L) and no active ovarian pathologies including PCOS. Subjects completed a questionnaire investigating potential sources of contamination. Blood and Follicular Fluid samples were taken for EDs measurement (MBP, MBzP, MEHP, MEHHP, MEOXP and BPA) using liquid chromatography tandem mass spectrometry (LC-MS/MS).
Main results and the role of chance: The main EDs found in BS and FF were MBP (median BS: 8.96 ng/ml, FF 6.43 ng/ml), MEHP (median BS: 9.16 ng/ml, FF 7.68 ng/ml) and BPA (median BS: 1.89 ng/ml, FF 1.86 ng/ml) which were above the limit of detection in both biological matrices in 97%, 77% and 25.4% of subjects, respectively. A significant correlation between serum and follicular concentration was present for MBP and BPA (Spearman's ρ: MBP 0.567, p<0.001; BPA 0.682, p<0.001). Multivariate analyses showed a significant interaction between serum and follicular MBP from the geographical area and the daily use of plastic food packaging (PFP) (p<0.001, partial η2=0.093). In particular, post-hoc univariate analyses detected that serum MBP concentration was significantly associated with geographical area (p<0.001, adj. mean 13.56 ng/ml, 14.40 ng/ml, 7.61 ng/ml, South, Centre and North Italy respectively) and negatively with home PFP (p=0.004), suggesting that different sources of exposure than PFP may impact more on serum MBP levels. Moreover, follicular but not serum MBP was associated with irregular cycles prior controlled ovarian stimulation (p=0.019). No association was detected between EDs and eating habits, living in the area of hazardous sites, work contact with potential toxicants and other clinical features.
Limitations, reasons for caution: Despite several potential environmental sources of EDs contamination, only a few of them were associated to EDs concentration in both serum and follicular fluid, suggesting other routes of exposure and justifying the need for more prospective investigations in larger sample size.
Wider implications of the findings: This study represents the first Italian biomonitoring of plastic EDs in FF. The finding of MBP and MEHP in follicular fluid confirms the few previous reports available from other countries. This investigation may prove to be the basis for future prospective evaluation to correlate follicular EDs concentration and oocyte quality.

P-618 IL-6/sIL-6R Increases COX-2 Expression and PGE2 Production in a Human Granulosa-Lutein SVOG Cell Line Via a JAK2/STAT3/SOCS3 Signaling Pathway

L. Saijiao[1], H.M. Chang[2], J.H. Wang[2], J. Yang[1], P.C.K. Leung[2]

[1]*Renmin Hospital of Wuhan University, Department of Reproductive Medicine Center, Wuhan, China ;*
[2]*BC Children's Hospital Research Institute- University of British Columbia-, Department of Obstetrics and Gynaecology, Vancouver, Canada*

Study question: The functional role of IL-6 in the regulation of ovarian Prostaglandin E2 (PGE_2) in human granulosa cells is controversial and the detailed molecular mechanisms remain to be elucidated
Summary answer: The IL-6 trans-signaling-induced activation of JAK2/STAT3/SOCS3 and subsequently increase COX-2 expression and PGE_2 production in hGL cells.
What is known already: As a critical paracrine regulator of multiple reproductive functions, the cytokine interleukin-6 (IL-6) is expressed in human

granulosa cells and detected in follicular fluid. At present, the functional role of IL-6 in the regulation of ovarian Prostaglandin E2 (PGE_2) is controversial. Moreover, the detailed molecular mechanisms by which IL-6 regulates the production of PGE_2 in human granulosa cells remain to be elucidated. Up to now, no reports were related to the effect of the IL-6 trans-signaling pathway on PGE2 production and need further investigation.

Study design, size, duration: Primary human granulosa-lutein (hGL) cells and a non-tumorigenic immortalized human granulosa-lutein cell line, SVOG, were used for this study. Dose, time-course, inhibitors, and siRNA were performed in this experiment.

Participants/materials, setting, methods: Primary human granulosa-lutein (hGL) cells and a non-tumorigenic immortalized human granulosa-lutein cell line, SVOG, were used for this study. The quantitative PCR and westerns blot were used to measure the mRNA, proteins, and phosphorylation of proteins expression; immunofluorescence staining was used to measure the translocation of STAT3; the small interfering RNA transfection was used to knockdown the STAT3 and SOCS3 RNA, and ELISA was used to measure the prostaglandin E2 production.

Main results and the role of chance: The IL-6 trans-signaling using the combined addition of IL-6 and soluble IL-6 receptor (sIL-6R) induced COX-2 expression and PGE_2 production in hGL cells. Additionally, IL-6/sIL-6R activated the phosphorylation of Janus activated kinase 2 (JAK2) and signal transducer and activator of transcription 3 (STAT3), induced the STAT3 nuclear translocation, which was inhibited by inhibitors AG490 (JAK2 inhibitor) and C188-9 (STAT3 inhibitor), as well as siRNA-mediated knockdown of STAT3. Moreover, the IL-6 trans-signaling-induced activation of JAK2/STAT3 unregulated the expression of suppressor of cytokine signaling 3 (SOCS3), which, in turn, negatively regulated the JAK/STAT3 signaling pathway by suppressing the activity of STAT3 and the subsequent COX-2 expression and PGE_2 production in hGL cells.

Limitations, reasons for caution: we did not study the interacting effect of IL-6/sIL-6R with gonadotropins because these hGL cells have been exposed to the high doses of gonadotropins during the clinical treatment cycles, which cause the cellular expression levels of gonadotropin receptors and the cellular response to gonadotropin could be relatively low.

Wider implications of the findings: Our findings shed light on the cellular and molecular mechanisms by which the IL-6/sIL-6R-induced JAK2/STAT3/SOCS3 signaling pathway modulates the synthesis of PGE2 in the human ovary.

P-619 Pregnancy outcomes in Turner syndrome

E. Burt[1], M. Davies[1], E. Yasmin[1], A. Cameron- Pimblett[1], G. Conway[1]

[1]University College London Hospital, Reproductive Medicine Unit, London, United Kingdom

Study question: Assessing pregnancy outcomes in women with Turner syndrome (TS)

Summary answer: Initial results show an overall high miscarriage rate, no acute cardiovascular morbidity and a 16% vertical transmission of TS.

What is known already: Turner Syndrome (TS) affects 1:2500 females and is caused by the partial or complete loss of one X chromosome. About 80% of women with TS experience primary amenorrhea and therefore the only option for fertility treatment is ovum donation (OD). The remaining 20% may have the opportunity for a spontaneous pregnancy. Pregnancy in women with TS has been associated with excess obstetric risk such as miscarriage and hypertension. Estimates for maternal mortality have varied between 0 and 2% in TS mainly due to the risk of aortic dissection but until now there was no UK data.

Study design, size, duration: Retrospective single centre cross-sectional study

Participants/materials, setting, methods: Over 850 women with TS have attended the adult TS clinic at University College London Hospital and those who had achieved pregnancy were identified. Telephone interviews were conducted to collect data regarding; mode of conception, mode of delivery, TS-specific complication such as cardiac events and hypertension and neonatal outcomes.

Main results and the role of chance: Seventy-nine women with TS had a total 136 pregnancies of which 37% were spontaneous conceptions and 63% were achieved with ovum donation (OD). The live birth rate was 58.1% and miscarriage rate 36%, and this was comparable in spontaneous and ovum donation pregnancies. There were no significant differences in the prevalence of gestational hypertension, preeclampsia and gestational diabetes between the two groups. No case of acute cardiovascular morbidity such as aortic dissection has been identified. There were 5 cases (16%) of vertical transmission of TS to daughters in those with spontaneous conception.

Limitations, reasons for caution: This is a retrospective study reliant on participant recall.

Wider implications of the findings: The higher rate of miscarriage has been previously documented but the comparable rates between those undergoing OD and spontaneous conception is reassuring. Whilst maternal cardiac morbidity has been reported, in our cohort there were no acute events identified. The 16% vertical transmission exceeds that previously recorded in the literature.

Trial registration number: n/a

P-620 miR-424 suppresses the proliferation and promotes the apoptosis of human ovarian granulosa cells by targeting Apelin and APJ expression

J. Du[1], X. Lin[1], R. Wu[1], Z. Gao[2], Y. Du[1], Y. Liao[1], J. Wu[1], W. Ke[1], S. Quan[3]

[1]Boai Hospital of Zhongshan, Reproductive Medical Center, Zhongshan, China ; [2]Boai Hospital of Zhongshan, Department of Gynecology, Zhongshan, China ; [3]Nanfang Hospital- Southern Medical University, Reproductive Medical Center-Department of Obstetrics and Gynecology, Guangzhou, China

Study question: This study aims to investigated the roles of miR-424 in modulating Apelin expression and GC functions of Polycystic ovary syndrome (PCOS) .

Summary answer: miR-424 suppresses the proliferation and promotes the apoptosis of human ovarian granulosa cells by directly targeting and inhibiting Apelin and APJ expression.

What is known already: Polycystic ovary syndrome (PCOS) development is mediated by alteration of Apelin signaling in ovarian granulosa cells (GCs).

Study design, size, duration: We aimed to investigate the roles of miR-424 in regulating Apelin and APJ receptor expression in the context of PCOS, as well as their involvement in granulosa cell proliferation and apoptosis.The follicular fluid and serum samples used for analysis were collected from patients with PCOS who were registered at the Reproductive Medical Center of Boai Hospital of Zhongshan between Jun 1st, 2015 and Dec 31st, 2018. Healthy volunteers were included as the control group.

Participants/materials, setting, methods: miRNA expression in GCs were altered by transfection with specific mimics and inhibitors. Apelin concentration was determined by ELISA, and gene and miR-424 expression were analyzed by quantitative RT-PCR. Protein abundances were measured by western blotting. Association of miR-424 with genomic sequences were validated by dual-luciferase reporter assay. Apelin gene expression was promoted by LV-003 plasmid-mediated cell transfection. GC proliferation was analyzed by MTS method, and its apoptosis were measured by flow cytometry.

Main results and the role of chance: Apelin concentration was increased in serum and follicular fluid from PCOS patients, accompanied with accelerated APJ (Apelin receptor) expression and suppressed miR-424 expression in GCs. miR-424 mimics suppressed Apelin and APJ expression in KGN cells by targeting Apelin and APJ 3'-UTR regions, which was recovered by miR-424 inhibitors. miR-424 inhibited KGN cell proliferation and cell cycle progression by down-regulating Cyclin-D/E expression. Moreover, miR-424 promoted KGN cell apoptosis by elevating truncated Caspase-3 level. The regulation of KGN cell proliferation and apoptosis by miR-424 was mediated by directly suppressing Apelin gene expression, but not the inhibition of Apelin peptide activity.

Limitations, reasons for caution: We use luteinized granulosa cells and KGN cell lines, so whether there is the same effect on non luteinized granulosa cells needs to be discussed.

Wider implications of the findings: We first revealed that miR-424 expression was greatly down-regulated in the ovarian granulosa cells from PCOS

patients, but Apelin and APJ expression showed opposite alterations, miR-424 could directly target the 3'UTR regions of both the Apelin and APJ gene in KGN cell line.

Trial registration number: not applicable

P-621 PRP in recurrent implantation failure, hope or hype !? A Prospective randomized controlled study

K.A. Ibrahim Rageh[1], A. Barakat[1], A. Mohamed[2]

[1]Al-Baraka fertility hospital, Ivf, Manama, Bahrain ;
[2]Al-Baraka fertility hospital, IVF lab, Manama, Bahrain

Study question: PRP in recurrent implantation failure, hope or hype !?

- We designed this study to evaluate the effectiveness of endometrial perfusion of PRP in improvement of pregnancy rate in RIF patients

Summary answer: The PRP significantly improved the pregnancy rate and may be a new hope for management of recurrent implantation failure; which is one of the nightmares

What is known already: The endometrial receptivity have been accepted to be major limiting factors in the establishment of pregnancy. In spite of improved almost all aspects of IVF: ovarian stimulation, embryo culture and transfer, the pregnancy rates still not satisfactory. The bottleneck is the process of implantation.

Recurrent implantation failure (RIF) is one of the nightmares in reproductive medicine and despite several strategies that have been described for management; there is no universal agreement yet.

Recently, PRPis described to promote endometrial growth and receptivity, PRP has been investigated as a therapeutic approach for several medical disorders, but its use in IVF is still limited.

Study design, size, duration: Study design;
prospective randomized controlled study
sample size ;
150 participants
duration;
from July 2018 to March 2019.

Participants/materials, setting, methods: 150 infertile women with history of RIF gave their consent to be included in this study- with age below 40 yrs, body mass index (BMI) below 30 kg/m2- from July 2018 to March 2019.Divided into 2 comparable groups; all underwent antagonist protocol, In the study group, intrauterine infusion of 0.5 to 1 ml of PRP was performed 48 hrs before blastocyst transfer, pregnancy tests were done 12 days after ET.

Main results and the role of chance: The result of our study revealed that endometrial perfusion of platelet-rich plasma (PRP) significantly improved the pregnancy rate and may be a new hope inthose patents with a history of recurrent implantation failure (RIF). Out of 75 participants in each group, 32 got pregnant (43%) in the study group after endometrial PRP infusion, compared to 11 pregnant participants (15%) in the control group.

The main strengths of our study include: (1) this is by far the first study discussing this topic in our country, as our hospital is the leader IVF center here in Bahrain. (2)The low risk of bias between study and control group as both of them were statistically comparable. (3) We exclude those patients with hematological and immunological disorders, hormonal disorders, chromosomal and genetic abnormalities and uterine abnormalities (acquired or congenital) as confirmed by HSG and U/S to limit additional factors that may affect the results of the study. (4) All Blastocyst transfers were performed under ultrasound guidance by only one expert gynecologist with infertility fellowship. (5) The use of individual patient data for direct comparison between both groups. (6) The consistency between our results and those of the previous trials in the literature.

Limitations, reasons for caution: as we are living in small country so, sample size may need to be increased in the further coming clinical trials, also at time of ET we select them phenotypically according to the embryo scoring, not based on genetic basis as we are usually not doing PGT as a routine;

Wider implications of the findings: RIF is hard to be managed, and if all available treatments fail, then PRP can add value. PRP that contains several growth factors and cytokines may improve endometrial receptivity and implantation. PRP is collected from autologous blood sample, so in comparison to G-CSF, PRP is more accessible and affordable

Trial registration number: NCT04085783

P-622 The entire range of trigger-day endometrial thickness values in fresh in vitro fertilization cycles is in direct independent correlation with the live birth rate

Y. Shufaro[1], M. Simeonov[2], Y. Lande[2], A. Ben-Haroush[3], G. Oron[3], E. Shlush[2], E. Altman[3], A. Wertheimer[2], T. Shochat[4], O. Sapir[3]

[1]Beilinson Women's Hospital- Rabin Medical Center- and the Felsenstein MRC- Tel-Aviv University, Infertility and IVF Unit, Petach-Tikva, Israel ;
[2]Beilinson Women's Hospital- Rabin Medical Center, Infertility and IVF Unit, Petach-Tikva, Israel ;
[3]Beilinson Women's Hospital- Rabin Medical Center- Tel-Aviv University, Infertility and IVF Unit, Petach-Tikva, Israel ;
[4]Beilinson Women's Hospital- Rabin Medical Center, Research Authority, Petach-Tikva, Israel

Study question: What is the association of the entire range of the trigger-day endometrial thickness (EMT) with the live birth rate (LBR) following in vitro fertilization (IVF) and fresh embryo-transfer (ET) ?

Summary answer: The entire range of EMT is in direct correlation with LBR in IVF-fresh-ET cycles, even after adjusting for age and ovarian response to stimulation.

What is known already: The association between EMT and LBR in IVF cycles with fresh ET is unclear. Some studies reported a positive association of EMT with pregnancy rates but in other studies such a correlation did not exist. There are also conflicting reports regarding the impact of an increased EMT (≥ 13 mm) on treatment outcome.

Study design, size, duration: A cohort study of all IVF cycles with fresh day-3 ET in patients age ≤42 in a single centre. LBR was calculated for all EMT values, stratified into 5 groups (≤6,7-9,10-12,13-15,and ≥16 mm), overall and within subgroups of patient age (≤35,36-40,41-42 years) and ovarian response(1-7,8-15,>16oocytes). Univariate analysis and multivariate logistic regression model were used for adjusting for various independent variables. General linear models were generated to compare continuous variables between EMT, age and oocyte groups.

Participants/materials, setting, methods: 5133 IVF cycles, performed in 2343 female patients age 42 or younger, in a single center between 2009-2017 were included. Fresh ET was performed on day 3 in all included cycles.

Main results and the role of chance: LBRs were as follows: 11.22% (35/312) in cycles with EMT ≤6mm, 17.98% (280/2114) in cycles with EMT 7-9mm, 23.44% (476/2031) in cycles with EMT 10-12mm, 25.62% (144/562) in cycles with EMT 13-15mm, and 34.21% (39/114) in cycles with EMT ≥16 mm (P <0.001). Similar findings were observed on further sub-group analysis according to patient age and ovarian response. The entire range of trigger-day EMT values in fresh cycles was found to be in direct correlation with the LBR, even after adjusting for confounders of age and ovarian response to stimulation. This observation was confirmed also by a multivariate logistic regression analysis in which the EMT was found to be a significant independent predictor of LBR controlling for various confounders. Excessively thick endometrium (≥13mm) was not detrimental, but rather beneficial, for treatment outcome.

Limitations, reasons for caution: Retrospective study, proving that EMT is an important independent prognostic factor for a favourable ART outcome. The findings of the study are relevant only for cycles in which fresh ET is performed. This study does not address the question if interventions to increase the EMT are beneficial.

Wider implications of the findings: The pre-trigger EMT is in significant independent correlation with the live birth rate. We suggest that stimulation cycles should be planned and managed to achieve maximal endometrial proliferation, and that fresh ET can be performed at high EMT values without endangering the outcome of the cycle.

Trial registration number: NA

P-623 Aberrant BMP15/HIF-1α/SCF signaling pathway in human granulosa cells is involved in the PCOS related abnormal follicular development

J. Tan[1]

[1]Jiangxi Provincial Maternal and Child Health Hospital, Reproductive Medicine Center, Nanchang, China

Study question: To explore the related regulatory mechanisms of stem cell factor (SCF) expression in PCOS related abnormal follicular development.

Summary answer: BMP15 induce SCF expression by up-regulating HIF-1α in human GCs, aberrance of this signaling pathway might be involved in PCOS related abnormal follicular development.
What is known already: Our previous studies have found that stem cell factor (SCF), which is an important granulosa cells (GCs) derived growth factor in follicular development, is significantly reduced in PCOS related abnormal follicles. However, the related regulator mechanisms of SCF expression in PCOS are still uncompleted clear. The present study is to further investigate the regulatory mechanism of SCF expression in human GCs, which can help us to better understand the abnormal development of PCOS related follicles
Study design, size, duration: The present study includes human serums, follicular fluids (FFs) and GCs were collected from 69 PCOS patients and 74 normal ovulatory patients during the IVF therapy, respectively. Human granulosa cell line (KGN) was also used in this study.
Participants/materials, setting, methods: ELISA was used to evaluate the concentrations of SCF and BMP15 in FFs and serums. KGN cells were treated with recombinant human BMP15 alone or in combination with BMP type I receptor inhibitors and transfected with hypoxia inducible factor-1α siRNA before detecting the target genes and proteins by RT-PCR and Western blot, respectively. The rates of metaphase II, oocyte, fertilization, embryo cleavage and good quality embryo between PCOS group and non-PCOS group were analyzed.
Main results and the role of chance: The results showed that the rate of MII oocyte and 2PN fertilization was significantly lower in PCOS group than those in non-PCOS group, though PCOS patients retrieved much more oocytes. No difference was observed for the cleavage rate and high-quality embryo rate between these two groups. Furthermore, the concentration of BMP15 in FF and the concentration of SCF in serum and FF were also significantly lower in PCOS patients. Interestingly, we found a weakened expression of HIF-1α and SCF in GCs from PCOS patients when compared with the non-PCOS patients. The expression of HIF-1α and SCF was significantly increased in KGN cells after treating cells with rhBMP15, However, this promotion effects of BMP15 on HIF-1α and SCF expression were obviously abolished by co-treatment with DM. Moreover, knock down of HIF-1α expression in KGN cells by transfecting cells with HIF-1α siRNA significantly reduced the expression of SCF in human GCs, in spite of activating BMP15 signaling pathway.
Limitations, reasons for caution: The present results were obtained from human GCs and KGN cell lines, which might not be fully representative of the true human PCOS environment.
Wider implications of the findings: This study showed a significantly reduction of BMP15, HIF-1α and SCF in PCOS related abnormal follicles, and demonstrated that BMP15 could induce SCF expression by up-regulating HIF-1α expression in human GCs. The aberrance of this signaling pathway might be involved in the PCOS related abnormal follicular development.
Trial registration number: not applicable

P-624 The ovarian yield – number of oocytes per antral follicular count (AFC) score and anti-Mullerian hormone (AMH) levels – does not predict ART outcome.

"Abstract withdrawn by the authors"

P-625 Hyperandrogenism regulates adipocytes expandasion and differentiation in polycystic ovary syndrome

Y. Qian[1], D. Yang[1]

[1]Sun Yat-sen Memorial Hospital, Reproductive medicine center, Guangzhou, China

Study question: What is the effect of androgen excess on adipocyte differentiation in PCOS?
Summary answer: Androgens, via the androgen receptors, exert direct effects on adipocyte differentiation and may leads to the metabolic disorder in PCOS women.
What is known already: Polycystic ovary syndrome (PCOS) women are at risk for developing metabolic syndrome, impaired glucose tolerance and cardiovascular disease. Androgen excess is a common feature among women with PCOS and has been suggested as associated with adipose tissue disturbance. We hypothesized that androgens play an important role in regulation of adipogenesis and adipocyte functions including lipid metabolism in PCOS.
Study design, size, duration: 17 women with PCOS and 24 normal women who underwent laparoscopic operation due to tubal factors were recruited. We collected omental adipose tissue samples (approximately 1 cm^3size) during the surgery and analyzed gene expression level.
Participants/materials, setting, methods: Primary human preadipocytes, isolated from omental adipose tissue, were cultured in vitro. Dihydrotestosterone-treated cells were used as study models. The regulation of adipogenesis was confirmed by Western blot and Oil Red O staining after androgen stimulation.
Main results and the role of chance: PCOS women had increased serum concentrations of testosterone (P = 0.001) and higher HOMA-IR levels (P = 0.04), with increased expression of androgen receptor (AR) in adipose tissue. In vitro studies indicated that androgens, via the AR, enhanced lipogenesis in human primary preadipocytes. DHT-treated cells produced more lipid droplets on Day8 in vitro. Dose-response experiments performed in human preadipocyte cultures showed that expression of adipogenic transcription factors CCAAT/enhancer-binding protein alpha (C/EBPα) and peroxisome proliferator-activated receptor γ (PPARγ) increased after androgen exposure.
Limitations, reasons for caution: The mechanism of adipocyte dysfunction and metabolic disorder mediated by androgen in PCOS should be further evaluated.
Wider implications of the findings: Our results suggested that adipose tissue was an important site linking androgen and metabolism in PCOS. PCOS is an androgen excess disorder associated with adipose tissue disturbances. For obese patients with hyperandrogenism, exercise accompanied with anti-androgenic therapy could be efficient than those only accept lifestyle interventions to achieve weight loss.

P-626 Vitamin D supplementation prior to initiate IVF: a randomized controlled study

M. Reschini[1], V. Sarais[2], S. Ferrari[1], G.C. Cermisoni[2], A. Paffoni[3], S. Signorelli[2], E. Papaleo[2], E. Somigliana[1], P. Viganò[2]

[1]Fondazione IRCCS Ca' Granda - Ospedale Maggiore Policlinico, Infertility Unit, Milano, Italy ;
[2]IRCCS San Raffaele, Centro Scienze Natalità, Milan, Italy ;
[3]ASST Lariana, Infertility Unit, Cantù, Italy

Study question: Does vitamin D supplementation improve pregnancy rate in women undergoing IVF?
Summary answer: In IVF cycles, Vitamin D supplementation does not increase the chances of pregnancy.
What is known already: Vitamin D plays an important role in human physiology and pathology and vitamin D insufficiency has been shown to be associated with several diseases. There is also growing evidence supporting a role of vitamin D in reproductive health, especially in female fertility. In particular, IVF success was shown to be higher in women with appropriate reserves of vitamin D. However, a causal relation has not been established and evidence from RCTs exploring the possible benefits of vitamin D supplementation is sparse, under-powered and inconsistent.
Study design, size, duration: A multicenter randomized double blinded placebo controlled study was conducted to investigate the possible benefits of vitamin D supplementation. Women referring for IVF in two ART Centres from October 2018 to January 2019 were considered for study entry. The main inclusion criterion was a serum vitamin D level <30 ng/ml. Eligible women received either Vitamin D (600.000 IU) or placebo in a single oral administration between 2 and 12 weeks before to oocyte retrival.
Participants/materials, setting, methods: Inclusion criteria of patients were: indication to IVF, age 18-39 years, ≤2 previous oocytes retrievals and BMI between 18 and 25 kg/m^2. Poor responders according to Bologna criteria were excluded as well as patients using surgically-retrieved spermatozoa. Both participants and physicians were blinded to the allocation. The main outcome was cumulative pregnancy rate per retrieval. The analysis was by intention to treat.
Main results and the role of chance: Overall, 738 patients were initially selected. Eighty-eight (12%) were subsequently excluded because their serum

vitamin D was ≥30 ng/ml and 20 (3%) declined participation after being initially selected. The remaining 630 women were randomized, 308 received Vitamin D and 322 were treated with placebo. 21 (7%) and 22 (7%) dropped-out prior to initiate the cycle, respectively. The total number of women obtaining a clinical pregnancy in treated and control women was 123 (40%) and 131 (41%), respectively (p=0.85). Women achieving ongoing pregnancies / live births were 100 (32%) and 111 (34%), respectively (p=0.59). The Relative Risk (RR) of clinical and ongoing pregnancy / live births were 0.98 (95%CI: 0.81 – 1.19, p=0.85) and 0.94 (95%CI: 0.76 – 1.17, p=0.59), respectively. When focusing on IVF cycles characteristics, no main differences emerged. In particular, duration of hyperstimulation (p=0.91), total dosage of gonadotropins administered (p=0.98), number of retrieved oocytes (p=0.22), IU of gonadotropins per retrieved oocyte (p=0.55) and fertilization rate (p=0.33) did not differ.

Limitations, reasons for caution: The mode of administration of vitamin D may be inappropriate for improving IVF outcomes. One may claim that an earlier initiation of the supplementation (5-6 months prior to initiate the cycle) and a daily administration could be effective.

Wider implications of the findings: The routine administration of vitamin D prior to initiate IVF in order to increase the probability of pregnancy is not recommended.

Trial registration number: EUDRACT 2015-004233-27

P-627 Impact of polyunsaturated fatty acid supplementation on assisted reproductive technology (ART) outcomes: a systematic review

E. Bayar[1], S. Saso[1], N. Galazis[2], B. Jones[1], T. Bracewell-Milnes[3], M. Chawla[4], Y. Ahmed-Salim[1], J. Ben Nagi[5]

[1]Imperial College NHS Trust, Obstetrics & Gynaecology, London, United Kingdom ;
[2]Northwick Park NHS Trust, Obstetrics & Gynaecology, London, United Kingdom ;
[3]Chelsea and Westminster NHS Hospital, Obstetrics & Gynaecology, London, United Kingdom ;
[4]North Middlesex University Hospital, Obstetrics & Gynaecology, London, United Kingdom ;
[5]The Centre for Reproductive and Genetic Health, Fertility, London, United Kingdom

Study question: This review explores the role of dietary polyunsaturated fatty acid (PUFA) supplementation in women undergoing assisted reproduction technology (ART) in order to guide recommendations for clinical practice.

Summary answer: There is a need for greater quality randomised control trials (RCTs) to facilitate an in depth understanding of how PUFA supplementation may impact ART success.

What is known already: Modifiable risk factors are important targets for improving reproductive health and often represent the first interventional step in maximising the chances of conception. Over recent years, diet and nutritional supplementations have received increasing attention. Women undergoing ART are frequently targeted with readily available over the counter supplementations in an attempt to boost conception chances. Fatty acids play an important role in basic cellular function and animal studies have suggested a beneficial role on oocyte quality and embryogenesis. This has led to the suggestion that PUFA supplementation may improve reproductive outcomes in women undergoing ART.

Study design, size, duration: The primary outcomes assessed included pregnancy, live birth, implantation and miscarriage rates. PRISMA guidelines were used to conduct this review. An electronic database search was performed using MEDLINE, EMBASE and the Cochrane Library to identify articles published from January 1978 to 2019. Abstracts were screened for suitability following which, full text articles were reviewed in detail. Additional studies identified through screening review articles were also considered.

Participants/materials, setting, methods: A total of 102 studies were identified through searching of databases. A further 12 studies were retrieved through manual searching and review papers. 114 papers were screened, with 90 exclusions, leaving 24 studies for full-text review. Of these, nine studies were then excluded (five papers did not address the proposed research question, three were review articles and one study was on-going). Overall 15 studies were eligible for inclusion in our systematic review.

Main results and the role of chance: In total, 15 studies met the inclusion criteria for this review, four of which were RCTs. Although the overall aim was shared between the included RCTs, meta-analysis could not be performed due to disparities between intervention including dose, content, population characteristics and measured outcomes.

Whilst most authors focus on identifying whether a health benefit of PUFA supplementation exists, potential risks must also be explored. None of the included studies explored miscarriage rates, congenital anomalies or obstetric outcomes such as birth weight and prematurity.

Importantly, a complex link between genetic variation and lipid metabolism exists, thus challenging the comparison between studies, which included different demographic groups. Gene-diet interactions must be considered but are difficult to evaluate.

Overall, there were distinct differences between population groups, study design and measured outcomes. Studies showing a benefit were of low quality and only six of the included studies assessed live birth rates as an outcome.

Limitations, reasons for caution: The main limitation was the disparity between study methodologies. Assessment of PUFA intake varied between studies; some assessed dietary intake via validated food questionnaires whilst others measured serum fatty acid or follicular fluid fatty acid concentrations. Comparison between studies was also hindered by different ART protocols used in institutions.

Wider implications of the findings: Although the ovarian micro-environment is an important contributor to conception and embryo development, there is a lack of high quality research to support dietary PUFA supplementation in women undergoing ART. In conclusion,a need exists for well-designed RCTs to facilitate the understanding of PUFA supplementation in women undergoing ART.

Trial registration number: N/A

P-628 A typical temperature patterns as an aid to identify infertility issues and miscarriage risk

M. Karoshi[1], B. Hurst, S[2], R. Milnes[3], T. Knowles[4], A. Pirrie[5]

[1]Royal Free Hospital and UCL Medical School, Gynaecology, London, United Kingdom ;
[2]Carolinas Medical Center, Department of Assisted Reproduction, Charlotte, U.S.A. ;
[3]Fertility Focus Limited, Research and Development, Warwick, United Kingdom ;
[4]University of Bristol, Faculty of Medical and Veterinary Sciences, Bristol, United Kingdom ;
[5]Fertility Focus Limited, Research & Development, Warwick, United Kingdom

Study question: To determine if ovulatory abnormalities and risk of miscarriage were associated with atypical Patterns of vaginal core body temperature (CBT) measurements from the OvuSense system.

Summary answer: Identified atypical OvuSense (OS) CBT Patterns are more likely to occur with "infertility related diagnoses" including PCOS, PCOS with regular cycles, and elevated miscarriage risk.

What is known already: Three novel, atypical CBT Patterns published previously, confirmed in updated population of 18,679 ovulatory cycles: (a) "Crash To Baseline" = first nightly averaged CBT falls by >0.2 degrees Celsius (^{0}C) to lowest cycle CBT point (baseline), (b) "False Start" = rise of >0.1^{0}C did not result in ovulation but instead a return to baseline CBT followed by ovulation two or more days later in the cycle, (c) "Crash After Ovulation" = final CBT >0.2^{0}C lower than the post ovulatory peak CBT. It is likely OS patterns closely reflect progesterone changes, hence cycle-related hormonal abnormalities may be associated with atypical patterns.

Study design, size, duration: Retrospective, longitudinal, comparative, observational study. Participants used OS vaginally at night to monitor CBT when not menstruating. The total study population (TSP) was 18,679 ovulatory cycles from 8,653 OS users recorded between March 2016 and December 2019. A detailed medical questionnaire was then issued to study participants and the answers from 375 respondents accounting for 1,491 of the TSP cycles was used for further assessment.

Participants/materials, setting, methods: TSP used to confirm prevalence of cycle Patterns (a)-(c); and questionnaire assessed per respondent for each following existing 'Diagnosis':

1. Any infertility related diagnosis
2. PCOS
3. PCOS and regular cycles
4. Previous miscarriage = gravida >0, number miscarriages >0.

Odds Ratio (OR) calculated as (a/b)/(c/d) for each Pattern + Diagnosis combination together with their 95% confidence interval: a. Positive Diagnosis (*+D*), Pattern >1 cycle for respondent (*+P*); b. *-D+P; c. +D-P; d. -D-P.*

Main results and the role of chance: The prevalence of each Diagnosis in the total respondent population of 375 was: 217 (57.9%) with 1. Any infertility related diagnosis; 156 (41.6%) with 2. PCOS; 53 (14.1%) with 3. PCOS and regular cycles (i.e. 34.0% of those with Diagnosis of PCOS report regular cycles); 145 (38.7%) with 4. Previous miscarriage. Note: respondents can potentially have more than one Diagnosis and Pattern.

(a) "Crash To Baseline" 14.0% of TSP, and 263 cycles from 164 respondents. OR: 1.44 for 1 (CI 0.95-2.18); 1.69 for 2 (1.12-2.56); 15.71 for 3 (7.90-31.23); and 6.17 for 4 (3.59-10.63).
(b) "False Start" 9.1% of TSP, and 202 cycles from 133 respondents. OR: 1.69 for 1 (CI 1.12-2.56); 2.84 for 2 (1.83-4.39); 9.52 for 3 (4.80-18.87); and 6.99 for 4 (3.89-12.57).
(c) "Crash After Ovulation" 11.4% of TSP, and 216 cycles from 128 respondents. OR: 1.10 for 1 (CI 0.71-1.70); 1.61 for 2 (1.04-2.47); 1.45 for 3 (0.80-2.62); and 7.04 for 4 (3.82-12.99).

These results indicate strong associations between reported Diagnosis and the atypical CBT Patterns identified using the OS system.

The high OR for each Pattern associated with miscarriage merits further investigation, as the cohort has a low pregnancy rate.

Limitations, reasons for caution: The authors note the co-existence of Pattern + Diagnosis is not strictly "predictive", as each Diagnosis is by definition historic. The population is by definition biased to one or more Diagnosis as over 57% of respondents report having been trying to conceive for a year or more prior to use.

Wider implications of the findings: Results suggest that atypical CBT Patterns may aid diagnosis, and in particular elevated risk of miscarriage. It should be noted that the absence of an existing Diagnosis does not necessarily render the results with positive Patterns "false", and the existence of a Pattern could anyway indicate investigation for ovulatory abnormalities.

Trial registration number: Atrium Health IRB File #03-19-16E

P-629 The Effect of Cushing's syndrome on Pregnancy Complication Rates: Analysis of More than 9 Million Deliveries

H. Baghlaf[1], A. Badeghiesh[2], E. Suarthana[2], M. Dahan[2]

[1]Toronto, Obstetrics and Gynecology, Toronto, Canada ;
[2]McGill University, Obstetrics and Gynecology, Montreal, Canada

Study question: What are maternal and fetal morbidities that increase with Cushing's syndrome (CS)?

Summary answer: CS increases risks of pre-eclampsia, blood transfusion, and operative vaginal deliveries, but unexpectedly not preterm deliveries and gestational diabetes compared to the control group.

What is known already: Cushing's syndrome (CS) rarely complicates pregnancy. This may be due to the induced infertility via alterations in gonadotropins and androgen. CS is believed to increases maternal and fetal morbidities, including preeclampsia, gestational diabetes, preterm delivery and intrauterine growth restriction. This knowledge is based solely on case reports and small case series. A recent systematic review and meta-analysis confirmed the above findings and it included only case reports and case series. Studies with control groups are lacking in the literature and this study was conducted to compare pregnancies complicated with CS to pregnancies in general population

Study design, size, duration: We conducted a retrospective population-based cohort study utilizing data from the Health Care Cost and Utilization Project-Nationwide Inpatient Sample database (HCUP-NIS) over 11 years from 2004 to 2014. We created a cohort of all deliveries between 2004 and 2014 inclusively. Within this group, all deliveries to women with CS were identified as part of the study group (n=135), and the remaining deliveries were categorized as non-CS births and comprised the reference group (n=9,096,653).

Participants/materials, setting, methods: Analysis was performed to identify the prevalence of pregnant women with CS over the study duration. Demographic and clinical characteristics were compared between women with and without CS using Chi-square test. All confounding variables were adjusted for using multivariate logistic regression, based on any significant differences between the two groups generating adjusted odds ratios (aOR).

Main results and the role of chance: We identified 9,096,788 pregnancies during the study period. CS complicated 135 pregnancies at a rate of 1-2 cases per 100,000 births. CS subjects were more likely to be older (p<0.001), obese (p<0.001), have private insurance (p<0.001), chronic hypertension (24.4% versus 1.8%, p<0.001), and pre-gestational diabetes (7.4% versus 0.9%, p<0.001). The maternal mortality rate was 0.7% and 0.007% in CS and control groups, respectively. Preeclampsia was higher in CS compared to controls after controlling for baseline risk factors, including pre-existing hypertension (aOR 2.20, 95% CI 1.18-4.41). Operative vaginal delivery and blood transfusion rates were high in CS compared to controls after controlling for confounding factors, aOR 6.49 (95% CI 4.50-9.38) and aOR 3.09 (95% CI 1.35-7.07), respectively. The rates of preterm delivery (8.9% versus 7.2%) and gestational diabetes (8.1% versus 5.8%) were not statistically different between CS and control groups, aOR 0.82 (95% CI 0.45-1.56) and aOR 0.82 (95% CI 0.44-1.56), respectively.

Limitations, reasons for caution: This retrospective analysis utilizes an administrative database, with its inherent limitations. Significant medical history or adverse pregnancy outcomes may be more often reported in patients with more significant conditions or outcomes

Wider implications of the findings: CS patients often begin pregnancies with maladies making them at risk for complications. These patients might benefit from prevention methods for preeclampsia, and increased surveillance to decrease maternal morbidity and mortality. Certain aflictions which were increased in case series were not found to be elevated in CS in this study

Trial registration number: not applicable

P-630 Early pregnancy loss in patients with polycystic ovary syndrome: in vitro maturation of oocytes versus controlled ovarian stimulation

L. Mostinckx[1], S. Mackens[1], P. Drakopoulos[1], I. Segers[1], S. Santos-Ribeiro[2], B. Popovic-Todorovic[1], H. Tournaye[1], C. Blockeel[1], M. De Vos[1]

[1]Universitair Ziekenhuis Brussel, Centre for Reproductive Medicine, Brussels, Belgium ;
[2]IVI-RMA Lisboa, Gynecology/Reproductive Medicine, Lisbon, Portugal

Study question: Is early pregnancy loss (EPL) increased in PCOS patients undergoing ICSI following in-vitro maturation of oocytes (IVM) when compared with controlled ovarian stimulation (COS)?

Summary answer: PCOS patients who achieved a pregnancy following IVM-ICSI were more at risk for EPL compared to their counterparts who were pregnant after COS-ICSI.

What is known already: Although some studies have reported comparable miscarriage rates after IVM and COS in women with PCOS, others have reported increased miscarriage rates after IVM. Nevertheless, apart from their limited sample size, many of these studies were performed using hCG-triggered IVM protocols, and patient or treatment characteristics that may contribute to EPL were not considered. Therefore, we aimed to compare EPL after non-hCG triggered IVM and COS following fresh or frozen embryo transfer in patients with a specific phenotypical diagnosis of PCOS.

Study design, size, duration: This was a retrospective, single-centre cohort study including 800 pregnant infertile women between 18 and 36 years of age with PCOS as defined by the extended Rotterdam criteria who underwent either IVM or COS between January 2010 and December 2017.

Participants/materials, setting, methods: Non-hCG triggered IVM (28-40h) after a short HP-hMG course, or conventional COS, followed by ICSI and fresh or frozen embryo transfer (ET). Only the outcome of the first ET resulting in a biochemical pregnancy was included in the analysis. The main outcome measure was EPL (biochemical pregnancy loss (BPL) + miscarriage) before ten weeks' gestation. Relevant patient characteristics were analysed in order to develop a multivariate logistic model for independent risk factors of EPL.

Main results and the role of chance: Outcomes in 329 IVM patients were compared with those of 471 COS patients. Rank of ET was comparable (0.84 ± 1.23 vs. 1.04 ± 1.64 previous ETs respectively in the IVM and COS groups). Pregnant IVM patients had higher AMH levels (11.5 ± 8.1 ng/mL vs. 7.2 ± 4.1 ng/mL, p< 0.001) compared to pregnant COS patients. Hyperandrogenic PCOS

phenotypes were more common among IVM patients (59.9% vs. 48.2%, p= 0.001). Women who were pregnant after COS had previously suffered EPL more often compared to IVM patients (28% vs. 17.6%, p= 0.003). Pregnancies after IVM were more often obtained after frozen ET (62.9%) compared to those after COS (35.2%, p< 0.001). Transfer of a cleavage stage embryo was more common in pregnant IVM patients (62.6%) compared to COS patients (32.1%, p< 0.001). The BPL rate (13.1% after IVM vs. 9.3% after COS, p=0.09) was similar, but IVM patients had a higher miscarriage rate before ten weeks' gestation (23.4% vs. 14.6%, p=0.002). In a multivariate logistic model allowing adjustment for relevant confounders, IVM was the only independent factor (adjusted OR 1.62, 95% CI 1.12-2.33) associated with increased odds of EPL.

Limitations, reasons for caution: This is a large observational study based on retrospective data collection. Despite our robust methodological approach, the presence of bias related to the retrospective design cannot be excluded.

Wider implications of the findings: The observation of an increased risk of EPL following IVM warrants further research that should result in improved IVM laboratory protocols conducive to enhanced embryo quality and improved developmental potential.

Trial registration number: not applicable

P-631 Association of ovarian stimulation with embryonic aneuploidy in in vitro fertilization (IVF) cycles: a narrative systematic review

J. Rodriguez-Purata[1], M.J. Gomez-Cuesta[1], E. Cervantes-Bravo[1]

[1]CdelaF, Clinica de la Fertilidad, Cuajimalpa de Morelos, Mexico

Study question: Is there an association of controlled ovarian stimulation (COS) with embryonic aneuploidy in IVF cycles coupled with preimplantation genetic testing (PGT)?

Summary answer: Although even natural cycles are associated with aneuploidy, more robust stimulations are associated with aneuploidy. Nevertheless, a higher response is associated with more euploid embryos.

What is known already: According to recent literature, the impact of COS on the rate of embryo aneuploidy in patients without the negative effect of age acting as a confounding factor is still a subject of lively debate. Moreover, embryo aneuploidy is present even in unstimulated cycles, suggesting that, either this is the real incidence in human beings, or there are factors other than COS related with the IVF procedure which may increase this incidence in comparison with in vivo fertilization. A systematic review of the available evidence is needed to provide a succinct analysis of the most relevant findings to date.

Study design, size, duration: The study adhered to the PRISMA guidelines. A systematic search for studies was performed at MEDLINE, ClinicalTrials.gov, PubMed, Embase, CINAHL and Cochrane Library. . Searches were coordinated by an expert librarian and a statistician in March'19. Search updates were conducted in July'19. The PICO model was used to select the study population. The search retrieved 73 citations, and 15 were eligible for analysis (4805 cycles). Average quality Newcastle-Ottawa scale (NOS) score was 8.

Participants/materials, setting, methods: Women/couples who underwent COS for an IVF cycle to genetically analyze her/their embryos through PGT were included. There were no restrictions in the amplification method, or the platform used to analyze the amplified DNA. Included studies were additionally subclassified according to the protocol of stimulation. Within subgroups, special attention was put to oocytes retrieved, average and total number of euploid embryos, and proportion of euploid/aneuploid embryos. When possible, an intention-to-treat (ITT) analysis was performed.

Main results and the role of chance: A clear direct correlation between COS and embryonic aneuploidy was not found. Studies have exposed that absence of COS does not rule out the occurrence of aneuploidy. It is important to consider that when only analyzing patients that reach biopsy-stage or had at least one embryo biopsied, we are excluding patients who are at the higher risk of producing an aneuploid embryo: older patients or with low-quality oocytes/embryos. Although there is evidence to believe that fewer oocytes retrieved render better quality under similar dose, more robust studies have proved that aneuploidy rate did not increase with ovarian response or gonadotropin dosage. Particularly, no differences were found when using an agonist or antagonist protocol. Nevertheless, FSH-only stimulations influenced aneuploidy rates under a long-agonist, but not under an antagonist protocol. Trigger medication (hCG vs GnRH-agonist) was not predictive of aneuploidy. Among the studies associating ovarian response to aneuploidy, only Haaf et al reported an increased aneuploidy rate, although statistical limitations were observed. All other 6 studies reported similar results, concluding that ovarian response did not alter the euploidy rate or the total number of euploid embryos. Moreover, a case can be made towards better results with an increasing number of biopsied embryos.

Limitations, reasons for caution: Only one RCT has been performed. Even though the quality of the rest of the studies is high, bias associated to retrospective studies cannot be ruled-out. Studies presented a large diversity in the assessment of embryonic aneuploidy, and, given the great heterogeneity between studies, a meta-analysis could not be performed.

Wider implications of the findings: Due to the fact that the number of euploid embryos available for transfer increases as the number of oocytes obtained does, considering the absolute number of euploid embryos seems more relevant than the proportion of euploid/aneuploid embryos, especially when cumulative LBR outcome is ascertained as the optimal outcome.

Trial registration number: CRD42019120803

P-632 Poor ovarian reserve and response are associated with interleukin 10 levels in women undergoing in-vitro fertilization

A.M. Fabregat Reolid[1], M. Hortal[1], B. Lledó[1], J.A. Ortiz[1], A. Bernabeu[2], J. Llácer[2], R. Bernabeu[2]

[1]Instituto Bernabeu, Biotech, Alicante, Spain ;
[2]Instituto Bernabeu, Reproductive Medicine, Alicante, Spain

Study question: Are cytokines related to ovarian reserve and response in ART?

Summary answer: Interleukin-10 is strongly and positively related to ovarian reserve and response parameters, providing a potential new tool in the prediction of controlled ovarian stimulation outcome

What is known already: Previous studies reported differences in the levels of IL-2, Il-6, IL-8, IL-10 and VEGF in follicular fluid between young patients with low ovarian response and normoresponder women. Cytokine levels have also been analyzed in women with low ovarian reserve who have Hodgkin lymphoma, obtaining a negative correlation between AMH, SIL-2R, IL-6 and IL-8 levels. Although there seems to be some evidence about the possible effect of the immune system on ovarian function and implantation, the role it plays in the success of ART remains unknown. Our aim was to investigate the effect of cytokines in ovarian reserve and response

Study design, size, duration: One hundred and twenty-six patients were included in a retrospective study between February 2016 and November 2018. Cytokines IL-2, IL-4, IL- 6, IL-8, IL-10, VEGF, IFNγ, TNFα, IL-1α, IL-1β, MCP-1 and EGF were measured previously to the ovarian stimulation cycle. Patients with abnormal results of karyotype and/or FMR1 gene or with any other factor that could alter the ovarian reserve or response were excluded from the study

Participants/materials, setting, methods: To measure the levels of the different cytokines, a sandwich immunoassay with specific antibodies for the cytokines IL-2, IL-4, IL-6, IL-8, IL-10, VEGF, IFNγ, TNFα, IL -1α, IL-1β, MCP-1 and EGF were used. The statistical analysis was performed with the Software Statistical Product and Service Solutions, version 20.0 (SPSS, Chicago, IL, EE.UU.)

Main results and the role of chance: We found that the most related cytokine with the different ovarian reserve and response markers is interleukin-10. It significantly correlates with AMH (p=0.011), antral follicle count (p<0.001), total oocytes (p<0.001) and MII retrieved (p=0.019). Statistically significant relationships had also been found between antral follicle count and IFN- γ (p=0.036), total oocytes with IL-6 and TNF- α (p=0.012 in both cases) and MII retrieved with IL-6 and TNF- α (p=0.043 and p=0.014, respectively). Through multivariate analysis, we obtained a model able to predict 49.9% of the variability in the number of total oocytes recovered using only 3 variables: age, antral follicle count and interleukin 10 levels. Statistical differences were observed when we compare patients with interleukin 10 below or above the threshold of 0.5 pg/ml in the mean number of total oocytes (6.52 versus 11.05; p<0.001) and MII retrieved (4.45 versus 8.05; p<0.001). Moreover, in women with interleukin 10 below 0.5 pg/ml, the dose of gonadotropins and the number of total oocytes recovered is not associated (p=0.495). Therefore, a higher dose of gonadotropins is not related to a better ovarian response in these patients

Limitations, reasons for caution: The retrospective study design and the sample size could be a limitation. The study was performed in patients with suspected implantation failure or endometriosis. Despite the strong relationship

of interleukin 10 with ovarian reserve and response, we cannot determine its role in the ovary, beyond its immunomodulatory function
Wider implications of the findings: Interleukin 10 level is lower in patients with low ovarian reserve and response compared to normoresponder patients. Moreover, if the interleukin 10 level is below 0.5 pg/ml, tailoring the treatment might not improve the outcome. In conclusion, interleukin 10 could be used as a biomarker to predict the ovarian response
Trial registration number: Not applicable

P-633 Could follitropin delta individualized dose, reduce the overall ovarian hyperstimulation syndrome risk (OHSS)?

A. VAZQUEZ SARANDESES[1], L. De la Fuente Bitaine[1], L. Marqueta Marquez[2], M. Abad[1], M. Carrera Roig[1]

[1]Hospital Universitario 12 de Octubre, reproductive medicine, madrid, Spain ; [2]Hopital Universitario 12 de Octubre, Reproductive Medicine, Madrid, Spain

Study question: Does the individualization of the starting dose of follitropin delta reduce the OHSS risk in selected patients at risk of high response to stimulation
Summary answer: Individualized dosing with follitropin delta (d-FSH) significantly reduced the risk of OHSS, allows more women to undergo fresh embryo and those embryos had better quality
What is known already: OHSS is an iatrogenic and potentially life-threatening complication of ovarian stimulation. It mostly occurs in patients at risk of presenting a high response to stimulation, *"high responders"*: antral follicle count (AFC), high serum levels of anti-müllerian hormone (AMH) or number of oocytes retrieved greater than 15. Managing each woman's risk of OHSS while maximizing her potential for a successful outcome constitutes one of the major clinical challenges in IVF treatment. Delta follitropin is administered according to an individualized dosing algorithm based on serum AMH levels and body weight, that seeks to administrate the most accurate dose to each patient.
Study design, size, duration: January 2017-December 2019, we included women aged 18–40 with regular ovulatory cycles and diagnosed with tubal infertility, unexplained infertility, endometriosis stages I/II or with partners with male factor infertility, that underwent a previous cycle using recombinant follicle-stimulating hormone(rFSH) and met one of the criteria for high responders. We performed a study with intrasubject measurements, to evaluate the changes in the response after each controlled ovarian stimulation(COS):1stcycle with rFSH Vs. 2ndcycle with d-FSH
Participants/materials, setting, methods: We collected data following a pre-post design and we compared the differences between each patient both cycles. T-student and χ^2 test were used to analyze quantitative and categorical variables respectively. Baseline characteristics and stimulation parameters were measured: age, BMI, duration of infertility, length of stimulation, antral follicle count(AFC), dose of rFSH and dFSH, pre-ovulatory follicle count(PFC), E_2 serum level previous to trigger, follicular output rate(-FORT), oocytes retrieved, metaphaseII oocytes, cleaved embryos, and endometrium thickness.
Main results and the role of chance: A total of 50 women (100 cycles) were included. We present the following values as mean± standard deviation: Age 32,9 (SD±), BMI 24,7 (4,2), AFC 20,8 (6,2), duration of infertility 34,7 months (19,1). Hormones were measured at cycle day 2-3 before starting each stimulation: AMH 6,4 (3,8). The mean individualized starting dose of rFSH was 149,3IU (45,6) whereas for dFSH was 7,7IU (1,9).
We observed significant difference between the length of the stimulation being shorter the rFSH one (**9,4**Vs.10,2 ***p0,031***) but no difference was found when comparing the use of dual trigger: Triptorelin plus Human chorionic gonadotropin (11 Vs.15 *p0,360*). We found no significant difference according to antagonist administration days (5,4Vs.5,04 days *p0,134)*, endometrial thickness (9,2Vs9,6 *p0,603*), PFC (10,1Vs.9,54 *p0,512*), FORT (53,7%Vs.48,7% *p0,616*), punctured follicles (15,1Vs.13,7 *p0,153*), retrieved oocytes (11,4Vs.10,2 *p0,246*), metaphase II oocytes (8,1Vs.7,1 *p0,193*), total cleaved embryos (1,9Vs.1,8 *p0,193*). No significant difference was observed between groups regarding cumulative pregnancy rate (34,4% Vs. 13,1%, *p0,08*).
However, we observed significant differences when comparing the E_2 serum levels (2600ng/mlVs.**1867ng/ml, *p0,031***) significantly lower with dFSH, number of grade A fresh embryos (0,06 Vs**. 0,2 *p0,045***), greater rate of fresh embryo transfer (38,8%Vs.**60,4% *p0,030***) and lower embryo freezing rate (30,6%Vs. **14,6% *p0,041***).
Limitations, reasons for caution: In these types of studies the investigator may incur in some manipulation about the exposure, as each subject acts as their own control. The degree of certainty also decreases since between pre-test and post-test there could have been other circumstances that alter the results. Also the population size is small.
Wider implications of the findings: dFSH might be useful in selected patients at risk of high response to stimulation in which we seek to minimize risks but still guaranteeing good results. Lower E_2 levels, greater rate of fresh embryo transfer and lower freezing rate were obtained in high responders
Trial registration number: 123

P-634 Transrectal ultrasound-guided oocyte retrieval and a successful IVF treatment outcome in a patient with vaginal agenesis.

D. Makhadiyeva[1], A. Ibragimov[1]

[1]Ecomed clinic, Reproductive medicine, Nur-Sultan, Kazakhstan

Study question: To report a case of a transrectal approach for an oocyte retrieval procedure in a patient with vaginal agenesis receiving *in-vitro* fertilization (IVF) treatment.
Summary answer: Transrectal ultrasound(US)-guided oocyte retrieval could be a valuable approach to achieve IVF pregnancy with a surrogate mother in a patient with complete vaginal agenesis.
What is known already: Despite of inability to child bear in the majority of patients with vaginal agenesis due to absence of normal reproductive tract, medically assisted reproduction is possible. Ovaries are usually present and patient's oocytes could be harvested and used in IVF. The challenge lies in oocyte retrieval procedure with complete absence of vagina. Abdominal US-guided oocyte retrieval including percutaneous transvesical, transurethral transvesical and transabdominal-transperitoneal have been previously reported as well as laparoscopy-guided oocyte retrieval in a patient with Müllerian agenesis. As of 2019 there have not been any published reports of transrectal approach in oocyte retrieval in humans.
Study design, size, duration: Case report of a patient with vaginal agenesis who undergone IVF treatment for primary infertility at a private reproductive medicine clinic.
Participants/materials, setting, methods: A 35-year old patient with a history of vaginal agenesis and hysterectomy presented with primary infertility. She was considered for transrectal US-guided oocyte retrieval and IVF with a standard controlled ovarian stimulation with recombinant follicle stimulating hormone and luteinizing hormone covered by gonadotropin-releasing hormone (GnRH) antagonist. When follicles were >15mm in mean diameter recombinant human chorionic gonadotropin (hCG) was administered to retrieve oocytes 36 hours later. A 22-year old woman served as a surrogate mother.
Main results and the role of chance: Following two short protocols of an ovarian stimulation and special preoperative bowel preparation with cleansing enema 5 oocytes (3 in the first cycle and 2 in the second cycle) were recovered transrectally under general anaestesia and subjected to IVF. There were no immediate or delayed postoperative complications. Transrectal approach for oocyte recovery was performed by an experienced urology and reproductive medicine specialist who had been operating transrectally urological patients in the past.
Normal fertilization was confirmed in 4 oocytes the next day. There were four (two in each IVF cycle) 6-9 cell Grade I embryos vitrified on day three postoocyte retrieval procedure. A few months later frozen-thawed embryo transfer of two embryos was performed following endometrial preparation with oestrogen in a healthy surrogate mother. A singleton intrauterine clinical pregnancy was confirmed four weeks later. Hormonal supplementation was continued until antenatal booking appointment. The pregnancy was uncomplicated and a healthy baby boy was delivered at term in August 2019.
Limitations, reasons for caution: a unique case of a rare condition
Wider implications of the findings: Transrectal approach may be useful in a select number of patients with vaginal agenesis who could not be eligible for previously reported abdominal methods of oocyte retrieval.
Trial registration number: not applicable

P-635 Premature ovarian insufficiency patients with viable embryos derived from autologous oocytes through repeated oocyte retrievals could obtain reasonable cumulative pregnancy outcomes following frozen-embryo transfer

X. Zhu[1], Y. Fu[2]

[1]Shanghai Ninth People's Hospital, Department of Assisted Reproduction, Shanghai, China ;
[2]Shanghai First Maternity and Infant Hospital, Department of Assisted Reproduction, Shanghai, China

Study question: To estimate cumulative pregnancy outcomes following frozen-embryo transfer (FET) in premature ovarian insufficiency (POI) patients undergoing in-vitro fertilization (IVF)/ intracytoplasmic sperm injection (ICSI) treatments with autologous oocytes.
Summary answer: Cumulative pregnancy outcomes following FET were reasonable for POI patients using autologous oocytes who could obtain viable embryos through repeated oocyte retrievals.
What is known already: Women with POI are often discouraged from using autologous oocytes because of the high cancellation rate during ovarian stimulation, the small number of available oocytes, the potential for poor oocyte quality, and the large economic burden in IVF cycles. Thus, oocyte donation is recommended to increase the chances of pregnancy in this population, which is still limited or even prohibited because of cultural, religious, or ethical issues in some countries. Additionally, some POI patients have a strong desire to be genetically linked to their offspring and insist upon pursuing IVF with their own eggs, despite the slim chances of success.
Study design, size, duration: This was a retrospective case-control study conducted in Department of Assisted Reproduction of the Ninth People's Hospital affiliated with Shanghai JiaoTong University School of Medicine between January 2012 and June 2019. Only patients undergoing IVF/ICSI treatments with a freeze-all strategy were screened, and 103 POI patients were matched with 515 normal controls in terms of the same number of viable embryos at the same embryonic age.
Participants/materials, setting, methods: The number of viable embryos was defined as the sum of all embryos obtained through repeated oocyte retrievals in POI patients, while it referred to embryos obtained from the first oocyte retrieval cycle at our centre for the control group. The embryonic age in the control group was considered as the age of women when the first viable embryo was obtained. The main outcome was cumulative clinical pregnancy rate (CCPR) following FET per patient.
Main results and the role of chance: Patients with POI and normal ovarian reserve had a comparable CCPR of 62.14% (64/103) and 65.24% (336/515), respectively (P = 0.547), and no statistical difference was found in the cumulative live-birth rate (CLBR) between the 2 groups (43.69% vs. 53.01%, P=0.084). Based on binary logistic regression, the CCPR and CLBR showed no association with the group (POI or normal ovarian reserve), whereas the numbers of embryos per transfer and the sum of all viable embryos per patient were positively associated with the CCPR and CLBR. The increase in the age of viable embryos was negatively related to the CLBR (OR, 0.944; 95% CI, 0.904–0.986; P=0.01 for the unadjusted model, and OR, 0.944; 95% CI, 0.903–0.986; P=0.009 for the adjusted model), while it had no relation to the CCPR. The clinical pregnancy rate (CPR) per FET cycle was 38.17% for the study group and 52.1% for the control group, while the CPRs per OPU cycle in the 2 groups were 11.25% and 69.9%, respectively; both were statistically different (P < 0.05). Moreover, POI patients had a lower implantation rate (27.8% vs. 37.94%) and higher early miscarriage rate per transfer (26.76% vs. 15%) than patients in the control group (P<0.05).
Limitations, reasons for caution: Only POI patients from whom viable embryos could be obtained were included, and the sample size was small. In addition, the primary outcome was calculated by the number of patients in our study instead of the number of oocyte retrieval and FET cycles in other published articles.
Wider implications of the findings: Our data may provide valuable information for POI patients who insist on using their own oocytes, and the method of repeated oocyte retrievals and FET may be beneficial for the treatment in POI patients.
Trial registration number: Not applicable

P-636 Is successful oocyte retrieval dependent on physician experience in natural IVF cycles?

S. Ertas[1], M. Ateskan[2], O. Bulduk[3], I. Keles[4], B. Balaban[3], K. Yakin[4]

[1]American Hospital, Women's Health Center, Istanbul, Turkey ;
[2]American Hospital, Asisted Reproduction Unit, Istanbul, Turkey ;
[3]American Hospital, Assisted Reproduction Unit, Istanbul, Turkey ;
[4]Koc University, Assisted Reproduction Unit, Istanbul, Turkey

Study question: Should follicle aspirations in natural IVF cycles be performed by only experienced clinicians?
Summary answer: Junior physicians are as good as their seniors are and even more tenacious in retrieving oocytes that develop into transferrable embryos in natural IVF cycles.
What is known already: Inexperienced clinicians may fail to retrieve the one and only oocyte available during natural cycle ICVF treatment.
Study design, size, duration: A retrospective analysis of 226 oocyte pick-up (OPU) procedures performed for natural IVF cycles between 2016-2018. Data regarding female age, time spent for oocyte retrieval, physician performing the procedure, oocyte maturity, fertilization, embryo transfer and pregnancy were extracted from the electronic database.
Participants/materials, setting, methods: Physicians were categorized based on their years of experience as senior (≥10 years, n=6), intermediate (1-10 years, n=4) and junior (<1 year, n=6). The time spent for oocyte retrieval was calculated from the entrance and withdrawal of the aspiration needle through the vaginal fornix. All OPU procedures were performed using a double lumen 17G needle and 180 mmHg aspiration pressure, under general anesthesia. Student's t test and chi-square test were used where appropriate.
Main results and the role of chance: Out of 226 OPU procedures, a single oocyte was harvested in 179 (79.2%) and the oocyte was in M-II stage in 156 (69%). The mean female age was 40.1 ± 4.6 years (27-46). The mean duration of the procedure was 586.6 ± 270.7 seconds (126-1288) and it was shorter (537.2 ±249.1 versus 777.7 ± 269.1 seconds, p<.001) when the oocyte could be retrieved. The rate of successful retrieval and the mean time to retrieve the oocyte were similar among physicians irrespective of their experience however, senior physicians terminated the procedure earlier when no oocyte could be obtained. The fertilization rate was 52.6% (82/156). Neither the rate of fertilized oocytes nor transferrable embryos were related with the experience of physicians. Among 66 women who had embryo transfer, 10 (15.1%) were pregnant.
Limitations, reasons for caution: This is a retrospective analysis from a single center and does not intend to confirm any causality.
Wider implications of the findings: Junior physicians are on a par with their seniors in retrieving oocytes in natural IVF cycles.
Trial registration number: Not applicable

P-637 Herbal medicine in women undergoing in vitro fertilization/ intracytoplasmic sperm injection: A systematic review and meta-analysis

J.Y. Jo[1], C.Y. Kwon[2], B. Lee[3], S.H. Lee[4]

[1]Conmaul Hospital of Korean Medicine, Korean Obstetrics and Gynecology, Seoul, Korea- South ;
[2]Kyung Hee University, Clinical Korean Medicine- Graduate School, Seoul, Korea- South ;
[3]Korea Institute of Oriental Medicine, Clinical Medicine Division, Daejeon, Korea- South ;
[4]Kyung Hee University, Pediatrics of Korean Medicine, Seoul, Korea- South

Study question: Does herbal medicine (HM) improve the live birth rate (LBR) and clinical pregnancy rate (CPR) in infertile women undergoing in vitro fertilization (IVF)/intracytoplasmic sperm injection (ICSI)?
Summary answer: Our analysis finds a benefit of HM in women undergoing IVF/ICSI.
What is known already: Combination of IVF and HM has widely used in Asian countries. A previous systematic review suggested that combination of IVF and CHM used in the included trials improve IVF success, however, high risk of bias observed with the trials and there were no studies that reported live birth rate (LBR).
Study design, size, duration: A systematic review and meta-analysis of randomized controlled trials (RCTs) (until September 2019) that evaluated the effects of HM as an adjunct to IVF was conducted.

Participants/materials, setting, methods: Studies were considered for inclusion if they were RCTs; included infertile women who were undergoing IVF/ICSI; compared the effectiveness of HM administrated immediately before, during and/or after IVF with placebo, no treatment, or other active treatments; and reported at least one of the pregnancy outcomes including LBR, ongoing pregnancy rate, and CPR.
Main results and the role of chance: From a total of 43 RCTs involving 4316 participants, HM was more likely to increase LBR (5 studies; risk ratio (RR) 1.34, 95% confidence intervals (CI): 1.05 to 1.72, P = 0.02) and CPR (35 studies; RR 1.38, 95% CI: 1.29 to 1.49, P < 0.00001) than not receiving adjunctive treatment. The CPR in HM treatment group was also improved when compared with that of the placebo group (5 studies; RR 1.85, 95% CI: 1.42 to 2.42, P < 0.00001). However, compared with active controls, HM did not significantly improved CPR (RR 1.19, 95% CI: 0.71 to 2.01, P = 0.51). Sensitivity analyses restricting to RCTs with high quality did not influence the results: HM improved LBR (2 studies; RR 1.86, 95% CI 1.24 to 2.80, I^2=0%) and CPR (30 studies; RR 1.42, 95% CI 1.30 to 1.54, I^2=0%), compared to no adjunctive treatment. HM also increased CPR (2 studies; RR 1.77, 95% CI 1.19 to 2.63, I^2=0%), compared to placebo. Reported adverse events such as miscarriage, ectopic pregnancy rate and incidence of ovarian hyperstimulation syndrome were not significantly different between the HM and control group.
Limitations, reasons for caution: Given poor reporting and methodological weaknesses of the existing studies, large-scale, long-term RCTs with rigorous methodological input are needed to clarify the role of HM in this population.
Wider implications of the findings: There is promising evidence from the currently available RCTs to judge the effectiveness and safety of HM on pregnancy or childbirth outcomes in women undergoing IVF.
Trial registration number: not applicable

P-638 Late-follicular phase elevated serum progesterone is associated with embryo quality but not cumulative live birth in IVF/ICSI

C. Minghui[1], G. Jun[1], L. Lu[1], M. Qingyun[1], X. Yanwen[1], C. Zhou[1]

[1]the First Affiliated Hospital of Sun Yat-sen University, Reproductive Medicine Centre, Guangzhou, China

Study question: Is late-follicular phase elevated serum progesterone (LFEP) associated with cumulative live birth when freeze-all strategy was adopted in patients with LFEP during IVF/ICSI?
Summary answer: Late-follicular phase elevated serum progesterone is not associated with cumulative live birth when freeze-all strategy was adopted in patients with LFEP during IVF/ICSI.
What is known already: Late-follicular phase elevated serum progesterone during IVF/ICSI detriment endometrium receptivity and impede embryo implantation. It is unclear whether late-follicular phase elevated serum progesterone still disadvantage cumulative live birth when freeze-all strategy was adopted in patients with late-follicular phase elevated serum progesterone during IVF/ICSI.
Study design, size, duration: This is a retrospective cohort study; A total of 6076 ovarian stimulation cycles and 5461 women who underwent IVF/ICSI treatment in our hospital from January 2016 to December 2017 were identified and reviewed.
Participants/materials, setting, methods: All the embryos were freezed in cycles with progesterone levels on trigger day higher than 1.50 ng/ml. Cumulative live birth rate was defined as the first live birth per ovarian stimulation cycle including fresh and frozen cycles and evaluated by group. Multivariable linear regression and binary logistic regression was used to assess the association between progesterone levels on trigger day and embryo quality and cumulative live birth after adjusting for confounding factors.
Main results and the role of chance: The cumulative live birth rate in cycles using GnRH agonist protocol was 52.7%, 58.3%, 59.9%, 49.2% and 50.0% (P=0.008); the CLBR in cycles using GnRH antagonist protocol was 38.5%, 51.2%, 51.7%, 62.9% and 37.5% (P<0.001) with progesterone level on trigger day ≤0.50, 0.51–1.0, 1.01-1.50, 1.51-2.00 and ≥2.01 ng/ml respectively. Progesterone level on trigger day was not associated with cumulative live birth (OR 0.946, 95%CI 0.773-1.158, P=0.589) after adjusting female age, thickness of endometrium on the hCG trigger day, ovarian stimulation protocol, the number of viable embryo and high-quality embryo. The progesterone level on trigger day was negatively associated with the number of viable embryo (B=-0.513, P<0.001) and high-quality embryo (B=-0.492, P<0.001) after adjusting female age and the number of mature oocyte.
Limitations, reasons for caution: As a retrospective study, our analysis depended on previously recorded data. The conclusion is limited to achieve one live birth per ovarian stimulation cycle.
Wider implications of the findings: Although late-follicular phase elevated serum progesterone does not affect the possibility to achieve one live birth per ovarian stimulation cycle, it may adversely affect the total live birth per ovarian stimulation cycle because it was associated with a decrease in number of viable embryo and high-quality embryo.
Trial registration number: N/A

P-639 Segmentation (elective freeze all) results in higher clinical pregnancy rates in women with high AMH (> 30 pmol/L)

F. Roebuck[1], P. Ambrose[2], L. Munn[2], T. Hamilton[2], C. Noble[1], J. Lyon[3], M. Gaudoin[4], R. Fleming[3]

[1]GCRM Fertility, Embryology, Glasgow, United Kingdom ;
[2]GCRM Fertility, Nursing, Glasgow, United Kingdom ;
[3]GCRM Fertility, Biochemistry, Glasgow, United Kingdom ;
[4]GCRM Fertility, Medical, Glasgow, United Kingdom

Study question: To determine if segmentation in high responder women resulted in higher clinical pregnancy rates (CPR) in the first frozen embryo transfer than with fresh transfer.
Summary answer: The CPR was higher in the first frozen embryo transfer (FET) compared to the fresh transfer in women with high AMH levels (P < 0.001).
What is known already: Pregnancy rates appear to be lower in GnRH-antagonist-controlled cycles, possibly because of greater endometrial sensitivity to circulating progesterone (Bosch et al, Fertil Steril, 2015).
Segmentation is probably not beneficial in ovulatory women with normal AMH levels (Vuong et al, NEJM, 2018) but might be beneficial in anovulatory women, especially as this latter group has an increased risk of ovarian hyperstimulation syndrome with a fresh embryo transfer (Roque et al, Hum Reprod. Update, 2019).
Study design, size, duration: Historical data from our centre showed a very modest CPR with fresh embryo transfer in women with high AMH using GnRH-antagonist control but substantially higher CPR with their subsequent frozen transfer.
From January 2019 we prospectively elected to culture all such patients to blastocyst and vitrified all suitable embryos for a subsequent frozen embryo transfer to determine if the subsequent first frozen transfer was superior to the historical fresh transfer outcomes.
Participants/materials, setting, methods: All patients with AMH ≥ 30 pmol/L received Menopur (Ferring Pharmaceuticals) using GnRH-antagonist control. The primary outcome was CPR in the women having a GnRH-trigger, undergoing segmentation and having their first frozen embryo transfer from January – October, 2019 (N = 81, Group-Seg^n). This was compared with the historical outcomes of the same subgroup of women in the preceding 2 years (but with HCG triggering) and a fresh embryo transfer (N = 158, Group-Hist).
Main results and the role of chance: There was no difference in age (Group-Hist = 34.1 ± 4.5 years, Group-Seg^n = 34.6 ± 3.7 years, P = 0.39), BMI (25.7 ± 7.0 vs. 26.5 ± 6.4, P = 0.39) or AMH (48.5 ± 21.0 vs. 46.5 ± 18.8, + P = 0.47). Group-Seg^n stimulated for longer (9.4 ± 2.2 days vs. 8.5 ± 0.7, P < 0.001), received more FSH (1402 ± 324 vs. 1275 ± 106, P < 0.001) and more eggs were retrieved (16.6 ± 8.4 vs. 13.6 ± 6.8, P = 0.003). Group-Seg^n got more 2PN embryos (10.1 ± 6.0 vs. 8.5 ± 5.3, P = 0.035) but there was no difference in the mean number of embryos transferred (1.1 ± 0.3 vs. 1.2 ± 0.8, P = 0.28). Group-Seg^n had a higher implantation rate (IR, 48% vs. 26%, P < 0.001) and higher CPR (heartbeat on scan at 8 weeks' gestation, 52% vs. 27%, P < 0.001).
This was a prospective study comparing an additional intervention with historical data. The groups appeared to be evenly matched morphometrically although, because there was little fear of ovarian hyperstimulation syndrome when using a GnRH-agonist trigger, Group-Seg^n were stimulated for longer and received more FSH.
Limitations, reasons for caution: We cannot as yet determine if the cumulative pregnancy rate/live birth rate from a single fresh treatment cycle will be equivalent.

Wider implications of the findings: In our study population, segmentation conferred benefit in terms of IR and ongoing CPR compared with a fresh embryo transfer. Our study population was older than other widely-cited studies so it is imperative that individual clinics examine their internal data to determine if a segmentation approach might benefit their patients.
Trial registration number: N/A

P-640 Ovarian sensitivity index -a novel marker of ovarian responsiveness in IVF cycles

C. JANDIAL[1], S. Malik[1], V. Bhatia[1], V. Prakash[1], S. Talwar[1]
[1]southend Fertility and IVF - NEW DELHI, IVF, NEW DELHI, India

Study question: To validate the use of OSI as measure of ovarian response during IVF cycles by correlating it with age, AMH ,AFC , total dose of gonadotropins and quality of embryos
Summary answer: OSI can be used as dynamic marker for ovarian reserve, a guide for gonadotropin dose in future IVF cycles and predictor of good quality embryos
What is known already: In Controlled Ovarian Stimulation, different women respond differently to similar doses of gonadotropins . Preliminary studies have suggested that a threshold level of gonadotropins may exist and no more competent oocytes are obtained if exceeded. Recent studies, on the contrary, indicate that high ovarian response to gonadotropins is not so detrimental. The key point is , not the gonadotropin dose or ovarian response alone, but a combination of these two , is important .This is the concept addressed in the ovarian sensitivity index. High OSI means, more oocytes are retrieved with fewer gonadotropin doses and offers best pregnancy outcomes
Study design, size, duration: This is a retrospective, single centre study which included 256 women over a period of one year.
Participants/materials, setting, methods: Retrospective analysis which included 256 women with age < 42 years , no previous history of ovarian surgery, chemoradiation and had no endocrine disorders. Baseline scan was done to determine the AFC. Subjects were treated with either long agonist / antagonist protocol as per clinical and biochemical markers. OPU was done 36 hours after trigger injection. Ovarian sensitivity Index was calculated and corelated with age, AMH, AFC, Total dose of Gonadotropins and top quality embryos
Main results and the role of chance: Out of 256 women enrolled in the study with a mean age of 32 years,175(68.36%) were a case of primary subfertility with an average duration of 4 years.208 women received antagonist protocol .Mean number of oocytes retrieved were 8.Statistical analysis as per Pearson's Correlation Coefficient showed a negative correlation of OSI with age and positive correlation with AMH and AFC (p value-0.0000).Positive correlation (0.8162,p value 0.000) was observed with number of oocytes recovered and top quality embryos (0.4 and 0.3,p values 0.0000 and 0.0000 respectively. Further analysis of data revealed that as OSI increases the mean number of top quality embryos increases
Limitations, reasons for caution: A retrospective analysis, single centre, smaller group and includes patients with different protocols
Wider implications of the findings: In failed IVF cycles, management of future cycle can be guided by OSI. Patients with higher values should receive same dose of FSH in future cycles while those with low OSI should receive higher dose of FSH. OSI can be used as a predictor of good quality embryos.
Trial registration number: NOT APPLICABLE

P-641 Prospective multi-centre non-interventional study to evaluate the application of individualized follitropin delta treatment in routine clinical practice.

C. Blockeel[1], P. Wijngaard-Boom[2], G. Griesinger[3], P. Larsson[4], Y.L. Yip Sonderegger[5], F. Beligotti[6], S. Riviere[6]

[4]Ferring Pharmaceuticals, Biometrics - Global Clinical R&D, Copenhagen, Denmark ;
[5]Ferring Pharmaceuticals, Global Market Access & Pricing, Saint-Prex, Switzerland ;
[6]Ferring Pharmaceuticals, Global Medical Affairs, Saint-Prex, Switzerland

Study question: To investigate the use of follitropin delta, a human cell line derived recombinant human Follicle Stimulating Hormone with individualised dosing regimen, in routine clinical practice.
Summary answer: The use of follitropin delta, in routine care setting with a broad and varied patient population, shows results aligned with the ESTHER-1 registration trial (NCT01956110).
What is known already: When compared to Chinese-hamster ovary (CHO) derived follitropin alfa, the individualised dosing of follitropin delta resulted in ESTHER-1 in: similar pregnancy rates; less frequent measures to prevent ovarian hyperstimulation syndrome (OHSS); more women with a target ovarian response (8–14 oocytes); fewer poor responses with anti-Müllerian Hormone AMH<15pmol/L; fewer excessive responses with AMH≥15pmol/L. For the follitropin delta arm, mean total dose was 90±25.3mcg, mean stimulation was 8.9±1.9days, mean number of oocytes was 10.0±5.6; 43.3% with 8-14 oocytes, 8.0±4.3 with AMH<15pmol/L (44.1%), 11.6±5.9 with AMH≥15pmol/L (55.9%). The clinical pregnancy rate was 34.9%, and the OHSS rate (all, any grade) was 3.5%.
Study design, size, duration: Interim analysis including 390 patients of a prospective multicentre non-interventional study using data collected from routine clinical practice performed across 38 sites in 10 countries. Women naïve to in vitro fertilisation (IVF) or intracytoplasmic sperm injection (ICSI) were included in this study. Women who did not achieve pregnancy could continue with the same treatment for up to three cycles. The study is still recruiting; 1300 patients are anticipated over a period of 3 years (2018-2020).
Participants/materials, setting, methods: Women are prescribed follitropin delta with an individualised daily dose using an approved algorithm based on the patient's Body weight (BW) and serum AMH levels measured by Elecsys® AMH plus (Roche Diagnostics). The decision to treat patients with follitropin delta is independent from the decision to enrol the patient into the study. During the observation period, the investigators collected data from the routine practice.
Main results and the role of chance: This interim evaluation included 390 patients with mean (SD) age 33.3±4.7 years, BW 67.3±12.7 kg, and AMH 20.4±15.2 pmol/L. The total dose determined with the algorithm was 102.6±33.5 mcg, mean treatment duration was 9.9±2.3 days. Both Gonadotropin-releasing hormone (GnRH) antagonist (84.9%) or GnRH agonist (15.1%) protocols were used. Cycle cancellation occurred in 19 patients prior to oocyte retrieval, mainly due to poor ovarian response. Final oocyte maturation occurred in 377 patients: 82.2% with human chorionic gonadotropin (hCG), 13.8% with GnRH agonist and 4.0% with dual trigger. Per patient who received triggering of final follicular maturation, mean number of collected oocytes was 10.5±6.2: 9.7% with <4 oocytes, 25.3% with 4-7 oocytes, 40.4% with 8-14 oocytes, 15.9% with 15-19 oocytes and 8.6% with ≥20 oocytes. Mean number of retrieved oocytes was 7.7±4.1 with AMH <15 pmol/L (43.3%), 12.7±6.7 with AMH ≥15 pmol/L (56.6%). The majority of patients had embryo transfer with fresh embryos (84.4%) on day 5 (54.7%). Per started cycle, 32.3% had a positive hCG test and 27.6% had a clinical pregnancy. In total, 4.1% of OHSS cases (all, any grade) were reported.
Limitations, reasons for caution: This interim evaluation including 390 patients, who started and finished (with an ovum pick-up or with cycle cancellation) a controlled ovarian stimulation treatment for IVF or ICSI, provides results from the first treatment cycle. The whole data-set (1300 patients) should confirm these findings and allow further exploration of patients' outcomes.
Wider implications of the findings: Individualised follitropin delta treatment of a broad patient population, as presented in the real-world clinical setting, reflects a variety in the treatment approaches. It also confirms that this new dosing regimen based on AMH levels and BW remains predictable and allows targeting the desired ovarian response for naïve patients.
Trial registration number: NCT03393780

P-642 Clinical relevance of serum progesterone level on the day before frozen embryo transfer when using a combined luteal phase support.

N. Ramos Seixas[1], P. Pirtea[1], A. Benammar[1], D. De Ziegler[1], R. Frydman[1], M. Poulain[1], J.M. Ayoubi[1]
[1]Hôpital Foch, Service de Gynécologie et Obstetrique, Paris, France

Study question: To determine serum progesterone levels (SPL) with a combined administration (subcutaneous and vaginal progesterone) and its impact on pregnancy outcomes in frozen embryo transfer (FET).

Summary answer: We reported that the association of vaginal and subcutaneous progesterone for luteal phase support (LPS) allows achieving optimal progesterone levels before FET for most patients.

What is known already: ART outcomes following FET depends on progesterone support efficiency. As previously reported, low SPL on the day of embryo transfer is associated with lower outcomes in FET. Different SPL thresholds have been described as having an impact on pregnancy rates. While Labarta reported decreased implantation rate for SPL under 9.2ng/ml after vaginal administration, Yovich found a lower implantation rate once SPL was lower than 15.7ng/ml or above 31ng/ml with a pessary vaginal regimen. Alur-Gupta reported lower pregnancy rates with intramuscular progesterone LPS when SPL were under 15ng/ml. No study has described SPL after combined subcutaneous and vaginal progesterone administration.

Study design, size, duration: Retrospective study in a public academic ART center between February 2019 and November 2019 including all single frozen-thawed blastocyst transfers for women up to 43 years of age. We included 231 FET cycles for 198 patients for data analysis.

Participants/materials, setting, methods: Patients included had a normal uterine cavity. They received hormonal replacement therapy (HRT) with a step-up estradiol (E2) oral doses protocol, starting with 4 mg/day, reaching 8mg/day on day 9.

After achieving appropriate endometrium thickness (>7mm), daily subcutaneous progesterone 25 mg and 800mg vaginal progesterone were introduced. FET was performed after 5 days of progesterone administration. SPL was controlled one- or two-days prior FET. Statistical analysis was performed using the two-sample Student t-test.

Main results and the role of chance: We included 231 FET cycles for 198 patients for data analysis. Main results showed a mean SPL of 34.8ng/ml, on the day before FET. The lowest value of SPL was 7.4ng/ml and the highest was 145.7ng/ml. With this combined protocol for LPS, only 1% of patients had progesterone levels under 9.2ng/ml, when they were 25% in Labarta's study with vaginal protocol support. This indicates that the combination of subcutaneous and vaginal progesterone as luteal phase support is efficient for this population.

We obtained a clinical pregnancy rate (CPR), defined as the presence of an embryo with cardiac activity of 29%. The miscarriage rate (clinical pregnancy loss before 12 weeks) was 18%. The ongoing pregnancy rate (OPR), (CPR after 12 weeks) was 24.7% (OPR/FET).

The mean SPL was significantly higher in the group with an OPR in comparison with those in the miscarriage group (41.1 ±30.9 vs. 23.3 ±14.5, p<0.01; CI 95%). And the OPR was significantly higher for patients presenting a SPL above 22.6ng/Ml compared to the ones underneath (19.0% vs. 30.4%, p<0.05; CI 95%), even though there was no statistical difference in terms of: age, E2 levels, endometrial thickness or embryo morphology between the two groups.

Limitations, reasons for caution: An important limitation of this study is that, as a retrospective and observational study, we couldn't compare the serum progesterone levels to a reference population having a different luteal phase support regimen.

Wider implications of the findings: These findings support the value of a combined progesterone regimen for LPS in FET, providing optimal levels of progesterone. Further studies with a larger population and a control group should be performed in order to confirm our hypothesis.

Trial registration number: Not applicable

P-643 Validation study of the stability of serum progesterone following cryo-conservation and the performance of standard immunoassay for quantifying supra-physiological serum progesterone levels following ovarian hyperstimulation

L. Thomsen[1], U. Kesmodel[2], P. Humaidan[1]

[1]Department of Clinical Medicine- Aarhus University- Denmark., The fertility Clinic-Skive Regional Hospital- Denmark., Skive, Denmark ;
[2]Department of Clinical Medicine- Aalborg University- Denmark., The fertility Unit- Aalborg University Hospital- Denmark., Aalborg, Denmark

Study question: Is standard immunoassays for progesterone (P4) measurements accurate in IVF-patients with supra-physiological P4-levels? Furthermore, are serum P4-levels stable over time when cryo-conservation is used?

Summary answer: The accuracy of a standard immunoassay is maintained in the P4-concentration range seen in IVF-patients. Furthermore, serum P4-levels are stable after 2.5 years of cryo-conservation.

What is known already: Several studies both in fresh IVF-cycles and frozen embryo transfer cycles have demonstrated the importance of luteal P4-levels on the chance of live birth. Serum P4-levels are easily obtained using standard immunoassays. However, consideration is required when a standard assay validated for measurements in a physiological P4-range in a normal population (i.e. during the natural cycle) is used in an "abnormal" population (IVF-patients) with supra-physiological P4-values. Furthermore, in large clinical trials study samples are cryo-conserved for several years before analysis. Current knowledge about the long-term stability of P4 in human serum is rather incomplete and, in part, contradictory.

Study design, size, duration: Validation study of laboratory factors with a possible impact on the interpretation of luteal P4-levels following ovarian stimulation: First, a test of the precision of P4-measurements in supra-physiological P4-ranges using a standard immunoassay (Siemens Immulite 2000XPi). Secondly, an assessment of the possible changes in serum P4-levels following cryo-conservation at -80°C during a 2.5-year period. Serum samples from the luteal phase were obtained from 602 IVF patients to assess the P4-range following ovarian hyperstimulation.

Participants/materials, setting, methods: Serum samples were pooled in three pools to reach a P4-concentration of roughly 125, 300 and 600 nmol/l, respectively. Following mixture, 10 serum samples from each pool were collected and frozen. During ten successive days, one sample from each pool was analyzed and the coefficients of variation (CV) were calculated. Another 60 luteal serum samples were analyzed at baseline, after 9 months and after 2.5 years to assess the long-term stability of P4-concentrations in serum.

Main results and the role of chance: The 602 serum samples for P4-measurement from the early or mid-luteal phase ranged from 19 nmol/l to 1224 nmol/l, thus up to x20 times the levels seen during the natural cycle. The inter-assay and intra-assay precision for the Siemens Immulite stated by the supplier based on measurements within the normal range of a menstrual cycle is <7%. The CV values for the sample pools (125 nmol/l, 300 nmol/l and 600 nmol/l) were 7%, 5% and 4%, respectively. In conclusion, the experimental runs of test samples showed that the precision of the used immunoassay is maintained in the P4-concentration ranges seen in IVF-patients following ovarian stimulation. Thus, luteal P4-levels in IVF-patients can be assessed by standard immunoassay quantification with sufficient accuracy and without the risk of misclassification bias.

To evaluate the effect of storage on the serum P4-levels, a test run of 60 serum samples was performed. The test runs showed comparable levels of P4 in study samples compared to the baseline results. The CV-value for P4-measurements performed at baseline and the first re-run (9 months) was 3.4±2.9% and 2,7 ±2.4% for the second re-run (2.5 years). Thus, the changes in P4-concentrations remained within the expected variation for the immunoassay.

Limitations, reasons for caution: The results are based only on measurements performed by Siemens Immulite 2000XPI. However, automated immunoassay analyzers are comparable in performance and precision, and therefore the results are expected to cover other immunoassay analyzers as well.

Wider implications of the findings: The precision of a standard immunoassay is maintained in supra-physiological P4-levels in IVF-patients and can be used in clinical and study set-ups without the risk of misclassification bias. Short-term cryo-conservation does not change serum P4-levels. Study samples can therefore be frozen and stored until analysis without compromising P4 test results.

Trial registration number: NCT02129998

P-644 Outcome of in vitro oocyte maturation (IVM) in patients with PCOS: does patient phenotype have an impact?

M. De Vos[1,2], S. Mackens[1], S. Pareyn[1], P. Drakopoulos[1], T. Deckers[3], L. Mostinckx[1], I. Segers[1], S. Santos-Ribeiro[4], M. Camus[1], G. Verheyen[1], H. Tournaye[1], C. Blockeel[1]

[1]Universitair Ziekenhuis Brussel, Centre for Reproductive Medicine, Brussel, Belgium ;
[2]Vrije Universiteit Brussel, Follicle Biology Laboratory FOBI, Brussels, Belgium ;
[3]AZ Sint-Lucas, Gynaecologie-Verloskunde, Brugge, Belgium ;
[4]IVI-RMA Lisboa, Gynecology/Reproductive Medicine, Lisbon, Portugal

Study question: Does the phenotype of patients with polycystic ovary syndrome (PCOS) affect clinical outcomes of assisted reproductive technology (ART) following *in vitro* oocyte maturation (IVM)?
Summary answer: Cumulative live birth rates (CLBR) after IVM are significantly higher in patients with a hyperandrogenic PCOS phenotype compared to those with a normo-androgenic phenotype.
What is known already: Hyperandrogenic PCOS phenotype has been reported to confer a lower CLBR after controlled ovarian stimulation (COS) and IVF/ICSI when compared to patients with a PCO-like ovarian morphology or with a normo-androgenic phenotype. Whether there is an influence of the different PCOS phenotypes on success rates of IVM remains unclear.
Study design, size, duration: This is a single-centre, retrospective cohort study including 320 unique PCOS patients performing their first IVM cycle between April 2014 and January 2018 in a tertiary referral hospital.
Participants/materials, setting, methods: Baseline patient characteristics and IVM treatment cycle data were collected. PCOS was diagnosed according to the Rotterdam criteria. The primary outcome was cumulative live birth rate (CLBR), defined as the rate of deliveries resulting from the transfer of all fresh and cryopreserved embryos from the same IVM cycle. The secondary outcome was live birth rate following the first IVM embryo transfer.
Main results and the role of chance: Half of the patients (n=160) presented with a hyperandrogenic PCOS phenotype. These patients had a higher BMI (27.4±5.4 kg/m^2 vs 23.3±4.4 kg/m^2, p<0.001) and used more often metformin (31.2% vs 11.2%, p<0.001) in comparison with the normo-androgenic ones. Significantly more cumulus oocyte complexes were retrieved in the hyperandrogenic group (24.9±18.3 vs 19.8±13.5, p= 0.003) and, after IVM, these patients had more mature oocytes (11.7±9.0 vs 9.1±6.9, p=0.002). Following the first embryo transfer, the positive hCG rate and LBR were comparable in the two patient groups (44.2% vs 36.7%, p=0.21 and 23.2% vs 26.6%, p=0.52, respectively). In hyperandrogenic patients, early pregnancy loss was more common (20.3% vs 10.2%, p= 0.02). The CLBR (when at least one embryo was available for transfer) was not significantly different following univariate analysis (42.7% vs 41.4%, p= 0.82). However, when using a multivariable logistic regression model to account for confounding factors, the PCOS phenotype appeared to be significantly correlated with CLBR, with more favorable results in the hyperandrogenic group (OR 2.24, CI 1.06-4.77, p= 0.03).
Limitations, reasons for caution: These data should be interpreted with caution in the light of the retrospective nature of the study and the possibility of unmeasured confounding.
Wider implications of the findings: Infertile hyperandrogenic PCOS patients undergoing IVM achieve a higher CLBR than their normo-androgenic counterparts. This is in contrast with previously reported outcomes following COS and ART in which hyperandrogenic PCOS patients performed significantly worse. Our data suggest that proper patient selection is of utmost importance in an IVM program.
Trial registration number: Not applicable

P-645 Anogenital distance in newborn infants conceived by assisted reproduction and natural conception

S. Ercin[1], S. Ertas[2], O. Dundar[3], O. Oktem[4], K. Yakin[2]

[1]American Hospital, Neonatology, istanbul, Turkey ;
[2]American Hospital, Women's Heath Center, Istanbul, Turkey ;
[3]American Hospital, Women's Health Center, Istanbul, Turkey ;
[4]Koc University, Women's Heath Center, Istanbul, Turkey

Study question: Does anogenital distance (AGD) differ in newborn infants conceived through assisted reproduction technologies (ART) compared with those conceived naturally
Summary answer: AGD measurements in infants conceived by ART are not different from those of infants conceived naturally
What is known already: AGD is an anthropometric measurement sensitive to changes in the in-utero hormonal environment during the early life of fetus. Alterations in AGD are associated with anomalies in neonates and reproductive dysfunction in adults
Study design, size, duration: A prospective descriptive cohort study was performed on randomly selected singleton neonates (n = 447) born at a single center between September 2017 and April 2019. Anthropometric and anogenital measurements were performed in 247 male and 200 female newborns born after ART (n=121) or natural conception (n=326), within 24 hours of birth by a single caregiver who was blind to the mode of conception.
Participants/materials, setting, methods: Gestational age, birth weight, length and head circumference were recorded for all newborns. In female infants, distance from anus to the anterior clitoris (AGDAC) and to the posterior fourchette (AGDAF) were recorded. In male infants, distance from the center of the anus to the posterior base of the scrotum (AGDAS) and to anterior base of the penis (AGDAP) were measured.
Main results and the role of chance: The mean age of mothers was 34.9 years and the mean gestational age at the time of delivery was 267 days. ART cohort was older, more likely to be nulliparous and delivered by cesarean section at an earlier gestational week. AGDAS of male infants was approximately twice as long as AGDAF of female infants (17.6±5.0 vs 9.1±3.6 mm, p<0.001). On average, female infants conceived by ART had shorter AGDAF (8.8±3.6 mm) than those conceived naturally (9.1±3.6 mm) but the difference was not significant (p >0.05). AGDAC were comparable for both groups (27.7 ± 7.1 vs 27.4 ± 6.3 mm, p>0.05). In male infants, no significant difference was seen between ART and natural conception groups in terms of AGDAS (17.4±4.6 vs 17.7±5.2 mm) and AGDAP (38.0 ± 6.7 vs 37.5 ± 6.6 mm, p >0.05 for both). Gestational age, weight, length and head circumference at birth were the strongest correlates of anogenital measurements. When adjusted for these covariates, mode of conception was not associated with differences in any of the anogenital measurements.
Limitations, reasons for caution: A single center study with relatively small sample size, it is not possible to rule out confounding by diet or endocrine-disrupting chemicals or drugs other than progesterone that women might have taken during pregnancy
Wider implications of the findings: Preliminary findings are reassuring for women undergoing ART but they need to be confirmed by future studies with larger sample sizes
Trial registration number: not applicable

P-646 Does quantity equal quality? – a morphokinetic assessment of embryos obtained from young women with decrease ovarian response to stimulation.

N. Schachter - Safrai[1], G. Karavani[1], Y. Kantor[2], I. Har- Vardi[3], A. Buxboim[2], Z. Shoham[4], Y. Or[4], A. Ben-Meir[1]

[1]Hadassah Hebrew University Hospital, Obstetrics and Gynecology, Jerusalem, Israel ;
[2]Institute of Life Sciences- The Hebrew University of Jerusalem, Alexander Grass Center for Bioengineering- School of Computer Science and Engineering, Jerusalem, Israel ;
[3]Soroka University Medical Center, The IVF Unit - Department of Obstetrics and Gynecology, Beer-Sheva, Israel ;
[4]Kaplan Hospital, Department of Obstetrics and Gynecology, Rehovot, Israel

Study question: Is there an association between oocyte quantity and quality in young women exhibiting decreased ovarian response?
Summary answer: The quantitative decrease in ovarian response is associated with reduced oocyte quality, reflected by a slower developmental rate and lower implantation and pregnancy rates.
What is known already: It is well known there is a physiologic decline in both oocyte quantity and quality attributed to aging. However, it is unclear if the two are related when a premature decline in oocyte quantity is observed. While most of the literature on this subject includes a heterogenous population and demonstrates conflicting results regarding embryo quality and pregnancy rate, a recent study included only women younger than 38 years with low ovarian response and demonstrated no difference in embryonic development and live birth rate .There is only scarce data regarding oocyte quality in poor responders using a time lapse microscopy (TLM).
Study design, size, duration: The study included a retrospective assessment of morphokinetic parameters performed by TLM from five medical centers between January 2013 and December 2017.The developmental process and kinetics of 519 embryos obtained from the study group, referred as the " decreased ovarian response" (DOR) group was compared to 3633 embryos of the control group ,known as the "normal ovarian response" (NOR) group.
Participants/materials, setting, methods: The study included patients younger than 38 years who underwent controlled ovarian stimulation (COS)

with consecutive aspiration of either 5 oocytes or less - the DOR group, or 6 oocytes or more- the NOR group. A comparison between the morphokinetic parameters, implantation and pregnancy rates of the two groups was made with additional subgroup analysis according to the implantation status. Logistic regression was conducted to assess the association between morphokinetic parameters and implantation rate

Main results and the role of chance: Implantation and clinical pregnancy rates were significantly lower in the DOR group compared to the NOR group (31.6% vs. 44.5% and 37.7% vs. 51.5%, respectively; p<0.05). Embryos from the DOR group reached the morphokinetic milestones later than embryos obtained from NOR patients. Implanted embryos in the DOR group developed faster than embryos which failed to implant, however manifested a protracted course compared with implanted embryos from the NOR group. In a multivariate analysis - normal ovarian response, age and tSB were associated with implantation.

Limitations, reasons for caution: The two patients' groups were not homogenous in their basic characteristics. A higher rate of blastocyst culture and blastocysts transfer was demonstrated in the NOR patients. Important information regarding the maximal dose of gonadotropins obtained, previous IVF response and ovarian reserve testing was lacking.

Wider implications of the findings: Decreased oocyte quality manifested by a multi-staged delayed preimplantation development in the DOR group may highlight another pathophysiology for decreased oocyte quality not related to age. Decreased ovarian response to COS and morphokinetic parameters may assist in predicting pregnancy.

Trial registration number: not applicable

P-647 Follicular fluid anti-mullerian hormone: a predictive marker of fertilization, implantation and clinical pregnancy in patients with unexplained infertility

A. Abdelmeged[1], O. Ahmed[1], A. Kotb[1], E. Elgindy[1], H. Baha[1]

[1]Faculty of Medicine, Gynacology and Obstetrics, El Menia, Egypt

Study question: Would follicular fluid anti-mullerian hormone (FF-AMH) measured values predict fertilization, implantation and clinical pregnancy in patients with unexplained infertility undergoing ICSI?

Summary answer: FF-AMH level could be associated with fertilization rate (FR), implantation rate (IR), and clinical pregnancy rate (CPR) in patients with unexplained infertility undergoing ICSI.

What is known already: In humans, AMH is considered a reliable marker for ovarian reserve, as well as for ovarian response to gonadotropin stimulation. AMH probably has a role in the regulation of follicle selection and maturation. FF-AMH inhibits the initiation of human primordial follicle growth and prevents multiple selections of a dominant follicle; by reducing their sensitivity to follicle stimulating hormone (FSH). Previous studies suggested that FF-AMH might be a better predictor of ovarian responses to controlled ovarian hyperstimulation than traditional parameters such as age, FSH, estradiol and inhibin-B.

Study design, size, duration: This is a single-arm uncontrolled clinical trial that was conducted between June 2018 and 2019. The study protocol was approved by the Institutional Ethics committee. Sixty women with the diagnosis of unexplained infertility who received controlled ovarian stimulation and ICSI treatment were enrolled. The inclusion criteria for women were age ≤ 38 years, normal ovulatory cycles and a body mass index (BMI) ranging from 18 to 28 kg/m2.

Participants/materials, setting, methods: This study was conducted at Minia Infertility center, Minia University. Follicular fluids (FF) were aspirated under transvaginal ultrasound guidance. The FF from the single dominant follicle of each patient (which is aspirated first) was separated. FF was stored at - *80* °C until assayed. AMH levels were measured by using an ultrasensitive enzyme-linked immunosorbent assay. Based on the median of cycles measured values; women were categorized as low and high FF-AMH groups.

Main results and the role of chance: The primary outcome of this study was fertilization rate, implantation rate, blastocyst development, embryo quality, chemical pregnancy and clinical pregnancy. Low FF-AMH group, compared to high FF-AMH group, showed a significant improvement with regards to percentage of top-quality oocytes (67.1±24.3% vs. 49.6 ± 30.3%, $p = 0.014$), FR (83.9±20.9% vs. 72.4 ± 21.4%, $p = 0.021$), IR (57.7% vs. 16.7%, $p = 0.001$) and CPR (57.57% vs. 16.67%, $p < 0.0001$). None of the remaining variables were significantly different between the two studied groups (p > 0.05). Further, FF-AMH value had a significant low correlation with follicular fluid estradiol (FF E2) (r = −0.409, p <0.001) and moderate correlation with clinical pregnancy (r = −0.618, p<0.001). FF-AMH pregnancy threshold was >1.75 ng/ml. Receiver operating characteristic (ROC) analysis showed a FF-AMH sensitivity of 73.1% in predicting CPR and a specificity of 85.3 %. The area under curve (ROC_{AUC}) was 0.715 ($p < 0.0001$).

Limitations, reasons for caution: The sample size was relatively small and does not reflect a wide variety of clinically seen cases such as women with ovarian cyst (> 3 cm in diameter), polycystic ovarian syndrome, endometriosis, or those with a history of previous ovarian surgery or endocrine disorders.

Wider implications of the findings: This study demonstrated that FF AMH levels were significantly lower in fertilized oocytes than in non-fertilized oocytes. FF-AMH is an adequate predictor of clinical pregnancy after ICSI; However further studies on a larger group of patients are needed to correlate its relation with ongoing pregnancy.

Trial registration number: not applicable

P-648 Does thyroid autoimmunity and more specifically anti-thyroglobulin antibodies affect IVF/ICSI outcome?

V. Uvin[1], M. De Brucker[1], P. Drakopoulos[1], K. Poppe[2], H. Tournaye[1], D. Unuane[3]

[1]UZ Brussel, Centre of reproductive medicine, Brussels, Belgium ; [2]Centre Hospitalier Universitaire Saint-Pierre, Endocrinology, Brussels, Belgium ; [3]UZ Brussel, Endocrinology, Brussels, Belgium

Study question: Does the thyroid autoimmune (TAI) status and especially anti-thyroglobulin antibodies affect IVF/ICSI outcomes of euthyroid patients?

Summary answer: Thyroid autoimmune status and more specifically anti-thyroglobulin antibodies do not affect the reproductive outcomes of euthyroid patients undergoing IVF/ICSI.

What is known already: The impact of TAI on fertility outcomes of euthyroid women undergoing IVF/ICSI has been controversial. In literature, in addition, TAI is predominately defined by elevated levels of thyreoperoxydase antibodies (TPO-Ab). The impact of anti-thyroglobulin antibodies (TG-Ab) on fertility outcome after IVF/ICSI remains unclear.

Study design, size, duration: This was a retrospective study including all euthyroid patients who underwent their first IVF/ ICSI cycle in a 6 month period at the center of reproductive medicine of the University Hospital Brussels. All patients were screened for both TPO-Ab and TG-Ab.

Participants/materials, setting, methods: Patients were categorized to four groups based on TAI status: TAI negative, only TG-Ab positive, only TPO-Ab positive and both TG- and TPO-Ab positive. The main outcome was fresh live birth rates (LBR). Secondary endpoints were positive human chorionic gonadotropin (hCG), early pregnancy loss and cumulative LBR. Cumulative LBR was defined as the delivery of at least one live-born infant (>24 weeks of gestation) in the fresh or in the subsequent frozen-thawed cycles.

Main results and the role of chance: In total, 464 patients were included in the analysis: 402 (86.6%) in the TAI negative group, 17 (3.7%) in the TG-Ab group, 15 (3.2%) in the TPO-Ab group and 30 (6.5%) in the TPO/TG-Ab group. Baseline characteristics such as age, body mass index, anti-Müllerian hormone (AMH) and antral follicle count (AFC) were similar between the four groups. Only thyroid-stimulating hormone (TSH) differed significantly [1.6 (0.7) vs. 2.4 (0.9) vs. 1.4 (0.8) vs. 1.8 (0.9), p value=0.005)]. Fresh LBR did not differ significantly between the four groups [131/402 (32.6%) vs. 3/17 (17.7%) vs. 6/15 (40%) vs. 8/30 (26.7%), p value=0.5)]. Similarly, positive hCG and early pregnancy loss rates were comparable between the four groups, while cumulative LBR did not show a statistically significant difference either [164/402 (40.8%) vs. 6/17(35.3%) vs. 6/15 (40%) vs. 11/30 (36.7%), p value =0.94]. Multivariate regression analysis indicated that after adjustment for relevant confounders the TAI status was not significantly associated with either fresh or cumulative LBR (p value = 0.24).

Limitations, reasons for caution: This is a large observational study based on retrospective data collection. Despite our robust methodological approach, the presence of bias related to the retrospective design cannot be excluded. Furthermore, the rarity of TG-Ab may preclude firm conclusions.

Wider implications of the findings: Our study adds further to the growing evidence that TAI (and especially TG-Ab) do not seem to affect the reproductive outcomes of euthyroid patients undergoing IVF/ICSI. These results should be confirmed in future prospective studies.

Trial registration number: not applicable

P-649 FF-MAS oxysterol related with hedgehog signaling pathway on folliculogenesis

S. ZIRH[1], E. Bahador Zirh[1], L. Karakoc Sokmensuer[1], G. Bozdag[2], S. Muftuoglu[1]

[1]Hacettepe University- School of Medicine, Histology and Embryology, Ankara, Turkey ;
[2]Hacettepe University- School of Medicine, Obstetrics and Gynecology, Ankara, Turkey

Study question: Does FF-MAS affect folliculogenesis via hedgehog cell signaling pathway?
Summary answer: The main effect of FF-MAS on folliculogenesis manifested by granulosa cell(GC) proliferation, is associated with the hedgehog pathway (HH) proteins SMO and GLI1.
What is known already: HH is one of the main cell signaling mechanisms effective on cell proliferation. It exerts its biological effects through signaling cascade that activated by smoothened(SMO) receptor consequently regulated glioma-associated oncogene(GLI) transcription factors. Follicular fluid–meiosis activating sterol(FF-MAS), which is a steroid derivative and present in follicular fluid, is involved in folliculogenesis. GC is critically important cell involved in follicular development during the ovarian cycle. Polycystic ovary syndrome(P-COS) defined as follicular development failure, lag of granulosa cell proliferation, and cystic follicles as a result, is one of the common endocrine disorders of today.
Study design, size, duration: Primary culture of granulosa cells from both PCOS (n=10) and healthy (male factor infertility)(n=10) woman undergoing IVF, were collected since 2018. The human immortalised granulosa cell line (hGL5, abm, Canada) were also used beside primary cell culture. Each GCs divide into four groups individually: FF-MAS, FF-MAS+cyclopamine, only cyclopamine and vehicle used for FF-MAS and cyclopamine. Cyclopamine was used for inhibiton of HH.
Participants/materials, setting, methods: Granulosa cells of women undergoing IVF, have isolated from follicular fluid at oocyte pick up in Hacettepe University Infertility Center. GCs (PCOS and control (male factor[MF] infertility)) were cultivated at least 3 passages after the isolation. ED50 dose of FF-MAS was maintained by WST assay. Hedgehog pathway mollecules(SMO, GLI1) were screened on granulosa cells from each group by using immunocytochemistry (immunofluorescence and immunoperoxidase) and cyto-ELISA. Mean fluorescence intensities evaluated in all micrographs by ImageJ 1.52K.
Main results and the role of chance: The ED50 dose of FF-MAS was determined as 10μM FF-MAS for 48h according to WST assays. Results were evaluated according to measurement of cell proliferation and viability in response to different doses of FF-MAS. Tests were performed in GCs of PCOS, MF and HGL5. Experiments carried out with 10μM FF-MAS for 48h according to maximum non-toxic dose and duration. All the GCs were assesed in terms of GLI1 and SMO by both IF, ICC. Hedgehog pathway was slightly inhibited with cyclopamine binding to signal transducer receptor SMO via canonical pathway. Indirect IF is widely considered for SMO-GLI1 proteins in all groups of granulosa cells screening with/without FF-MAS and cyclopamine.

The expression of GLI1 and SMO showed different flourescence intensities between groups. GLI1 and SMO were mostly expressed in all FF-MAS groups. The mean fluorescence intensities were compared in all groups by ImageJ analysis. A significant difference were obtained between quantitative reading of intensities in FF-MAS and FF-MAS+cyclopamine groups. Results of immunoperoxidase cyto-ELISA for GLI1 and SMO expressions of FF-MAS groups confirmed the IF analysis.

According to our findings, the highest expression was observed in FF-MAS groups especially in PCOS patients than MF group. Cyclopamine significantly suppressed the expression of proteins.
Limitations, reasons for caution: Since human cells were used in study and the cells of each patient do not exhibit the same characteristics, the lowest number of patient samples identified in the statistical power analysis were included in the study.
Wider implications of the findings: First time, the effect of FF-MAS via HH was evaluated on human GCs, which has been used in animal ART before. We have introduced a new approach to the literature on the molecular mechanisms of FF-MAS and to be considered as a new approach in human IVF treatments of PCOS.

P-650 Steroid levels in single follicular fluid: relation to ovarian stimulation protocol and destiny of the corresponding oocyte in assisted reproduction

E. Baldi[1], S. Marchiani[2], L. Tamburrino[1], F. Benini[3], M. Pallecchi[4], C. Bignozzi[3], A. Conforti[5], C. Alviggi[5], L. Vignozzi[4], G. Danza[4], S. Pellegrini[3]

[1]University of Florence, Department of Experimental and Clinical Medicine, Florence, Italy ;
[2]Azienda Universitario Ospedaliera Careggi, Department Materno Infantile, Florence, Italy ;
[3]Centro Procreazione Assistita Demetra, none, Florence, Italy ;
[4]University of Florence, Department of Experimental Clinical and Biomedical Sciences, Florence, Italy ;
[5]University of Naples- Federico II, Department of Neuroscienze- Reproductive Science and Odontostomatology, Naples, Italy

Study question: Are steroid hormone levels in single follicular fluid related to ovarian stimulation (rFSH or rFSH+rLH) and to Assisted Reproduction Technique outcomes of the corresponding oocyte?
Summary answer: FF steroid levels were found different between the two protocols of ovarian stimulation. FF Progesterone levels predicts the attainment of fertilization in the FSH group.
What is known already: Conflicting results have been reported in studies concerning the relationship between steroid levels in FF and oocyte maturity or Assisted Reproduction Technique (ART) outcomes. Controversy may depend on the fact that most of these studies did not consider the destiny of individual oocytes and utilize immunoassay to measure steroid levels, which is affected by cross-reactivity and shows poor specificity and sensitivity.
Study design, size, duration: We enrolled in a prospective cohort study 41 couples undergoing ICSI cycles from November 2016 to August 2018. In 13 cases follicle stimulation was performed with recombinant r–FSH alone and in 28 women, with previous poor ovarian responsiveness, with r-FSH plus r-LH. 316 oocytes and the corresponding collected follicular fluids (FF) were included in the study. The destiny of each oocyte was followed during the entire cycle.
Participants/materials, setting, methods: Levels of six steroid hormones (progesterone (P), 17-OH-Progesterone (17-OH-P), Androstenedione (A), Testosterone (T), Estradiol (E1) and Estrone (E2)) were evaluated in the single FF by High Performance Liquid Chromatography coupled with tandem Mass Spectrometry (HPLC/MS-MS). Such levels were related to ovarian stimulation protocol and oocyte maturity, fertilization and quality of blastocysts. Clinical pregnancy, due to the limited number of achieved pregnancies of our cohort, was evaluated as explorative outcome.
Main results and the role of chance: Our study demonstrates that FF steroid levels vary among different follicles collected from the same woman and that the two ovarian stimulation protocols lead to differences in the steroid composition of FF, as 17-OH-P, A, E2 and E1 were significantly higher in FSH+LH group. In the latter group, P, 17-OH-P and E2 were more expressed in FF of follicles which yield a mature oocyte than in immature ones (median values (ng/ml): P, 7352.7 [IQR:4252.2-11378.2] vs. 4270.2 [IQR: 2466.4-8064.9]; 17-OH-P, 991.2 [IQR: 596.2-1620.4] vs. 571.4 [IQR: 352.6-1072.3]; E2, 396.0 [IQR: 238.5-551.4] vs. 245.9 [IQR: 165.3-385.6], $p<0.01$) and 17-OH-P was higher in FF of follicles which yield fertilized oocytes respect to non-fertilized oocytes (median values (ng/ml): 1076.6 [IQR: 663.7-1694.6] vs. 811.9 [IQR:362.3-1385.7], $p<0.05$). Moreover, P FF levels of the oocytes which achieved clinical pregnancy were significantly higher respect to non-pregnant (median values (ng/ml): 11136.9 [IQR: 9294.1-15275.5] vs. 8305.6 [IQR: 4688.3-11238.9], $p<0.05$). In the group stimulated only with FSH, we observed no differences in steroid levels for none of the analysed ART outcomes, except for P levels, which were found to be predicted of successful fertilization with an accuracy of 70.3±6.0%, $P<0.005$.
Limitations, reasons for caution: The low absolute number of embryos in the three quality categories and the paucity of women achieving pregnancy in the two groups may have limited the statistical power regarding the role of FF steroids in predicting embryo quality and pregnancy.
Wider implications of the findings: LH supplementation modifies the ovarian steroidogenic activity better resembling the physiological steroid pattern likely improving ovarian response. Our study does not support a direct association between FF steroid levels and ART outcomes, with the exception of Progesterone, which predicts with fair sensitivity and specificity the attainment of fertilization.
Trial registration number: not applicable

P-651 AMP-activated protein kinase (AMPK) controls dormancy of the primordial follicle pool in murine ovarian tissue

J. Nielsen[1], M. Amoushahi[1], E.H. Ernst[2], K. Lykke-Hartmann[1,3,4]

[1]*Aarhus University, Department of Biomedicine, Aarhus C, Denmark ;*
[2]*Herning Region Hospital, Department of Obstetrics and Gynaecology, Herning, Denmark ;*
[3]*Aarhus University Hospital, Department of Clinical Genetics, Aarhus C, Denmark ;*
[4]*Aarhus University, Department of Clinical Medicine, Aarhus C, Denmark*

Study question: Can inhibition of AMPK stimulate growth of primordial follicles in ovarian tissue?
Summary answer: AMPK signaling is an essential signaling pathway governing dormancy of primordial follicles and inhibition of AMPK enhances the number of activated follicles.
What is known already: Molecular signaling pathways including PI3K/AKT, AKT/mTOR, and HIPPO contribute to regulate the primordial-to-primary follicle transition in the mammalian follicle development. It is, however, widely acknowledged that we are only beginning to elucidate the molecular mechanisms maintaining dormancy and activation of primordial follicles. Recently, our team performed transcriptomic profiles of human primordial and primary follicles providing molecular clues towards which alterations in gene expression that dictate dormancy and activation of primordial and primary follicles. One promising gene candidate identified was *AMPK*; a kinase responsible for restoring cellular energy homeostasis.
Study design, size, duration: Whole murine ovaries were excised from female juvenile mice (C57BLxCBA F1) and randomly divided into two groups of equal size and grown in a primary three-dimensional culture system in culture medium supplemented with an inhibitor of AMPK (IHB) or without (NT). After five to seven days of culture, ovaries were collected.
Participants/materials, setting, methods: *In vitro*-cultured ovaries were collected for histological analysis to address the balance between follicular activation and quiescence after drug-exposure. Additionally, we addressed important parameters that can evaluate the follicle quality after drug-exposure. Towards this, we performed assays e.g. TUNEL, BAX-to-BCL-2 ratio, cytochrome c oxidase activation, and ROS generation. Furthermore, follicles from the drug-exposed and NT ovaries were mechanically isolated and cultured in an alginate hydrogel, culminating in meiotic competent oocytes.
Main results and the role of chance: We found that *in vitro* culture with an AMPK inhibitor for five days significantly increased the number of activated follicles (NT: 18.97%±1.017 *vs.* IHB: 39.73±1.28%, $p<0.0001$; n=17/15). As the level of activated AMPK were significantly decreased ($p<0.05$, n=18), and the activation of PI3K-AKT signaling was unaffected ($p<0.05$; n=18) by the drug-exposure, our results indicated that inhibition of AMPK can trigger follicular growth synergistically with PI3K-AKT signaling. Furthermore, we assessed the inhibitor's impact on oocyte quality parameters. We showed that inhibitor-exposure increased the survival rate by conducting a TUNEL analysis (number of apoptotic cells NT:7.48% *vs.* IHB:3.30, $p<0.05$, n=5-6) and the BAX-to-BCL-2 ratio were also significantly decreased after drug-exposure ($p<0.01$, n=12). Moreover, we showed that the activity of cytochrome c oxidase ($p>0.05$, n=12) and ROS generation ($p>0.05$, n=6) were not significantly affected by the drug-exposure. In line with these observations, we elucidated that follicles isolated from drug-exposed ovaries had the ability to release meiotic competent oocytes in response to an ovulating dose of human chorionic gonadotropin, with the same survival rate as the control-exposed ovaries (NT: 76.47% *vs.* IHB: 73.33%; n=34/30).
Limitations, reasons for caution: The study is for now limited to murine tissue and further studies are needed to assess if the murine findings are translatable into the human reproductive system. Moreover, the inhibitor has previously been reported to promote promiscuous AMPK-independent affairs, therefore the results must be interpreted with potential off-targets in mind.
Wider implications of the findings: This study furthers our understand on cellular signaling which dictate the balance between follicular activation and dormancy, and understanding the details of ovarian biomechanics may have substantial clinical implications.
Trial registration number: Not applicable

P-652 Automated quantification of the distribution of pre-antral ovarian follicles to facilitate accurate and unbiased counting

E. Bruun[1], M. Amoushahi[1], K. Lykke-Hartmann[2,3]

[1]*Aarhus University, Department of Biomedicine, Aarhus C, Denmark ;*
[2]*Aarhus University, Department of Biomedicine and Department of Clinical Medicine, Aarhus C, Denmark ;*
[3]*Aarhus University Hospital, Department of Clinical Genetics, Aarhus, Denmark*

Study question: We sought to improve and more precisely determine the follicle distribution of primordial, primary and secondary follicles in ovaries from juvenile mice by automated counting.
Summary answer: Fluorescent labeling of oocytes and quantification of follicles by automatic analysis software generates comparable data with conventional methods and ensures objective results.
What is known already: Knowledge of the number of ovarian follicles is of interest to investigators studying mammalian reproductive biology. One of the most widely used approaches for estimating the number of follicles in different developmental stages is based on histological sampling of the total ovarian mass followed by manual classification and counting using a microscope. This procedure is time-consuming and highly operator dependent. Improving the accuracy of the follicle classification and quantification will reduce time and produce more reliable results.
Study design, size, duration: In this pilot study, whole ovaries isolated from juvenile mice (7-8-days old) were used for quantification of the number of follicles in three different developmental stages; primordial, primary and secondary follicles. Ovaries were kept in organ culture for four days in basic medium in a well-insert culture system.
Participants/materials, setting, methods: Ovaries were fixed, processed, and embedded in paraffin. Samples were cut in 5-µm sections and stained with hematoxylin and eosin (H&E) or immunofluorescence (IF) staining. The number of follicles at three developmental stages was either counted manually using an inverted research microscope or automatically using high-content image analysis software (MetaXpress). The follicle distribution of every 5th section of each ovary was counted. Germ-cell marker MVH was used to visualize oocytes for IF.
Main results and the role of chance: IF staining results showed a strong MVH signal in oocyte cytoplasm of follicles in all three developmental stages present in the cultured juvenile mouse ovaries. The average distribution of follicles classified and counted manually was 83% (SD 3%), 13% (SD 2%) and 4% (SD 1%) among primordial, primary, secondary follicles, respectively. The preliminary customized analysis module in MetaXpress was programmed to recognize all MVH-positive follicles with a certain intensity and with a visible nucleus. Only about 5% of the visible follicles were not recognized by the analysis module. Since stage-specific IF markers were still not identified, the preliminary results of the analysis module were based on the number of follicles rather than classification of the follicles. By setting a diameter range for the different follicular stages, the analysis software discovered 10% (SD 3%) more follicles in the primordial stage compared to manual counting. This method is a way of eliminating workload and subjectivity in microscopic image analysis, however, human assessment of the health of the ovary is always important.
Limitations, reasons for caution: The main limitations of this study are the lack of stage-specific markers for the different pre-antral developmental stages. Additionally, this method will not provide the total number of follicles of the whole ovary, but the method can be used as an estimation of the effect of an experimental intervention.
Wider implications of the findings: Automated image analysis provides an important advantage by significantly reducing manual counting variability. IF methods also efficiently enhance the visibility of primordial follicles that are difficult to see and ensures accurate recording of the number of follicles. Focus on finding stage-specific markers would further improve the classification of follicles.
Trial registration number: Not applicable

P-653 Human oocytes and granulosa cells from primordial and primary follicles revealed expression patterns of genes encoding Toll-like receptors (TLRs)

G. Saritas[1], E.H. Ernst[2], M. Amoushahi[1], K. Lykke-Hartmann[1,3,4], T. Wenzel Kragstrup[1], A.S. Sørensen[1]

[1]*Aarhus University, Department of Biomedicine, Aarhus C, Denmark ;*
[2]*Herning Region Hospital, Department of Obstetrics and Gynaecology, Herning, Denmark ;*
[3]*Aarhus University Hospital, Department of Clinical Genetics, Aarhus N, Denmark ;*
[4]*Aarhus University, Department of Clinical Medicine, Aarhus C, Denmark*

Study question: Does the early hormone-independent, primordial-to-primary follicle development involve inflammatory-like responses mediated through TLRs?
Summary answer: The hormone-independent transition from primordial to primary follicles in human folliculogenesis revealed oocyte- and granulosa cell-specific expression patterns and biological functions of TLR3 and TLR4.
What is known already: Later stages of follicle development and ovulation, encompassing the maturation of secondary to antral/preovulatory follicles, involves inflammatory-like responses similar to the innate immune-related cell surveillance system including: inflammation, rupture (or ovulatory) event and reparation. Cumulus oocyte complex, which appears in antral follicles, secretes luteinizing hormone and amphiregulin inducing expression of immune-related receptors as TLRs. Murine granulosa and cumulus cells exposed to these hormones revealed gene expression levels of various immune components, e.g. TLR2, TLR4 and TLR9. The impact of immune system on the primordial-to-primary follicle transition remains unknown which could clarify molecular mechanisms protecting these early follicle stages.
Study design, size, duration: Expression data of *TLR* transcripts was extracted using bioinformatic tools from previous global RNA transcriptome studies in human Laser Capture Microdissection (LCM)-isolated oocytes and granulosa cells from primordial (n= 539) and primary (n= 261) follicles. Ovarian tissues were donated by three women undergoing ovarian removal surgery for cryopreservation before gonadotoxic treatment of non-gynecological cancer. As a proof of concept, intrafollicular localization and functionality of selected TLRs investigated by immunohistochemical and interleukin 6 (IL-6)-specific ELISA analyses.
Participants/materials, setting, methods: qPCR was performed on LCM-isolated oocytes and granulosa cells from two independent patient samples to confirm *TLR* transcriptome data. Intrafollicular localization of TLR3 and TLR4 were studied in two patient samples using immunohistochemistry with anti-TLR3 and -TLR4 antibodies. For ELISA analysis, supernatants were extracted from juvenile murine ovaries *in vitro* cultured without or either with polyinosinic:polycytidylic acid (poly I:C), or with lipopolysaccharides (LPS) (known as ligands for TLR3 and TLR4, respectively).
Main results and the role of chance: Among other *TLR* transcripts, *TLR3*, *TLR4* and *TLR5* were differentially and stage-specific consistently expressed genes (SSCEG) in both/either oocytes and/or granulosa cells from primordial and primary follicles. Inconsistent *TLR5* expression across the three patient samples was the cause to exclude from this study. The qPCR analysis on *TLR3* transcript aligned with the transcriptome expression levels indicating highly upregulation only in granulosa cells from both follicle stages. Immunohistochemistry indicated a halo-shaped TLR3 staining in the interspace between surrounding granulosa cells and the oocyte in primordial and primary follicles, respectively. Primary follicles showed a more intense TLR3 staining correlating with the significant mRNA levels from the transcriptome data. TLR4 staining indicated presence in both the oocyte and granulosa cells from primordial and primary follicles, however a weaker staining in primordial follicle than observed for TLR3 in primordial follicle. ELISA revealed higher IL-6 production in ovarian supernatants treated with LPS than the level in untreated and poly I:C-treated supernatants. These TLRs are clearly present in the earliest hormone-independent follicle stages in human ovary which may have a potential defensive role (especially in murine ovaries).
Limitations, reasons for caution: This is a descriptive study of *TLR* transcripts in human ovary supported with their biological functions in murine ovary. The number of human samples was limited which eliminates the considerations of the natural biological variance in the samples according to the experimental design.
Wider implications of the findings: This study has indicated, for the first time, presence and functional role of pattern recognition receptors as *TLR3* and *TLR4* in human oocytes and granulosa cells from the hormone-independent primordial and primary follicle stages.
Trial registration number: Not applicable

P-654 Serum selenium level in women with idiopathic premature ovarian insufficiency: A case-control study

B. Sadeghzadeh[1], M. Bazrafkan[2], P. Shahabi[3]

[1]Tabriz university of Medical sciences, midwifery Department, Tabriz, Iran ;
[2]Reproductive Biotechnology Research center- Avicenna Research Institute, Reproductive Biology, Tehran, Iran ;
[3]Tabriz University of Medical Sciences, Physiology, Tabriz, Iran

Study question: What is the relationship between selenium level and premature ovarian insufficiency?
Summary answer: Patients with abnormal low level of selenium have low ovarian reserve.
What is known already: Selenium is a co-factor of the antioxidant enzymes responsible for prevention of ROS production. Glutathione peroxidases (GPxs) are the main selenoprotein enzymes associated with reproductive and pregnancy processes.The importance of serum selenium assessment in infertile women with POI lies in the fact that antioxidants, including selenoprotein enzymes such as GPxs, are highly sensitive to changes in selenium status and decrease significantly with selenium deficiency. The present study was therefore conducted to assess serum selenium level and GPx activity (main objectives) and nutrition status in terms of selenium intake (secondary objective) in infertile women with POI compared to healthy fertile women.
Study design, size, duration: Study design: Case-control study.
size: Case group consisted of 29 infertile women with idiopathic POI, amenorrhea and FSH >40 mIU/ml and three occult OI with oligomenorrhea and AMH <0.3 ng/ml. Control group cosisted of 31 healthy fertile women matched with the case group in terms of age and BMI.
Duration: from August 2018 to Feb 2019.
Participants/materials, setting, methods: Case group consisted of 29 infertile women with premature ovarian insufficiency (POI), amenorrhea and FSH >40 mIU/ml.
Infertility referral centers and tertiary hospital.
methods: The serum selenium level was measured by an atomic absorption spectrophotometer, and plasma GPx activity was measured by a Glutathione Peroxidase Activity Assay Kit after about 12 hours of fasting.
Main results and the role of chance: There was a significant reduction in the serum selenium level in the case group compared to the control group (Adjusted Mean Difference (AMD) = -15.1 µg/ml, 95% CI: -24.8 to -5.3). The plasma GPx activity was lower in the case group compared to the control group, although not significantly (AMD = -67.0 U/ml, 95%CI: -194.5 to 60.3).
Limitations, reasons for caution: present study limitations were selenium measurement fee.
Wider implications of the findings: This study showed a significant decline in selenium status in infertile women with POI. It could weaken the selenium-dependent antioxidant defense against reactive oxygen species and may lead to POI.
Trial registration number: IRCTID: IRCT2016041002731 1N6

P-655 Bilirubin in follicular fluid: a biochemical signature of female infertility

R. Pallisco[1], G. Bilotta[2], I. Listorti[2], P. Bilotta[3], G. Lazzarino[4], B. Tavazzi[5], T. Capozzolo[3], A. Guarino[3], G. Lazzarino[6], R. Mangione[7]

[1]Alma Res fertility center, Laboratory of Embriology, roma, Italy ;
[2]Alma Res Fertility Center, Laboratory of andrology and embriology, Rome, Italy ;
[3]Alma Res Fertility Center, Obstetrics and Gynecology, Rome, Italy ;
[4]University of Catania, Department of Biomedical and Biotechnological Sciences-Division of Medical Biochemistry, Catania, Italy ;
[5]Catholic University of Rome and Fondazione Policlinico Gemelli, Institute of Biochemistry and Clinical Biochemistry, Rome, Italy ;
[6]Saint Camillus International University of Health Sciences, Biochemistry, Roma, Italy ;
[7]Catholic University, Institute of Biochemistry and Clinical Biochemistry, Rome, Italy

Study question: To assess whether bilirubin in follicular fluid (FF) of fertile females differs from infertile. To correlate FF bilirubin concentration with in vitro fertilization (IVF) outcomes.
Summary answer: Despite normal plasma levels, FF bilirubin concentrations in infertile females are higher than in fertile females. FF bilirubin concentrations negatively correlate with main IVF measures.
What is known already: Successful in vitro fertilization (IVF) are unexplainably low (about 32%), not only in females with full-blown pathologies, but also in those known as idiopathic. Studies indicated that the composition of FF of infertile female may show altered levels of proteins, lipids, hormones respect to values found in fertile females. Such changes were associated to endometriosis, polycystic ovarian syndrome (PCOs), diminished ovarian reserve (DOR). To date, no studies have been dedicated either to determine potential differences in the FF concentration of bilirubin in fertile and infertile females or to evaluate possible correlations with main IVF outcome measures.

Study design, size, duration: Cross-sectional study in seven female groups: 1) controls (n = 34); 2) endometriosis (n = 19); 3) PCOs (n = 12); 4) DOR (n = 31); 5) age related DOR (n = 55); 6) unexplained infertility (n = 16); 7) genetic disorders (n = 11). Patients were enrolled over a period of 16 months, from September 2018 to January 2020. As inclusion criteria, patients should have total plasma bilirubin within normal physiological range (3.4-17.1 µmol/l).
Participants/materials, setting, methods: We enrolled a total of 178 patients being tested for infertility. All patients underwent oocytes retrieval and 135 of them were submitted to conventional in vitro fertilization (IVF) or intracytoplasmic sperm injection (ICSI). FF was processed by high performance liquid chromatography (HPLC) to quantify bilirubin concentration. For all patients were counted the number of cumulus-oocyte complexes (COCs), MII oocytes, zygotes and blastocysts. FF analysis was performed in blind with respect to IVF outcome measures.
Main results and the role of chance: FF total bilirubin concentration was 1.20 ± 0.42 mmol/l in controls (n = 34) and 3.07 ± 1.20 mmol/l in pooled infertile patients (+256%, $p < 0.001$). Total bilirubin in patients with endometriosis, PCOs, DOR, age related DOR, unexplained infertility and genetic disorders was, respectively 2.34 ± 0.80, 2.74 ± 0.84, 2.99 ± 0.74, 2.66 ± 0.93, 3.18 ± 0.90, 4.77 ± 1.90 mmol/l FF (values of all groups were significantly different from those of controls, $p < 0.001$). To evaluate whether increase in FF total bilirubin might affect IVF outcome, we pooled all patients into a single group (n = 178) and calculated the Pearson's correlation coefficients of bilirubin (y) and number of MII oocytes (fx); bilirubin (y) and number of zygotes (fx); bilirubin (y) and number of good quality blastocysts (fx). Increase of FF total bilirubin negatively correlated with the number either of mature oocytes ($r = -0.348$, $t = -4.876$, $p < 0.001$), or zygotes ($r = -0.247$, $t = -2.959$, $p < 0.005$), or blastocysts ($r = -0.251$, $t = -3.033$, $p < 0.005$). Results strongly suggest that increase FF total bilirubin levels are detrimental for good oocyte quality and embryo development.
Limitations, reasons for caution: At present, the main limitation of this study is the lack of data on pregnancy rate that should better allow to understand the role of FF total bilirubin in infertility and IVF success rate.
Wider implications of the findings: If reinforced by the data of pregnancies and newborns, findings of the present study might represent a significant advancement in IVF treatment. Measuring total bilirubin in FF might be helpful in selecting the best oocytes for IVF/ICSI procedures, thereby possibly leading to a significant increase of IVF success rate.
Trial registration number: not applicable

P-656 Is there an effect of late-follicular phase elevated serum progesterone on the embryo quality?

F. Van Wynsberge[1], I. De Croo[1], F. Vandekerckhove[1]

[1]UZ Gent, Department for reproductive medicine, Gent, Belgium

Study question: Does late-follicular phase serum progesterone during ovarian stimulation have an effect on embryo quality on day 3 and day 5?
Summary answer: Late-follicular phase elevated serum progesterone does not have an influence on the embryo utilization rate.
What is known already: Ovarian stimulation promotes the production of progesterone which, when elevated during the follicular phase, has been demonstrated to have deleterious effect on the endometrium and IVF outcome.
Study design, size, duration: Retrospective study analysis of all IVF/ICSI cycles between July 2015 and June 2018. A total of 1456 unique cycles were included. The primary outcome was embryo utilization rate (number of embryos transferred and cryopreserved/number of zygotes). Secondary outcomes were the number of oocytes, the fertilization rate, the percentage of good quality embryos on day 3 (at least 7 cell stage), and the percentage of blastocysts on day 5.
Participants/materials, setting, methods: Serum progesterone levels on the day of ovulation triggering were analysed as a continuous variable. All IVF/ICSI cycles were included in the analysis, using a multivariate regression to account for potential confounders (female age, AMH concentration, BMI, down regulation protocol, infertility factors and IVF or ICSI).
Main results and the role of chance: The average female age was 34.5 ± 5.0 years and the number of oocytes retrieved was 11.1 ± 6.3. The mean number of oocytes retrieved significantly increased with an increase of progesterone of 0.1 ng/ml. The percentage of embryos with at least 7 cells on day 3 was not affected by an increase of progesterone on the day of ovulation triggering. The percentage of blastocysts on day 5 significantly decreased with an increase of progesterone of 0.1 ng/ml ($p=0.002$). A multivariate regression analysis accounting for confounders confirmed this effect on the percentage of blastocysts on day 5 ($p=0.008$). It showed no correlation between late-follicular phase elevated serum progesterone and embryo utilization rate ($p=0.126$).
Limitations, reasons for caution: This study is limited by its retrospective design. A variation in the time interval between the administration of medication (gonadotrophins, antagonist) and the blood test for determination of progesterone levels can lead to different results.
Wider implications of the findings: We need larger data sets before we can definitively rule out that elevated progesterone levels at the late-follicular phase have no effect on any stage of embryonic development.
Trial registration number: EC/2018/0818)

P-657 Examining the effect of nicotine on a mouse model of the ovarian reserve

S. Idrees[1], M. Fenwick[1]

[1]University of Sheffield, Reproductive and Developmental Medicine, Sheffield, United Kingdom

Study question:
Does nicotine, or the metabolite cotinine, or the combination of both have an effect on the development of small follicles in the mouse ovary?
Summary answer:
Small follicles were reduced in size when exposed to nicotine *in vitro*; however, exposure to cotinine caused no further effect on follicle size.
What is known already: Over the past decade, there has been a dramatic shift in the number of people who have exchanged tobacco-based cigarette smoking for less harmful alternatives such as electronic cigarettes. However, users are still exposed to variable levels of nicotine, and the metabolic by-products of this stimulant. Nicotine exerts its effects by binding to nicotinic acetylcholine receptors (nAChRs) and we have previously shown that specific nAChRs are expressed in small follicles in the mouse ovary; therefore, we aimed to analyse the effect of nicotine and cotinine on the ovarian reserve.
Study design, size, duration:
Day 4 mouse ovaries densely populated with small follicles (primordial, transitional and early growing) were cultured for 7 days and exposed to nicotine, cotinine, or a combination of both using concentrations derived from published serum levels from e-cigarette users. Nicotine: 0 (control), 5 (low), 15 (medium) or 45 (high) ng/ml (5-7 ovaries/ group). Cotinine: 0 (control), 12 (low), 60 (medium) or 300 (high) ng/ml (8-10 ovaries / group).
Participants/materials, setting, methods: Ovaries from wild-type C57/Bl6 mice were dissected and cultured for 7 days in 6 well transwell plates containing membrane inserts. For morphological assessment of follicle development ovaries were fixed, sectioned and immunofluorescently labelled with antibodies DDX4 (green) and SMAD2/3 (red) to clearly identify oocytes and granulosa cells, respectively.Follicles were classified by stage and measurements of oocyte, follicle size and granulosa cell area were determined from high-resolution confocal images using imageJ.
Main results and the role of chance: Mean follicle size was reduced in primordial and transitional follicles with all concentrations of nicotine ($P<0.05$). In early growing follicles, a small, but significant reduction in size was also detectable in the high nicotine group only ($P<0.05$). These effects were mainly attributable to a reduction in mean size of the granulosa cell compartment, rather than mean oocyte size. By comparison, cotinine had no observable effect on overall follicle, oocyte or granulosa cell compartment size, regardless of concentration used ($P>0.05$). When ovaries were exposed to nicotine and cotinine in combination, mean follicle size and granulosa cell compartment size were reduced in primordial follicles in the medium and high groups only ($P<0.05$); however, no size differences were observed in transitional and early growing follicles with any concentration.
Limitations, reasons for caution: A single endpoint was evaluated after short-term culture and therefore the effects on reproductive outcomes are

unknown. This is also an *in vitro*study on mouse tissues, which may differ from human physiology.
Wider implications of the findings: Preliminary findings from this study suggest that nicotine alone can cause subtle developmental effects on the small follicles that make up the ovarian reserve. This raises further questions about the impact of an increasing trend for consumption of e-cigarettes, on female fertility.
Trial registration number: Not applicable

P-658 Correlation between 3 qualitative markers of ovarian function with IVF outcomes and embryo euploidy. Analysis of 4947 patients

M.I. Riqueros Arevalo[1], M. Martín Salat[1], M. Esbert Algam[1], J. Peñarrubia Alonso[1], N. Garrido Puchalt[2], A. Ballesteros Boluda[3]

[1]IVI Barcelona, IVF Laboratory, Barcelona, Spain ;
[2]IVI Fundation, IVI Fundation, Valencia, Spain ;
[3]IVI Barcelona, Reroductive Medicine, Barcelona, Spain

Study question: Are Ovarian Sensitivity Index (OSI), Follicular Output Rate (FORT) or Follicular Sensitivity Index (FSI) related to IVF outcomes and embryo euploidy?
Summary answer: Gestational IVF outcomes are linked to both OSI's and FORT's levels, while embryo euploidy depends on OSI.
What is known already: Whereas regulatory mechanisms determining the extent of sensitivity of antral follicles to FHS remains to be elucidated, the correct response of antral follicles (AF) to gonadotropins and a high quality oocytes results in good outcomes after IVF/ICSI.

It is well known that maternal age is strongly correlated with euploidy rate, and recently, three ovarian biomarkers (OSI, FORT and FSI) have also been proposed as good predictors of clinical outcomes. However, to date, the literature about them is still scarce and there is not any study comparing these three biomarkers with the embryo euploidy status.
Study design, size, duration: This is a retrospective multicentric study including 4947 patients that underwent IVF cycles with their own fresh oocytes in 10 ART clinics (part of a single network) between January 2018 and December 2019. Patients were split into two groups (A: non-PGT-A cycles; B: PGT-A cycles) and were analysed individually correlating the three biomarkers of ovarian responsiveness with gestational results in the first group, and with embryo euploidy in the second group.
Participants/materials, setting, methods: Group A included 1795 patients [mean age: 35.15(±3.62), BMI: 23.21(±4.08)] and group B was constituted by 3152 patients [mean age: 38.69(±3.44), BMI: 23.46(±4.11)].

According to the literature, the biomarkers were obtained applying the following formulas: FORT= (number of pre-ovulatory follicles on hCG day x 100)/ AF count at baseline, OSI= (total administered rFSH dose/ number of oocytes at OPU) x 1000 and FSI= (pre-ovulatory follicles on hCG day x 10000)/(AF count x total FSH dose).
Main results and the role of chance: To assess the correlation between the 3 ovarian biomarkers and IVF outcomes in group A, univariate logistic regression models were applied. Interestingly, we found a statistically significant correlation between OSI and clinical pregnancy (OR=1.006, p<0.001), ongoing pregnancy (OR=1.004, p=0.008) and livebirth (OR=1.003, p=0.047). The two other biomarkers (FORT and FSI) were not correlated.
Poisson regression models were used to assess the relationship between the embryo ploidy status and the biomarkers studied. The number of euploid embryos was analysed by controlling the total number of informative biopsied embryos. In the univariate models, both the OSI (p<0.001) and the FORT (p=0.003) were statistically significant, while the FSI (p=0.187) was not.

We created a multivariate regression model in which all three biomarkers were included as explanatory variables, and the patient's age was added as a control variable. We used the Akaike information criterion in both directions as a method of variable selection and both age (p<0.001) and OSI (p=0.036) proved to be statistically significant in the final optimal model. For this model, the estimated coefficients for age and OSI were 0.0697 and 0.0018 respectively, so we associated a direct relationship between the euploidy rate and the OSI.
Limitations, reasons for caution: Retrospective design of the study.
Wider implications of the findings: To our knowledge, this is the largest multicentric study aiming to correlate OSI, FORT and FSI with both gestational and embryo aneuploidy rates.

Patients with lower OSI and FORT should be counseled to undergo PGT because they are more prone to have aneuploid embryos leading to lower gestational rates.
Trial registration number: not applicable

P-659 Comparison between the outcome of consecutive versus separate distant IVF cycles in poor responders

M. Simeonov[1], O. Sapir[1], H. Lande[1], A. Ben-Haroush[1], G. Orona[1], E. Shlush[1], E. Altman[1], A. Wertheimer[1], T. Shochat[2], Y. Shufaro[1]

[1]Rabin Medical Center – Beilinson Hospital, Infertility and IVF Unit- Helen Schneider Hospital for Women, Petach Tikva 4941492, Israel ;
[2]Rabin Medical Center – Beilinson Hospital, Medical Statistics, Petach Tikva 4941492, Israel

Study question: Is it better to start an additional IVF cycle in poor responders immediately after an unsuccessful cycle, or to perform them at a time distance?
Summary answer: In poor responders, the difference in the number of oocytes and embryos is higher if the cycles are performed consecutively rather than at a distance
What is known already: Different protocols and treatments adjustments have been attempted in order to improve the ovarian response in poor responders without proven superiority. It is unclear if there is a difference between immediate consecutive and separate ovarian stimulations and oocyte pickups in this population
Study design, size, duration: : A cohort of all fresh IVF-ET cycles performed in a referral IVF unit between 2001-2019 in patients producing £4 oocytes following high dose (³300IU/d) FSH stimulation without achieving an ongoing pregnancy, who had a second pickup within 180 days. Patients who had surplus embryos cryopreserved in the first cycle were excluded. If more than two pickups were performed in a patient, only the first 2 cycles, meeting the criteria, were included in the cohort
Participants/materials, setting, methods: The cycle pairs were divided into two groups based on whether the second pickup was consecutive (performed within 45 days from the first one, group 1; 143 cases) or if at least one full menstrual cycle (46-180 days) passed between the pickups (group 2; 489 cases). The clinical and embryological data of both IVF cycles was compared between the groups
Main results and the role of chance: All the clinical basic and treatment characteristics did not differ between groups 1 and 2. Compared to the first cycle, oocyte yield in the second cycle improved by 0.29±1.54 in group 1, while in group 2 the difference in oocyte yield was -0.09±1.45 (p< 0.005). The difference in the number of embryos available for transfer between the first and second cycles was in 0.22±1.18 for group 1 and -0.06±1.3 for group 2 (p<0.019). There was no difference between groups 1 and 2 in the ongoing pregnancy rate following the second cycle
Limitations, reasons for caution: Although these results suggest that consecutive stimulations in low responders offer an advantage in the number of aspirated oocytes and available embryos in comparison with separate stimulations, this did not translate into a significant advantage in the ongoing pregnancy rate in a cohort of this size
Wider implications of the findings: Administration of high dose FSH might be beneficial for follicular recruitment also in the cycle to follow. Although this effect is modest in low responders, it might be beneficial for this patient population in which every aspirated oocyte counts. Cycle postponement under those circumstances was detrimental
Trial registration number: not applicable

P-660 Endocrine profile in Polycystic Ovary Syndrome (PCOS) patients performing frozen thawed embryo transfer in artificial cycle is significantly correlated with the ongoing pregnancy rate (OPR).

A.R. Oumeziane[1], N. Chabane[1], N. Tazairt[1], S. Barbara[1], B. Nadjia[2], F. Nanouche[3], A. Lachehab[1], S. Chemoul[1], S. Mouhoub[1], R. Bourihane[1], F. Ould el hocine[4], S. Aithadi[5], P.L. Devroey[6]

[6]none, none, brussels, Belgium

Study question: Is endocrine profile in PCOS patients, performing a single frozen thawed embryo transfer in hormonal replacement therapy (HRT) correlated with pregnancy outcomes?
Summary answer: In PCOS patient performing a single frozen thawed embryo transfer, LH and progesterone concentrations either FSH/LH ratio are strongly correlated with pregnancy outcomes.
What is known already: Since the development of vitrification embryo cryopreservation became wildly used (Rienzi 2016).To date it is not clear to recommend a specific regimen for patients who undergo frozen thawed embryo transfer (Ghobara 2017,Groenewoud 2018). HRTcycle or natural cycle are equally used .Recently it has been demonstrated that serum progesterone (P) concentration at the day of embryo transfer could negatively interfere with OPR in HRT cycle (Brady 2014,Yovitch2015,Labarta 2017).The duration of exposition to estrogen as well as the estradiol (E2) serum concentration and the route of administration of these hormones in HRT cycle are still in debate(Kahraman2018, Devine2018,Wen He2017).
Study design, size, duration: It is an observational prospective cohort study, conducted from April 1 2018 to December 31 2019, including 121 PCOS and normo-ovulatory patients, who performed a single frozen thawed embryo transfer in an artificial cycle .Patients with uterine abnormalities, auto immune pathology and implantation failure, were excluded. Chi^2, Student and Wilcoxon tests,either ROC curve, were applied for the statistical analysis .

The multivariate analysis regression was used, adjusting potential confounders to the OPR.
Participants/materials, setting, methods: 121 patients under 37 years performed a single frozen thawed embryo transfer.Only a good quality blastocyst at day 5 was replaced. Endometrium preparation was done with oral estrogen and vaginal progesterone .E2,LH and P were analyzed three times: on day two of the cycle,the day of introducing progesterone and the day of embryo replacement. 27 endometrium biopsy for histological evaluation were done in a previous simulated cycle.

Setting of the study: TIZIRI IVF Center Algeria.
Main results and the role of chance: Out of 121 patients, 39 suffered from PCOS (groupe1) and 82 were normo -ovulatory ones(groupe2). In the group 1,the threshold value of baseline LH up to 11.05IU/ml determinate by ROC curve was negatively correlated to OPR 2,5% vs 25,6% P= 0,018 with an area under curve(AUC) of 0.73. FSH/LH ratio below 0,645 was also a predictor of reduced OPR 5% vs 23% P= 0,016,AUC 0,79.Low serum progesterone the day of embryo transfer less than 12,5ng/ ml was associated with a significant diminished OPR 5% vs 23%p=0,028 ,AUC of 0,64. On the other hand in the group 2 the baseline LH level, the FSH/LH ratio, the progesterone at the day of embryo transfer are not correlated to the ongoing pregnancy rate. In this group the lowest OPR 9% vs 28% P=0,021, was associated with an endometrium thickness<8,6mm.After multivariate logistic regression, age, FSH/LH ratio and P on the day of transfer remained significant predictors for OPR .Whereas, the histologic evaluation of luteal phase endometrial receptivity didn't show any correlation with the OPR.
Limitations, reasons for caution: The pathogenesis of PCOS patients is complex; moreover the hormonal disorders of the PCOS could be link to an impaired pregnancy outcome.
Wider implications of the findings: The Polycystic Ovary Syndrome patients should benefit from a different regimen of endometrium preparation regarding to their specific endocrine profile ,while in normo-ovulatory patients, the endocrine profile didn't interfere with ongoing pregnancy.
Trial registration number: none

P-661 Gene Expression of Steroid Sulfatase and Transporter OATP2B1 is increased In Human Granulosa Cells from Women with Diminished Ovarian Reserve in IVF cycles

K.A. Sequeira Alvarado[1], S. Henriquez[1], P. Kohen[1], A. Fuentes[1], A. Tapia-Pizarro[1], P. Cespedes[1], A. Godoy[1], L. Devoto[1]

[1]Maternal and Child Research Institute, Faculty of Medicine- University of Chile, Santiago, Chile

Study question: Are transcript levels for Steroid sulfatase (STS) and organic anion transporting polypeptide (OATP)2B1 different in granulosa cells from older patient with diminished ovarian reserve vs normo-responder women?
Summary answer: Women with decreased ovarian reserve (POSEIDON 4) have higher transcript levels for STS and OATP2B1 in granulosa cells compared with women with normal ovarian response.
What is known already: Increasing evidence suggest that decreased circulating levels of dehydroepiandrosterone sulfate (DHEA-S) is associated with women with poor ovarian response to controlled ovarian hyperstimulation (COH). The uptake of DHEA-S is facilitated by the trans-membrane organic anion-transporting polypeptide OATP2B1. Once in the cytoplasm, STS enzyme catalyzes its transformation to DHEA. We hypothesize that if DHEA-S supply is important for ovarian function, in patients with diminished ovarian reserve, transcript levels for OATP2B1 and STS might be differentially expressed in granulosa cells form women of POSEIDON group 4 compared to controls.
Study design, size, duration: Prospective study which included 23women who had a cycle of in vitro fertilization at the Institute of Maternal and Child Research (IDIMI, Chile) between November 2017 and April 2019. Women who had Anti-mullerian hormone (AMH) <1.2 ng/dL and older than 35 years, met the criteria for low ovarian reserve POSEIDON 4 (n=13). The control group (n=10) included women of <30 years who had more of 12 oocytes picked-up after COH.
Participants/materials, setting, methods: Participants were treated using a gonadotropin-releasing hormone antagonist protocol for COH. We determine the gene expression (mRNA) by RT-PCR real time and the cellular distribution of sulfatase and the OATP2B1 transporter by immunofluorescence. In addition, the determinations of mRNA were related to age, AMH concentration, antral follicle count (AFC), DHEA-S and DHEA, in serum and in follicular fluid.The significance of the in vivo results was determined using Student's t-test.
Main results and the role of chance: As expected, subjects in group 4 of the POSEIDON classification had more age (38 ± 4,01 vs 25 ± 3,27 p< 0.05) and lower AMH levels (0.61 ± 0.05 vs. 2.29 ± 0.72 ng/dL p< 0.05) and AFC (4.33 ± 0.09 vs. 10.21 ± 2.45 p< 0.05). DHEA-S (383,62 ± 90,07 vs. 170,25 ± 79,04 µg/dlp< 0.05) DHEA (113,44 ± 47.23 vs 168.12 ± 38.63 µg/dlp= 0.06). The POSEIDON 4 women have significantly more expression of mRNA of STS and OATP2B1. (n=13, p< 0.05)
Limitations, reasons for caution: Caution is warranted due to the limited sample size of the study.
Wider implications of the findings: Our results suggest that up-regulation of STS and OATP2B1 in granulosa cells from women in POSEIDON group 4 could be a compensatory mechanism to overcome the decreased circulating levels of DHEA-S possibly required as substrate for intraovarian generation of DHEA.
Trial registration number: not applicable

P-662 The strategy to improve the number of competent embryos in carriers of translocation

J. Liss[1],[2], A. Knight[1], K. Lukaszuk[1,3,4]

[1]Invicta, Fertility and Reproductive Centre, Gdansk, Poland ;
[2]University of Gdansk, Department of Medical Biology and Genetics, Gdansk, Poland ;
[3]Medical University of Gdansk, Department of Obstetrics and Gynecological Nursing- Faculty of Health Sciences, Gdansk, Poland ;
[4]Medical University of Warsaw, Department of Gynecological Endocrinology, Warsaw, Poland

Study question: To evaluate the efficacy of double stimulation in terms of competent embryos in carriers of translocation.
Summary answer: Shorter time of oocyte recruitment can help increase the number of balanced blastocysts.
What is known already: The theory of a multicyclic development of follicles during the same menstrual cycle allows to collect the highest number of oocytes in the shortest possible time. Recent evidence indicates that embryos from this type of stimulation have similar developmental potential and euploidy rate compared to traditional ovarian stimulation. Translocation carriers have elevated numbers of unbalanced gametes. Reduced fertility may in part be the result of formation of a quadrivalent or trivalent structure during meiosis. It is important to know if the shorter time of oocyte recruitment can help to improve the number of balanced embryos.
Study design, size, duration: This was a retrospective case-control study and consisted of 35 women (median age 34 years, range 26-41), carrier of

translocations who were undergoing IVF treatment with PGT-SR with double ovarian stimulation in the follicular (FPS) and luteal phase (LPS) between November 2017 and October 2019 at INVICTA Fertility Centre, Poland.
Participants/materials, setting, methods: A total of 477 MII were derived (240 FPS and 237 LPS) and 149 blastocyst (68 FPS and 81 LPS) were evaluated with the NGS protocol. Ion Torrent Suite Software and Invicta Bioinformatics Team Script were used for chromosome copy number variation analysis.
Main results and the role of chance: No significant differences were observed in the mean number of metaphase II oocytes (6.8 ± 3.3; median 7; range 1-15 vs. 6.7 ± 4.3; median 6; range 1-18), fertilized oocytes (4.6 ± 2.3, median 5; range 0-10 vs. 4.9 ± 3.3, median 5; range 0-15) and top quality blastocyst (1.9 ± 1.3; median 2; range 0-6 vs. 2.3 ± 1.6; median 2; range 0-5) between FPS and LPS. The number of balanced embryos was significantly higher ($p<0.01$) in LPS compared to FPS. The mean number of balanced blastocysts in LPS was 1.2 ± 1.1; median 1; range 0-4 vs. 0.6 ± 0.5; median 0; range 0-2 in FPS. The mean rate of balanced blastocysts per MII was also significantly higher ($p<0.01$) in LPS compared to FPS (21.6% vs. 9.8% respectively).
Limitations, reasons for caution: More data are required to confirm that higher number of balanced embryos is a result of shorter recruitment time of oocytes from antral follicles.
Wider implications of the findings: The evidence of multiple follicular waves during a single menstrual cycle in women has important implications for the treatment of infertility. This strategy can maximize the number of oocytes obtained per menstrual cycle, in turn increasing the chance to obtain reproductively competent, balanced embryos in the shortest possible time.
Trial registration number: not applicable

P-663 Androgen treatment in women undergoing IVF/ICSI with poor ovarian reserve (POR): a systematic review and meta-analysis

N. Bradley[1], D. Vorster[1], L. Robinson[2], J. Ghosh[3], Y. Jeve[4], J. Chu[5]

[1]University of Birmingham, Medical School, Birmingham, United Kingdom ;
[2]Birmingham Women's and Children Hospital NHS Trust, Fertility and Menopausal Services, Birmingham, United Kingdom ;
[3]Birmingham Women's and Children Hospital NHS Trust, Academic Department of Obstetrics and Gynaecology, Birmingham, United Kingdom ;
[4]Birmingham Women's and Children Hospital NHS Trust, Reproductive Medicine and Surgery, Birmingham, United Kingdom ;
[5]Birmingham Women's and Children Hospital NHS Trust, Reproductive Medicine, Birmingham, United Kingdom

Study question: Is treatment with androgens effective for women with poor ovarian reserve undergoing IVF/ICSI treatment?
Summary answer: Current evidence suggests that Dehydroepiandrosterone (DHEA) supplementation may improve IVF/ICSI outcomes in women with POR, however, well-designed studies supporting this are lacking.
What is known already: Ovarian aging, which occurs due to a decreasing quality and quantity of oocytes, is a major factor for declining fertility. Poor ovarian reserve (POR) means women who suffer from ovarian aging have worse outcomes when undergoing assisted reproductive techniques such as IVF/ICSI due to poor response to ovarian stimulation. Exogenous steroids, such as DHEA or testosterone gel, have been used as a therapeutic intervention to improve IVF/ICSI outcomes in those with POR.
Study design, size, duration: This is a systematic review and meta-analysis of 13 RCTs encompassing 1661 patients with POF undergoing IVF/ICSI. We also conducted a study of fertility clinicians on the 'Smart Survey' platform, to gain a picture of the use of androgens (specifically DHEA) in current practice in the UK. This was open from 12/11/2019 - 27/01/2020.
Participants/materials, setting, methods: We conducted a literature search of Embase, Pub-Med, MEDLINE and Cochrane Library for articles that included the terms 'dehydroepiandrosterone', 'ovarian reserve', 'assisted reproduction techniques' 'in vitro fertilisation' and 'intracytoplasmic sperm injection'. The search was restricted to include randomised controlled trials only. Studies were excluded if they did not have live birth, clinical pregnancy rates or oocyte retrieval numbers as outcomes. We also created and distributed a retrospective cross-sectional survey to fertility settings across the UK.
Main results and the role of chance: In total 13 trials (1661 women) were included in this systematic review and meta-analysis. The meta-analysis showed that compared to the placebo, patients treated with exogenous androgens showed no improvement in live birth rate; however, there were improvements in clinical pregnancy rate and the number of oocytes retrieved during IVF/ICSI. Three trials (212 women) reported on the outcome of live birth. There was no significant difference in live birth rate between the two groups (relative risk 1.53, 95% CI 0.69-3.38, p = 0.29) with significant heterogeneity detected between these three trials (I^2=51%). Twelve studies (345 patients) reported on clinical pregnancy with the pooled analysis favouring androgen treatment (relative risk 1.41, 95% CI 1.15-1.73, p = 0.0009). Nine studies (849 patients) reported on the number of oocytes retrieved with the pooled analysis supporting the intervention (mean difference 0.80, 95% CI 0.35-1.25, p = 0.0004).

Our survey received 53 responses from a variety of UK clinicians. Of the responders, 21 (39.6%) use DHEA prior to assisted reproductive techniques (IVF/ICSI) in the treatment of patients with POR, and 17 (35.4%) would recommend the use of DHEA to a colleague.
Limitations, reasons for caution: Strict inclusion criteria were used to conduct the systematic review. As only three trials reported live birth, strong inferences cannot be made. Furthermore, we found significant statistical heterogeneity between these studies. Further interventional studies are required to assess the effectiveness of exogenous androgen in women with POR undergoing IVF/ICSI.
Wider implications of the findings: The findings of this systematic review suggest that DHEA supplementation may improve outcomes of IVF/ICSI for women with POR. However, further large, high-quality RCTs are needed to provide a clear picture of the benefits and potential risks of using DHEA as a fertility treatment.
Trial registration number: not applicable

P-664 Association between follicular fluid anti-Müllerian hormone level and oocyte quality

K. Kacem[1], B. Molka[1], M. Hamdoun[2], M. Braham[3], A. Fadhlaoui[3], F. Zhioua[3], N. Chakroun[1], O. Bahri[2]

[1]Aziza othmana hospital, cytogenetic and reproduction medecine, Tunis, Tunisia ;
[2]Aziza Othmana hospital, Biochemistry laboratory, Tunis, Tunisia ;
[3]Aziza Othmana hospital, Gynecology and obstetric, Tunis, Tunisia

Study question: What is the relationship between the anti-Müllerian hormone (AMH) concentration within
Follicles, and oocytes quality or pregnancy after ICSI and a transfer of more than one fresh embryo?
Summary answer: Among the analysed markers on the day of oocyte retrieval, AMH concentration in follicular fluid (FF)is associated with oocyte quality or pregnancy after embryo transfer.
What is known already: The serum anti-Müllerian hormone (AMH) level is a poor predictor of oocyte quality and pregnancy after IVF .However, it has been demonstrated that follicular fluid anti-Müllerian hormone of one oocyte was an excellent predictor of live birth after fresh a single embryo transfer .In fact, this embryo was matched to that oocyte.
Yet, it is still unclear whether the aptitude ofmany follicles to produce AMH reflects serum AMH concentration or their reproductive potential after embryo transfer without matching between embryos and oocytes.
Study design, size, duration: This prospective cohort study included 58 FF samples from 58 infertile women scheduled for ICSI over a 3-month period.
The FF samples were taken from at least two different follicles.
Participants/materials, setting, methods: Cycles were performed with HMG or recombinant FSH and GnRh antagonist.Concentrations of AMH in serum were measured at the start of stimulation,concentrations of AMH in follicular fluid were measured the day of oocyte pick-up.Elecsys AMH assay and electrochimiluniscence technology was used on e411 Roche cobas diagnostics to measure the two types of AMH .SPSS25 was used for the statistical analysis and comparison of averages with test for independent samples and was significant if <0,05.
Main results and the role of chance: Our patients were divided into three groups based on the follicular AMH level:

Group1: Follicular AMH <2ng/ml (29 patients)
Group2: 2ng/ml≤ Follicular AMH<3ngml (10patients)
Group3: Follicular AMH≥3ng/ml (19 patients)

The comparison of averages showed that the oocyte quality was significantly better in group 2.

In fact,the oocyte maturity rate was 72% in the second group higher than in groups 1 and 3 (59% p=0.02 and 66% p=0.048 respectively).The degenerative rate was 14,88% in group2 lower than in groups 1 and 3 (23.59% p=0.028 and 18.6% p=0.07 respectively).

The fertilisation rate was 92.38% in the second group higher than in group 1 (57.2%,p=0.001)and In group 3 (58.8%,p=0.001).

The top embryo rate was 25.48% and the pregnancy rate was 32% in the second group which is better than in group 1 (12% ;p=0.04 and 22%,p=0.058 respectively)and in group 3(15.6%,p=0.06 and 25% p=0.07 respectively).

An analysis of these FF concentrations revealed that AMH concentrations were twice as low as serum AMH in all the groups

Limitations, reasons for caution: The serum AMH concentration were not measured the day of oocyte pick up, y it was impossible to link the level of intrafollicular AMH level of a given follicule with the quality of the oocyte derived from the same follicle.

Wider implications of the findings: Group 2 was associated with a better rate of oocyte maturity,fertilisation,top embryo and pregnancy.FFAMH concentration may reflect granulosa cell proliferation during gonadotropin-stimulated follicle growth.Finally,serum AMH concentration is markedly higher than the FF AMH concentration,with no correlation between serum and FF AMH,involving ovarian follicles autonomy with regards to their secretory products.

Trial registration number: not applicable

P-665 What is the value of monitoring by ultrasonography in ovulation induction with clomiphene citrate?

J.P. De Bruin[1], S. Braam[2], N. Weiss[2], N. Lamballk[2], T. Konig[2], B.W. Mol[3], M. Van Wely[2]

[1]Jeroen Bosch Hospital, Obstetrics & Gynaecology, 's Hertogenbosch, The Netherlands ;
[2]Amsterdam UMC, Obstetrics & Gynaecology, Amsterdam, The Netherlands ;
[3]Monash University, Obstetrics & Gynaecology, Melbourne, Australia

Study question: Should women undergoing ovulation induction with clomiphene citrate (CC) be monitored with ultrasound to prevent multiple pregnancy?

Summary answer: Ultrasound monitoring with cancellation in multifollicular growth prevents multiple pregnancies but leads to lower live birth rate and higher costs.

What is known already: Ovulation induction with CC in women with normogonadotropic anovulation can lead to multifollicular growth increasing the probability of multiple pregnancy. There is no consensus on the need to monitor follicular development by transvaginal ultrasound (US).

Study design, size, duration: We performed a retrospective cohort study among 484 anovulatory infertile women treated with CC.

Participants/materials, setting, methods: Data from the first ovulatory cycle with CC in 484 women on number of dominant follicles per cycle, the number of ongoing singleton and multiple pregnancies. In order to investigate possible prediction of multifollicular growth, we performed linear regression analysis. The data were used in a decision model simulating two treatment scenarios, CC treatment with or without US monitoring and with varying outcomes such as the costs of monitoring and the incidence of multiple births.

Main results and the role of chance: In 484 women undergoing a first cycle, 393 had monofollicular growth (81.2%) resulting in 66 ongoing singleton pregnancies (16.8%). There were 73 women (15.1%) with a cycle with two dominant follicles that resulted in 22 ongoing pregnancies (30%), of which four were ongoing twin pregnancies (18.2%). There were 13 cycles (2.7%) with three dominant follicles, one of which was cancelled. These cycles led to three ongoing singleton pregnancies (23.1%).

Under the scenario that a CC cycle was not monitored by US and none of the cycles were cancelled, we estimate the ongoing pregnancy rate to be 19.2% (95% CI 16.0 to 22.9%). In this scenario the average costs for 484 basal body temperature charts (BBTs) with 6 (6.5%) twin pregnancies was estimated at € 4,272 (95% CI 3,418 to 5,127) per live birth.

Under the scenario that all cycles were monitored with US with cancellation of those with multifollicular growth, we would have cancelled 91 of the 484 cycles (cancellation rate 18.8%), thus preventing four multiple pregnancies but at the cost of 21 singleton pregnancies. This would have reduced the ongoing pregnancy rate to 13.6% and increased the average costs to € 4,721 (95% CI 3,976 to 5,466) per live birth.

Limitations, reasons for caution: Results are based on a combination of two cohort studies with limited sample size, which may have impact on the external validity of the data.

Wider implications of the findings: Our results suggest, in view of the low multiple pregnancy rate, that withholding ultrasound monitoring in CC cycles can be considered. In case ultrasound monitoring is applied, we recommend cancelling all cycles with more than one follicle to prevent multiple pregnancies and consequently accept lower pregnancy rates.

Trial registration number: -

P-666 Decreased concentrations of branched chain amino acids, tryptophan, methionine and threonine in follicular fluid of idiopathic infertile females.

I. Listorti[1], P. Bilotta[2], R. Pallisco[1], B. Tavazzi[3], G. Bilotta[1], G. Lazzarino[4], T. Capozzolo[2], A. Guarino[2], A.M. Amorini[5], M. Saab[5]

[2]Alma Res Fertility Center, Obstetrics and Gynecology, Rome, Italy ;
[3]Catholic University of Rome and Fondazione Policlinico Gemelli, Institute of Biochemistry and Clinical Biochemistry, Rome, Italy ;
[4]Saint Camillus International University of Health Sciences, Biomedical and Biotechnological Sciences, Rome, Italy ;
[5]University of Catania- Italy, Department of Biomedical and Biotechnological Sciences- Division of Medical Biochemistry, Catania, Italy

Study question: To assess whether females with unexplained infertility have free amino acids concentrations in follicular fluid (FF) different from those in FF of control fertile females.

Summary answer: FF of idiopathic infertility females has lower values of valine, isoleucine, leucine, tryptophan, methionine and threonine than those in fertile female FF.

What is known already: Previous studies analyzing FF amino acid content in female with fertility problems gave conflicting results. Either increase or decrease in specific amino acids were reported in patients with endometriosis, polycystic ovarian syndrome, diminished ovarian reserve. To date, no data are available concerning free amino acid concentration in FF of females with unexplained infertility.

Study design, size, duration: Cross-sectional study in two female groups: 1) fertile female controls (n = 34); 2) idiopathic infertile females (n = 20). FF of each participant was analyzed to determine concentrations of free amino acids and amino group-containing compounds (25 compounds). Patients were enrolled and studied over a period of 16 months, from September 2018 to January 2020.

Participants/materials, setting, methods: All participants were tested for infertility and underwent oocytes retrieval; 51 of them were submitted to conventional in vitro fertilization (IVF) or intracytoplasmic sperm injection (ICSI). FF of each participant was properly processed by high performance liquid chromatography (HPLC), to quantify FF concentration of free amino acids. For all patients were counted the number of cumulus-oocyte complexes (COCs), MII oocytes, zygotes and blastocysts. FF analysis was performed in blind with respect to IVF outcome measures.

Main results and the role of chance: Among the 25 free amino acids (FAA) quantified in FF, idiopathic infertile females had lower values (expressed in mmol/l) of valine (147.27 ± 41.06, $p < 0.005$), isoleucine (28.89 ± 9.62, $p < 0.001$), leucine (56.79 ± 16.12, $p < 0.01$), tryptophan (33.37 ± 8.79, $p < 0.05$), methionine (13.81 ± 7.27 $p < 0.005$) and threonine (131.11 ± 44.18, $p < 0.05$) than the corresponding concentrations found in fertile controls (valine = 189.88 ± 36.83 mmol/l; isoleucine = 39.60 ± 8.63; leucine = 67.57 ± 13.77; tryptophan = 39.32 ± 7.39; methionine 21.16 ± 5.17; threonine (159.60 ± 43.22). Due to the relatively limited number of patients, no statistical correlations were found among the concentrations of aforementioned essential amino acids in FF and IVF outcome. Although tendency to increase oocyte quality and good blastocysts rate were observed in patients with higher essential amino acids concentration. Since these defective amino acids are involved not only in protein synthesis, but also in energy-related metabolic functions and DNA or protein methylation it is possible that their defect in FF affects negatively oocyte and embryo development in unexplained infertility.

Limitations, reasons for caution: The main limitation of the study is related to the limited number of patients enrolled that did not allow reaching statistical correlations among the biochemical parameters of FF and the biological outcome measures of IVF.
Wider implications of the findings: These results showed that idiopathic infertile females have amino acid dysmetabolism signatures in FF. It would be possible supply FF with these compounds, to improve oocyte quality, embryo development and IVF outcome.
Trial registration number: not applicable

P-667 Expression alterations of enzymatic genes involved in the metabolism of branched-chain amino acids in subcutaneous adipose tissue in pregnant women with polycystic ovary syndrome.

S. Hajitarkhani[1],[2], A. Alizadeh[1], M. Shahhoseini[1], A. Moini[1]

[1]Royan Institute for Reproductive Biomedicine- ACECR- Tehran-, Department of Embryology- Reproductive Biomedicine Research Center., Tehran, Iran ;
[2]University Science and Culture Tehran- Iran, Department of Cell and Molecular Biology Science- Faculty of Basic Sciences and Advanced Technologies in Biology, Tehran, Iran

Study question: Is expression of BCAT2, BCKDHA, BCKDHB, DBT, DLD genes different in subcutaneos Adipose Tissue of pregnant women with polycystic ovary syndrome compared with control group?
Summary answer: Overexpression of BCKDHB, DBT genes and decreased expression of BCKDHA gene were detected in subcutaneos Adipose Tissue of pregnant women with polycystic ovary syndrome.
What is known already: Polycystic ovary syndrome (PCOS) is one of the most common endocrine disorders in women at reproductive ages and is a biochemical and metabolic abnormality too. This disorder is often associated with insulin resistance. White adipose tissue is known as an active region in the metabolism of many amino acids, including branched-chain amino acids (BCAAs). Previous studies had indicated that impaired BCAAs metabolism in adipose tissue can be a prognostic factor in insulin-resistant diabetes in the future. It is necessary to investigate gene expressions related to BCAAs metabolism in adipose tissue of women with PCOS.
Study design, size, duration: In this study, we used 13 pregnant women with PCOS and 6 pregnant women without PCOS. All samples were obtained from women who had no evidence of Abortion history or women who had not used insulin treatments during the last 3 months and were Non-diabetics, Non-Smoking. No significant differences were found in age and body mass index (BMI) betwen women with PCOS and non-PCOS women. All women filled the consent letter consiously.
Participants/materials, setting, methods: Abdominal subcutaneous fat biopsy was performed during cesarean section, samples were washed, cut and snap-freezed immediately, then cDNA synthesis was done. Real-time PCR technique was used for relative gene expression of BCAT2, BCKDHA , BCKDHB , DBT , DLD. Gene expression data were analyzed based on $2^{-\Delta\Delta CT}$ to estimate the relative fold change value. It was analyzed by t-test. Differences with $P < 0.05$ were considered significant.
Main results and the role of chance: The level of mRNA expression of BCAT2 and DLD genes in PCOS samples was not significantly different from non-PCOS samples ($P > 0.05$). Level of mRNA Expression of BCKDHB and DBT genes was increased in PCOS samples compared with control samples. These increases were statistically significant ($P < 0.001$). Level of mRNA expression of BCKDHA gene was decreased in PCOS samples compared to non-PCOS samples. These decreased were statistically significant ($P = 0.001$).
Limitations, reasons for caution: For getting more information, we need to study these genes in a larger number of women with and without PCOS and this study should be performed on subcutaneous and visceral adipose tissue of non-pregnant women due to the multifactorial pathology of pregnancy.
Wider implications of the findings: Expression changes of these genes from PCOS groups can be considered as a molecular scenario for the pathophysiology and the occurrence of insulin-resistance diabetes due to impair of Branched-Chain Amino Acids metabolism in white adipose tissue.
Trial registration number: not applicable

P-668 Variation of Antimullerian Hormone (AMH) Measurements and Its Impact on Prescription and Predicted Response in Controlled Ovarian Stimulation

G. Maciel[1], G. Maffazioli[2], V. Heirich[2], C. Lopes[2], R.P. Biscolla[3], J. De Sá[3], C. Ferrer[3], J. Vieira[3], E. Baracat[2]

[1]Hospital das Clínicas HCFMUSP & Laboratorio Fleury Medicina e Saude, Obstetrics and Gynecology, Sao Paulo, Brazil ;
[2]Hospital das Clínicas HCFMUSP, Obstetrics and Gynecology, Sao Paulo, Brazil ;
[3]Laboratorio Fleury Medicina e Saude, Endocrinology, Sao Paulo, Brazil

Study question: To analyze the variation of AMH concentration in an interval <12 months and its clinical impact on the ovarian stimulation planning in assisted human reproduction.
Summary answer: Although the variation of AMH level within 12 months was low, in 19.2% of the cases it would change the ovarian stimulation protocol.
What is known already: AMH is one of the most reliable tools for the evaluation prediction of response in controlled ovarian stimulation (COS) and ovarian reserve of female reproductive capacity. Depending on AMH levels and body mass index, it is possible to predict ovarian response and to choose the best gonadotropin doses, in order to avoid cycle cancellation due to either an excessive (hyper) or poor response. However, some questions about the physiology of AMH and the stability of laboratory determination systems have been raised lately. Due to its good stability, it is considered a good indicator of ovarian response to assisted reproduction cycles**.**
Study design, size, duration: Observational retrospective study with 554 women who had measured AMH levels by the same assay in an interval of <12 months (T1 and T2) between the years of 2014 and 2018 at a large clinical analysis laboratory. Samples were divided into 3 groups according to AMH levels at T1 and the prognosis of controlled ovarian stimulation: risk of poor response (LR):<1.2 ng/mL; normal response (NR): 1.2-3.4 ng/mL; risk of ovarian hyperstimulation (rOH): >3.4ng/mL.
Participants/materials, setting, methods: Mean age of women included was 37.0±4.4 years old, FSH 11.0±16.1 IU/L, LH: 10.1±14.9 IU/L and AMH 1.60±2.44 ng/mL. Exclusion criteria were the use of hormonal contraceptive, biotin and ovulatory induction medications or follicle stimulated hormone (FSH) and/or luteinizing hormone (LH) levels < 1.0 UI/L at the time of AMH dosage. AMH was measured by platforms Elecsys™, Roche and Pico AMH™, Ansh Labs. Chi-squared statistical test was used to evaluate proportion differences between groups.
Main results and the role of chance: The mean interval between the two measurements was 6.5±3.4 months, and the mean variation of AMH was 0.05±1.86 ng/dL. At T1, 61% presented LR; 29% NR; and 10% rOH. After T2, 103 women (19%) had changed their prognosis in RHA. From these, 6.7% changed from LR to NR; 6.3% from NR to BR; 3.2% from NR to rOH; 2.6% from rOH to NR and 0.2% from LR to rOH. In a subset analysis, women were then divided into two groups according to age range: younger than 35 years old (n=161) and older than 35 years old (n=383). Mean ages for both groups were 31.9±2.7 and 39.1±3.0 years old, respectively. Mean variation of AMH levels were 0.39±2.64 ng/mL at < 35 years old group and 0.09±1.38 ng/mL at > 35 years old group. There was no difference in the proportion of prognosis change in assisted human reproduction between the two age range groups (22.9% vs 17.6%, p=0.16).
Limitations, reasons for caution: These findings are limited by lack of clinical data regarding the reason of AMH measurement, phase of the menstrual cycle and information of antral follicle count, another important predictor of ovarian response in assisted reproduction cycles. However, it raises a question about the best clinical practice when predicting ovarian response.
Wider implications of the findings: At a timeframe lower than 12 months, the mean variation of AMH was low, but enough to change the protocol and prognosis in assisted human reproduction in 19% of the cases. These data suggest that the measurement of AMH should be performed close to the beginning of the ovarian stimulation.
Trial registration number: Not applicable

P-669 which gonadotropin, recombinant or urinary,works better in aging women.

R. Hu[1], W. Yafei[2]

[1]General Hospital Of Ningxia Medical University, Reproductive Medicine Center of General Hospital Of Ningxia Medical University, Yingchuan, China ;
[2]Ningxia Medical University, Ningxia Medical University Clinical medicine, Yinchuan, China

Study question: To determine which gonadotropin, recombinant or urinary,works better in aging women from efficacy and economic perspective.
Summary answer: For aging women, superiority of HMG over rFSH and uFSH in clinical outcomes could not be concluded from this study, but noninferiority was established.
What is known already: Although potential benefits of LH activity were large quantity reported, it remains controversial whether adding LH during ovarian stimulation improves oocyte quality. A recent systematic review found that the addition of LH activity may improve ongoing pregnancy rates than FSH alone, but not live birth rates. Some papers reported that adding rLH to patients below 35 did not bring any benefit, but may be beneficial for advanced age and patients with decreased ovarian reserve. However, few reports indicated that aging women (≥35 years) have a beneficial effect on rLH supplementation during a antagonist protocol.
Study design, size, duration: This is a retrospective analysis.From January 2009 to December 2017, collecting 500 infertile women ≥35 years old undergoing in vitro fertilization (IVF)/intracytoplasmic sperm injection cycles (ICSI) received ovarian stimulation with HMG (n=199) or with uFSH (n=198) or with rFSH (n=103) in a gonadotropin-releasing hormone(GnRH) antagonist protocol.
Participants/materials, setting, methods: The primary end points were clinical pregnancy and live birth rate ,while the secondary endpoints were total dose administered to FSH, mean stimulation days, serum estradiol levels and endometrial thickness on the day of hCG administration, number of oocytes retrievaled, MII oocyte numbers, number of frozen embryos, fertilization rate, embryo cleavage rate,implantation rates, Abortion rate, cycle cancellation rate, incidence rate of OHSS and the costs per cycle, cost-effectiveness ratio of the three regimens.
Main results and the role of chance: There were no statistically significant differences in demographic data and baseline characteristics for three groups.The mean numbers of oocytes retrieved was lower in HMG group compared with uFSH and rFSH groups (4.6±2.9 vs. 6.2±3.8 vs. 7.1±4.7,P=0.000), while the clinical pregnancy per started cycle (23.6 vs. 27.3 vs. 31.1%,P=0.367), implantation (16.1 vs. 20.8 vs. 22.1%) and live birth rate per started cycles (13.6 vs. 20.2 vs. 20.4%) were comparable. Data were further analyzed performing separate comparisons in subpopulations with different ranges of age, i.e.35-37, 38-40, and >40. Major differences between the three regimens were observed in women with age>40. In this subpopulation, not only the implantation rate was higher in the uFSH group compared with HMG and rFSH groups (15.4 vs. 4.4 vs. 13.0%, $P < 0.05$), but also live birth rate was significantly higher (12.9 vs. 1.3 vs. 6.7%, $P < 0.05$). The cost-effectiveness ratio in the HMG group was $564.6 and $2,170.5 in the uFSH group and $17,561.3 in the rFSH group.
Limitations, reasons for caution: However, considering its retrospective study, there is a certain limit to the evidence. It is strongly suggests the necessity to carry out large RCTs for patients with advanced age or DOR to guide clinical applications.
Wider implications of the findings: In the era of individualized treatment, this study provides the most effective and economical treatment options for aging women undergoing IVF and ICSI treatment.
Trial registration number: not applicable

P-670 Oophorectomy in pre-menopausal women, long-term risk of breast cancer and the modifying effects of menopausal hormone therapy: A prospective cohort study.

T. Koch[1], J. Therming Jørgensen[2], L. Priskorn[1], A. Juul[1], C. Dehlendorff[3], A.K. Dunn-Henriksen[3], J. Christensen[3], E. Bräuner[1], Z. Andersen[2], M. Hickey[4]

[1]Rigshospitalet, Growth and Reproduction, Copenhagen, Denmark ;
[2]University of Copenhagen, Section of Environmental Health- Department of Public Health, Copenhagen, Denmark ;
[3]Danish Cancer Society Research Center, Statistics and Pharmacoepidemiology, Copenhagen, Denmark ;
[4]University of Melbourne, Obstetrics and Gynaecology, Melbourne, Australia

Study question: Does pre-menopausal oophorectomy (surgical menopause) change the long-term risk of breast cancer and how does menopausal hormone therapy modify this risk?
Summary answer: Statistical analyses are ongoing, results will be ready prior to the meeting in July 2020
What is known already: Existing evidence suggests that pre-menopausal oophorectomy reduces the risk of breast cancer in the general population and in women at high inherited risk of breast cancer. However, the effect of menopausal hormone therapy (MHT) on breast cancer after oophorectomy is poorly understood. This is of clinical importance because MHT is widely recommended after surgical menopause in women without contraindications. However, existing evidence is limited by self-report of oophorectomy and use of MHT potentially leading to misclassification bias.
Study design, size, duration: Prospective register-based cohort study of 28,731 participants in the Danish Nurse Cohort with detailed lifestyle information. Information about oophorectomy (unilateral or bilateral) and hysterectomy was recorded in national patient registers, use of MHT was recorded in national prescription registries and incidence of breast cancer following oophorectomy was identified from the Danish Cancer Registry using a unique identification code.
Participants/materials, setting, methods: Cox regression analyses with age as underlying timeline is used to assess the effects of pre-menopausal oophorectomy (stratified according to unilateral and bilateral) on the subsequent risk of breast cancer. Analyses are adjusted for potential confounders. Further, the modifying effects of MHT, hysterectomy (registry-based date of procedure), BMI and work patterns including shiftwork are evaluated.
Main results and the role of chance: Of the 28,731 nurses we excluded 632 with a breast cancer diagnosis before baseline, 645 with a diagnosis of other cancer (not non-melanoma skin cancer) before baseline, 505 with mastectomy before baseline and 3 with an inactive status in CPR before baseline leaving nurses 27,422 eligible for follow-up. During follow-up, we identified 2,165 cases of breast cancer.

Breast cancer cases had a slightly higher median baseline age, were more likely to have had a bilateral oophorectomy and use of MHT, but were similar in regard to unilateral oophorectomy, hysterectomy, use of oral contraceptive, parity, age at menarche, physical activity and working conditions. Further, cases were older when they had their first child and were more likely to have an unhealthy lifestyle (higher BMI, current smokers and heavy drinkers) compared to nurses without breast cancer. Regression analyses are being executed and results will be ready before ESHRE2020.
Limitations, reasons for caution: Gene mutation status is not available so the indication of risk-reducing oophorectomy cannot be determined. Genetic variants known to affect breast cancer risk such as BRCA1/BRCA2 are not known. Secondly, confounder variables (for example smoking, alcohol, BMI, etc.) are based on baseline questionnaire data and may have changed during follow-up.
Wider implications of the findings: Bilateral salpingo-oophorectomy is the only evidence-based intervention to reduce morbidity and mortality from ovarian cancer. However, the optimum timing of risk-reducing oophorectomy and the effects of MHT usage are uncertain. This study will provide new information to inform clinical practice in this area and may translate into improved health outcomes.
Trial registration number: Not applicable, this is a register-based study.

P-671 Association of luteinizing hormone/choriogonadotropin receptor G935A and Ins18LQ gene polymorphisms with polycystic ovary syndrome in Indonesian women

H.P. Lubis[1], M.F.G. Siregar[1], B. Halim[1], I. Adenin[1]

[1]Faculty of Medicine- Universitas Sumatera Utara, Obstetrics and Gynecology, Medan, Indonesia

Study question: Is there an association between luteinizing hormone/choriogonadotropin receptor (LHCGR) G935A and ins18LQ gene polymorphisms and polycystic ovary syndrome (PCOS) in Indonesian women?
Summary answer: Luteinizing hormone/choriogonadotropin receptor (LHCGR) G935A and ins18LQ gene polymorphisms were not associated with PCOS in Indonesian women.
What is known already: Polycystic ovary syndrome (PCOS) is one of the most common endocrine-metabolic disorders and a complex genetic disorder. Study on genes susceptible to PCOS has focused mainly on gene polymorphisms that encode sex hormones and regulatory proteins such as follicle-stimulating hormone ß (FSHB), follicle-stimulating hormone receptor (FSHR), Luteinizing Hormone Chorionic Gonadotropin Receptor (LHCGR), estrogen receptor alpha receptor (ESR1), and estrogen receptor ß (ESR2). Variants of genetic markers have implications for the predisposition of PCOS, however, there are no variants that are directly and repeatedly linked to PCOS.

Study design, size, duration: A case-control study was performed in 50 women with PCOS as the case group and 50 healthy women with none of the pathological characteristics as the control group from May 2019 until October 2019 in Halim Fertility Center, Division of Reproductive Endocrinology and Infertility, Faculty of Medicine, Universitas Sumatera Utara, Indonesia.
Participants/materials, setting, methods: All participants were women of reproductive age. Polymorphisms of LHCGR G935A and ins18LQ genes were genotyped in all subjects using *polymerase chain reaction-restriction fragment length polymorphism* (PCR-RFLP). The allelic frequencies of each case group were compared with the controls.
Main results and the role of chance: From this study, we found that there was no significant association between LHCGR G935A and ins18LQ gene polymorphisms with PCOS. There were significant differences in the characteristics of Body Mass Index (BMI), FSH level, LH level, and LH / FSH ratio between the PCOS and control groups ($p<0.05$). In the LHCGR G935A gene polymorphisms, the proportion of homozygote mutant AA genotypes was higher in the PCOS group (6%) compared to the control group but there was no significant difference between them ($p= 0.391$). The frequency of allele A was higher in the PCOS group compared to the control group. Then, in the LHCGR ins18LQ gene polymorphisms, the proportion of heterozygote variant nonins/ins was higher in the PCOS group (12%) than the control group (4%) but there was no significant difference between the polymorphisms of the nonins-ins and nonins-nonins variants between the PCOS and control groups ($p=0.269$). The frequency of ins allele was higher in the PCOS than the control group.
Limitations, reasons for caution: The sample size of this study was relatively small, which therefore limited the statistical power of the analysis to a certain extent.
Wider implications of the findings: This is the first report studying the association of LHCGR G935A and ins18LQ gene polymorphisms with PCOS in Indonesia. The increased frequency of homozygote mutant genotypes of LHCGR gene in PCOS group suggests that these subjects have an elevated risk of developing the syndrome, although the association is not significant.
Trial registration number: not applicable

P-672 Long-term effects of premenopausal oophorectomy on mental health and modifying effects of Menopausal Hormone Therapy. A prospective Cohort Study.

E. Bräuner[1], T. Koch[1], L. Priskorn[1], A. Juul[1], C. Dehlendorff[2], J. Christensen[2], A.K. Dunn-Henriksen[2], J. Therming Jørgensen[3], Z. Andersen[3], M. Hickey[4]

[1]Rigshospitalet, Growth and Reproduction, Copenhagen, Denmark ;
[2]Danish Cancer Society Research Center, Statistics and Pharmacoepidemiology, Copenhagen, Denmark ;
[3]University of Copenhagen, Section of Environmental Health- Department of Public Health, Copenhagen, Denmark ;
[4]University of Melbourne, Obstetrics and Gynaecology, Melbourne, Australia

Study question: Does premenopausal oophorectomy affect the long-term risk of depression, dementia, Parkinsonism and Alzheimer's Disease? How does Menopausal Hormone Therapy (MHT) modify this risk?
Summary answer: Preliminary analysis from this large prospective cohort study indicates that premenopausal oophorectomy increases both depression and dementia. All analysis will be complete for ESHRE2020.
What is known already: Premenopausal oophorectomy (surgical removal of one/both ovaries) is performed in around 30% of hysterectomies for benign gynecological conditions and is the only intervention shown to reduce morbidity and mortality from ovarian cancer in women at high genetic risk. Premenopausal bilateral oophorectomy leads to an immediate reduction in circulating sex steroids. Preclinical and clinical evidence indicates that ovarian sex steroids particularly estrogen, have neuroprotective action and that oophorectomy may increase depression, Parkinson's Disease and dementia. However, existing studies are limited, the evidence is conflicting, the modifying effects of MHT are uncertain.
Study design, size, duration: The nationwide Danish Nurses Cohort (est. 1993, n=28,731 women) will be used to prospectively determine the long-term effects of premenopausal oophorectomy on dementia, Parkinsonism, Alzheimer's Disease and depression (symptoms/major disorder) risk and the modifying effects MHT on this. Extensive baseline data including socio-economic/working conditions, weight, height, lifestyle and reproductive history/health have been collected. Information on oophorectomy, health outcomes and MHT are extracted from national patient and prescription registers and data access is approved.
Participants/materials, setting, methods: Time-varying cox regression models, with age as underlying timeline are used to assess the risk of each outcome separately. All nurses (exposed and unexposed, matched by age on the index date of oophorectomy) are followed up for the date of outcomes of interest (separate analyses), death, disappearance and emigration and censored on that date or end of follow-up (31st December 2018), whichever comes first. Modifying effects of MHT use, BMI and hysterectomy will be measured.
Main results and the role of chance: Participants with cancer (apart from non-melanoma skin cancer) and those with missing baseline information have been excluded, leaving 22,882 female nurses for the analyses. Of these 22,882 women, 1,084 (4.7%) nurses underwent premenopausal oophorectomy (unilateral/bilateral: 685/399) and 2,262 (9.9%) underwent post-menopausal oophorectomy (unilateral/bilateral: 685/399) defined as age > 51 years. During a mean follow-up of 18.6 years, 8,077 nurses developed depression (depressive symptoms or major disorder), 1,534 developed dementia, 1,013 Parkinson's Disease and 1,157 Alzheimer's Disease. In general, cases had a slightly higher median age at baseline, were more likely to have had an oophorectomy, but were similar in regard to hysterectomy, use of MHT, use of oral contraceptive, parity, age at menarche, physical activity and working conditions. Further, cases were more likely to have an unhealthy lifestyle (higher BMI, current smokers and heavy drinkers) compared referent nurses. We will report hazard ratios (HRs) reflecting the risk of these outcomes stratified according to unilateral and bilateral oophorectomy and further stratified according to reproductive stage at oophorectomy (pre or postmenopausal). Cox regression analyses are in progress, but preliminary results suggest significantly increased risks for depression and dementia and borderline effects for Parkinsonism and Alzheimer's Disease.
Limitations, reasons for caution: Gene mutation status is not available so the indication of risk-reducing oophorectomy cannot be determined. Also, genetic variants known to affect dementia risk such as genetic information APOE or ESR1 are not known. Secondly, confounder variables are based on baseline questionnaire data and may have changed during follow-up.
Wider implications of the findings: The global health burden of mental health disease in women is enormous and understanding the modifiable factors contributing to these is of international importance. This will be the first prospective cohort study investigating these risks after premenopausal oophorectomy, generating new evidence to inform clinical practice and improve health outcomes.
Trial registration number: Not applicable, this is a register-based study.

P-673 Physiological temperature in human follicles during oocyte growth is around 35°C: does lowering temperature to 35°C affects maturation rate and quality of human oocytes?

D. Nikiforov[1], J. Cadenas[1], S.E. Pors[1], L.A.Z. Jara[1], W. Yu[1], S. Gry Kristensen[1], C. Yding Andersen[1]

[1]Laboratory of Reproductive Biology, The Juliane Marie Centre for Women-Children and Reproduction- Copenhagen University Hospital, Copenhagen, Denmark

Study question: Does the physiological temperature of 35°C, observed within large antral human follicles *in vivo*, affect maturation rate of human oocytes undergoing *in vitro* maturation (IVM)?
Summary answer: Immature human oocytes cultured at 35°C demonstrated a similar maturation rate and morphological quality as immature oocytes matured at 37°C.
What is known already: Studies on several mammalian species, including humans, revealed that the temperature inside large antral follicles is lower compared to the surrounding stroma. Within the human ovary, this difference is, on average, 2.3°C. Therefore, growing oocytes are under physiological conditions exposed to temperatures below 37°C. No studies have evaluated the maturation capacity of human oocytes at different temperatures. This study aimed to compare nuclear maturation (i.e., MII-transition of GV-oocytes) of human oocytes after IVM at 35°C (*in vivo* temperature inside preovulatory follicle) versus 37°C (deep body temperature in humans). Correlation between oocytes' quality, diameter and maturation rate were also analyzed.

Study design, size, duration: In a prospective cohort study, patients undergoing ovarian tissue cryopreservation (OTC) were recruited. After isolation and cryopreservation of ovarian cortex, the remaining medulla tissue was examined for the presence of immature oocytes, released from small antral follicles during dissection. Oocytes were collected and matured *in vitro* for 44-48 hours following standard IVM procedures. The oocytes were randomly allocated to incubation at 35 °C or 37°C.

Participants/materials, setting, methods: Twenty-five patients, aged 19-38 years, were included. The MII rate was compared between oocytes cultured at 35°C vs 37°C. Temperature monitoring was ensured by wireless pre-equilibrated data logging devices controlling the temperature inside both incubators. After IVM, oocyte nuclear maturation, diameter, and morphology were evaluated.

Main results and the role of chance: On average, 25 immature oocytes were collected from each patient (range 6-53, N=637). No significant difference was found in the overall maturation rate between oocytes incubated at 35°C and 37°C (37% vs 33%, respectively; p=0.25). When analyzing the maturation rate in a subgroup of oocytes found in large cumulus-oocyte complexes (COCs) (> 15-19 layers of cumulus cells), a significantly higher rate was observed in oocytes incubated at 35°C as compared to 37°C (MII rate 52% vs 42%, respectively; p=0.03). Furthermore, oocyte diameter was found to be significantly associated with maturation rate, regardless of cumulus size (large COCs, small COCs or naked oocytes) or temperature: oocytes with larger diameter had better chances for maturation (p<0.0001). Oocyte quality evaluation based on morphology, which comprised a strict assessment of cytoplasm, perivitelline space and zona pellucida, demonstrated no differences after maturation at the two temperatures (p=0.25) and was not related to oocyte diameter (p=0.09).

Limitations, reasons for caution: A limitation of the study is the lack of data regarding the developmental potential of MII oocytes after IVM. Additional data regarding fertilization and blastulation rates of oocytes may provide insight into the impact of temperature during IVM on developing embryos.

Wider implications of the findings: The study demonstrated that the temperature range for IVM of human oocytes is surprisingly wide. *In vitro* maturation of oocytes collected from small antral follicles had sufficient MII rate at both 35°C and 37°C. The use of IVM in connection with OTC should be considered clinically.

Trial registration number: not applicable

P-674 Serum progesterone measurement in frozen embryo transfers following hormone replacement therapy: a systematic review and meta-analysis

P. Melo[1], Y. Chung[1], O. Pickering[1], M.J. Price[1], S. Fishel[2], M. Khairy[2], P. Lowe[3], M. Rajkhowa[2], A. Tozer[4], M. Wilcox[4], I.D. Gallos[1], A. Coomarasamy[1]

[1]Tommy's National Centre for Miscarriage Research, Birmingham Women's Hospital, Birmingham, United Kingdom ;
[2]CARE Fertility, ProFET, Birmingham, United Kingdom ;
[3]CARE Fertility, ProFET, Manchester, United Kingdom ;
[4]CARE Fertility, ProFET, London, United Kingdom

Study question: How do serum progesterone levels in frozen embryo transfers following hormone replacement therapy (HRT-FET) correlate with pregnancy outcomes?

Summary answer: High serum progesterone is associated with an increased chance of clinical pregnancy and reduced risk of miscarriage in HRT-FET, although high-quality prospective studies are required.

What is known already: Endometrial receptivity is one of the principal factors influencing early pregnancy success in assisted reproductive treatment (ART). Progesterone is essential to ensure optimal endometrial receptivity, and in its absence, pregnancy inevitably fails. In women undergoing frozen embryo cycles, exogenous progesterone is administered to ensure synchrony between the endometrium and the developing embryo. There is conflicting evidence on the association between serum progesterone and pregnancy outcomes in HRT-FET, and no consensus exists among clinicians as to whether serum progesterone testing should be used routinely for predicting pregnancy outcomes in HRT-FET cycles.

Study design, size, duration: A systematic review and meta-analysis was performed. Electronic searches of the Cochrane Gynaecology and Fertility Specialised Register of Controlled Trials, CENTRAL, MEDLINE, EMBASE, PsycINFO, CINAHL and ClinicalTrials.gov were conducted to December 2019 to identify relevant cohort, case-control and randomised controlled studies where serum progesterone was measured around the time of HRT-FET. The key search terms were the following: [MeSH/Emtree] progesterone AND (in vitro fertilization OR intracytoplasmic sperm injection, frozen embryo, embryo transfer, assisted reproduction techniques).

Participants/materials, setting, methods: We included studies where serum progesterone was measured during HRT-FET cycles (any time from the onset of progesterone supplementation to the day of pregnancy test) and correlated with pregnancy outcomes. The primary outcome was ongoing pregnancy/live birth rate (OPR/LBR); secondary outcomes included clinical pregnancy rate (CPR) and miscarriage rate (MR). Two authors screened studies and extracted data independently. Risk ratios (RR) were calculated with 95% confidence intervals (CI). Heterogeneity was examined with the I^2 statistic.

Main results and the role of chance: Six studies were included in the meta-analysis, involving 4,369 women. Seven additional studies are awaiting classification, and two are ongoing.

The final meta-analyses consisted of data from cohort studies; five were published in peer-reviewed journals and one as a conference abstract. All studies were retrospective and reported on pregnancy outcomes according to serum progesterone concentrations. The progesterone cut-off values ranged between 32 and 50 nmol/L.

On comparing high *versus* low serum progesterone, the evidence was uncertain on the effect of high serum progesterone upon OPR/LBR compared to low serum progesterone (three studies, 3,834 women, RR 1.51, 95% CI 1.00 to 2.27). Nevertheless, high serum progesterone was found to result in more clinical pregnancies compared with low serum progesterone (four studies, 4,121 women, RR 1.39, 95% CI 1.05 to 1.84). Furthermore, high serum progesterone was linked to a reduction in miscarriage rate compared to low progesterone (four studies, 721 women, RR 0.45, 95% CI 0.29 to 0.69). None of the studies reported on any adverse events attributable to exogenous progesterone supplementation.

The included studies scored well on the Newcastle-Ottawa quality assessment scale.

Limitations, reasons for caution: The high degree of clinical heterogeneity owing to various administration routes, timings of testing and serum progesterone thresholds, as well as the retrospective nature of all studies, were the main limitations of this review. This precludes the generalisation of findings and limits the clinical applicability of this test to date.

Wider implications of the findings: Although higher serum progesterone was linked to an increased chance of clinical pregnancy and reduced risk of miscarriage, the optimal progesterone level required for HRT-FET treatment success remains uncertain. High-quality, adequately powered prospective studies are required to further investigate the diagnostic and prognostic value of serum progesterone in HRT-FET cycles.

Trial registration number: Not applicable

P-675 Serum progesterone measurement and optimization reduce pregnancy loss in frozen-thawed embryo transfer cycles with hormone replacement therapy

D. Tarasconi[1], M. Aura[1], M. Arque[1], M. Julia[1], M.Á. Checa[1], J.J. Espinós[1]

[1]FERTTY Centro de Reproducción Asistida, Medicina Reproductiva, Barcelona, Spain

Study question: Does progesterone (P) optimization by measuring and correcting serum levels when appropriate reduce pregnancy loss following IVF-ET?

Summary answer: Serum progesterone determination and its supplementation by adding subcutaneous injections when P<10,0ng/ml reduced miscarriage rates among patients undergoing ET using their own oocytes

What is known already: Progesterone has been consistently associated with pregnancy achievement and development. A significant number of biochemical pregnancies and miscarriages following In Vitro Fertilization - Embryo Transfers (IVF-ET) might be due to progesterone deficiency. Previous studies suggest that serum progesterone values lower than 9,2 to 10,64 ng/ml are detrimental to achieve optimal reproductive results in artificial replaced cycles for frozen-thawed embryo transfer. However, the best approach in daily practice combining both effiency and patient convenience is yet to be established

Study design, size, duration: Cohort study from March 2018 to December 2019 (22 months) in a private infertility centre. We included 153 IVF-ET cycles of frozen-thawed embryo transfers, with a conventional hormone replacement therapy (HRT) for endometrial preparation

Participants/materials, setting, methods: Patients with HRT in order to transfer frozen embryos. All women were treated with a sequencial combination of oral estradiol valerate (EV)(6 mg/day) for 11-15 days followed of EV plus vaginal micronized progesterone (P)(200mg/8h). In group study, at 4th day of P administration we determined serum P. With levels lowers than 10ng/dl we added 25 mg of daily subcutaneous progesterone. Conversely, patients from the control group were routinely treated. Primary outcome was ongoing pregnancy rate

Main results and the role of chance: We determined serum P values in 89 patients (study group). P levels < 10.0 ng/dl were found in 26 (29.3%), with a median value of 8.8 ng/dl (7.4–9.2). Average P levels in the rest of the group was 13.39 ng/dl (11.5–16.2). Both groups were comparable to all the parameters studied, including ongoing pregnancy rate (*P*=1.0) and pregnancy loss (*P*=0.3). Age, BMI and embryo quality were also equivalent between the study and control (N= 64) groups. The miscarriage rate was lower in the study group (10.8% versus 30%; *P* = 0.03, 95% CI) without diferences in ongoing pregnancy rates (46.1% versus 44.1%; *P* = 0.86).

Limitations, reasons for caution: As we want to combine both efficiency and patient convenience we do not perform a ¨second-look¨ in progesterone levels after supplementation to verify if we achieved better serum progesterone concentration in these patients, so this missing data could be a limitation of the study.

Wider implications of the findings: The present study suggests that with only one additional blood determination of serum progesterone, on the day prior the embryo transfer, may identify patients who will benefit of additional subcutaneous progesterone in the luteal phase support in cycles of ET with HRT using their own oocytes, reducing the miscarriage rate.

Trial registration number: not applicable

P-676 Empty follicle syndrome(EFS) in PCOS patients after GnRH agonist trigger at a tertiary level infertility centre in India: A prospective cohort study

Nayar K.D.(1)*[kdnayar@usa.net], S. Gupta[1], M. Singh[1], R. Bhattacharya[1], G. Kant[1], R. Gahlot[1], N. Sharma[1], D. Nayar[1]

[1]Akanksha IVF Centre, Reproductive Medicine, New Delhi, India

Study question: To analyze the incidence and underlying physiology of EFS following GnRH agonist trigger in PCOS patients at a tertiary level infertility centre in India.

Summary answer: EFS following GnRH agonist trigger in PCOS is a rare event. The False EFS group can have favorable outcomes following rescue trigger.

What is known already: EFS is failure to retrieve oocytes after ovarian stimulation, despite normal follicular development, incidence being 0.045%–7% . EFS is diagnosed retrospectively, since it cannot be predicted by USG or hormonal levels. GnRH agonist trigger acts on the pituitary and causes gonadotropin release leading to LH surge lasting for 24-36hours in comparison to hCG trigger where it lasts for 8-9days. False EFS is mainly due to human error in timing, administration of trigger or manufacturing and cold chain problem. For genuine EFS, receptor polymorphisms, inability of the pituitary to release gonadotropins and dysfunctional folliculogenesis due to PCOS are implicated.

Study design, size, duration: A prospective cohort study including 225 patients diagnosed with PCOS according to Rotterdam`s criteria was carried out between January 1, 2017 through 31 December 2019.

Participants/materials, setting, methods: All patients underwent Controlled ovarian hyperstimulation using fixed GnRH antagonist protocol and GnRH agonist trigger. If no oocytes were retrieved from one ovary, serum progesterone levels were done to classify as genuineEFS (S. progesterone levels >3.5ng/ml) or false EFS(S. progesterone < 3.5ng/ml). In cases of False EFS, rescue hCG trigger was given and ovum pick up scheduled 35 hours after the trigger. Freeze all strategy was employed and embryo transfer done in a subsequent cycle.

Main results and the role of chance: Incidence of EFS in PCOS patients following GnRH agonist trigger was 3.11%(7/225). The age, BMI , parity, cause and duration of infertility were similar in EFS and non EFS group. There was no significant difference in AMH and AFC levels between the two groups. However, significantly higher doses of gonadotropins(2500±743 vs. 1850±690; p=0.02) and prologend duration of stimulation(11.6±1.79 vs. 9.5±1.2; p=0.001) was noted in the EFS group. Out of 7 cases, False EFS was identified in 5 cases(71.43%) and 2 cases (28.57%) were attributed to Genuine EFS, wherein no cause was identified. Out of 5 False EFS cases, eggs were retrieved in 4 patients following rescue hcg trigger and 2 patients achieved a clinical pregnancy(40%). For Genuine EFS cases, GnRH antagonist protocol with Dual trigger was planned in the subsequent cycle. Eggs were retreived in one patient, however genuine EFS recurred in the second patient.

Limitations, reasons for caution: Although it is a prospective study, it has limitation of small sample size.

Wider implications of the findings: Our experience at a tertiary infertility care centre in India suggests that EFS is a rare occurrence in PCOS patients following GnRH agonist trigger. False EFS can have favourable outcomes following the rescue trigger and Genuine EFS is most likely attributed to intrinsic ovarian dysfunction.

Trial registration number: MCDH/2019/17

P-677 The selection of ovulation induction protocols in patients with PCO syndrome undergoing IVF procedures

J. Bila[1], S. Spremovic Radjenovic[1], A. Gudovic[1], G. Srejic[1]

[1]Clinical Centre of Serbia, Clinic for Gynecology and Obstetrics, Belgrade, Serbia

Study question: To examine the significance of the ovulation induction protocols selection in patients with PCOS in successful IVF cycles.

Summary answer: Short protocol with antagonists has proved to be the most efficient for conception. Positive predictors of conception were younger age and lower serum progesterone levels.

What is known already: Polycystic Ovary Syndrome (PCOS) is a complex endocrine syndrome that affects about 6% of women during their reproduction period. PCOS is one of the leading factors of anovulation-induced infertility and the most frequent endocrine cause for the IVF procedures. In PCOS patients, stimulation of ovulation results in maturation of more follicles and therefore increases the chances of getting the quality and healthy egg cells. However, at the same time the risk of severe OHSS might be increased.

Study design, size, duration: In this retrospective study we have included 332 patients with PCOS in the period between 2014-2018 at the Clinic for Gynecology and Obstetrics Clinical Centre of Serbia. Study inclusion criteria were: age less than 40, PCOS diagnosed prior to IVF procedures and absence of other infertility-associated factors. Study exclusion criteria were: age over 40, the presence of other infertility-associated conditions like other endocrine disorders, endometriosis or tubal factor infertility and male infertility.

Participants/materials, setting, methods: In this study were included patients who underwent both short and long stimulation protocols. Patients undergoing long protocol (A group) were on the GnRH agonist-protocol. Patients undergoing short protocols were divided in two groups – the first (B1) group using GnRH agonist-protocol and the second group (B2) group using GnRH antagonist-protocol. The protocol selection was based on the patient's age, endocrine status (FSH, LH, E2, Pg and AMH serum levels) and antral follicles count (AFC).

Main results and the role of chance: An average patient's age was 35.3 ± 3.6, average BMI was 22.6 ± 2.8. Out of 332 women included in the study, 274 (82.5%) were in the short protocol groups and 58 (17.5%) were in the long protocol group.

Short protocol with antagonist proved to be the most efficient one for the favorable outcome (69.4%), compared to short protocol with agonist (6.5%) and long protocol with agonist (24.1%).

131 patients have conceived (39.5%), regardless on used protocol. Out of 131 conceptions, 62.9% of pregnancies resulted in live births and 37.1% resulted in pregnancy termination.

Statistical analysis of conception rates between ovulation-induction protocols has shown that age (p<0.001), BMI (p=0.03) and progesterone levels (p=0.04) were statistically significantly different in favor of short protocol. Mean age, BMI and progesterone level median in patients who successfully conceived were 34.4±3.5, 22±2.6 and 0.89 ng/mL, respectively. Mean age, BMI and progesterone level median in patients who didn't conceive were 36±3.6, 22.8±2.7 and 1ng/mL, respectively.

These variables (age, BMI and progesterone level) were included in Multiple Binary Regression Model with successful conception described as a dependent variable. The Multivariate Logistic Regression analysis confirmed that age (p<0.001) and progesterone levels (p=0.027) were predictors for the successful outcome.

Limitations, reasons for caution: Despite the satisfactory number of patients the limitations were the retrospective study design, as well as the common use of short protocol with antagonists as the recommended treatment for patients with PCOS in IVF.

Wider implications of the findings: Further prospective studies would be recommended, especially in the context of determining the endocrine milieu of obtained follicles using the short protocol in patients with PCOS, as well as assessing the quality of oocytes and embryos, and factors that may affect implantation.

Trial registration number: not applicable

P-678 Is there a critical LH level for hCG trigger after the detection of LH surge in modified natural frozen thawed blastocyst transfer cycles? Clinical outcomes.

Y. Sahin[1], S. Kahraman[1], U. Gokturk[1], B. Yuksel[1], F. Gokdagli Sagir[1], G. Ozer[1]

[1]Istanbul Sisli Memorial Hospital, Assisted Reprodutive Technologies and Reproductive Genetics Center, Istanbul, Turkey

Study question: After the detection of LH surge, are different LH levels on hCG day or the day before hCG trigger significant in modified natural cycles?

Summary answer: Once LH surge has been detected, LH levels on hCG day or the day before hCG trigger does not significantly affect clinical outcomes.

What is known already: Opinions are divided on the appropriate timing of hCG with regard to LH hormone levels in modified natural cycles for frozen thawed blastocyst transfer (mNC FET). Two studies report a deleterious effect of hCG triggering on implantation and pregnancy rates in spontaneous LH rise patients (Fatemi et al. 2010, Litwicka et al. 2017), proposing that high LH levels at the time of hCG are associated with extremely low implantation rates. Results of studies focusing on LH levels at the time of hCG trigger have been variable and optimal LH level on hCG trigger day in mNC FET is controversial.

Study design, size, duration: This retrospective study was based on 1163 mNC-FET cycles initiated between January 2015 and September 2019 in Istanbul Memorial Hospital. Patients were divided into 4 groups according to serum LH levels on hCG day or the day before hCG. Group A: LH the day before hCG (n=282), Group B: LH >16-25 (n=245), Group C: LH 26-40 (n=253) and Group D, LH >40 (n=383). LH surge was defined as ≥15mI/mL.

Participants/materials, setting, methods: 1163 cycles were evaluated. Inclusion criteria were: age <43 years, body-mass index <35 kg/m2, repeated pregnancy losses cases (<3), implantation failure (<3 cycles), endometrial thickness ≥ 8 mm on HCG day. Patients were monitored to detect an LH surge and the presence of a dominant follicle, using serum assays of LH and e2 and transvaginal ultrasound scans. Patient and cycle characteristics, LH and e2 levels and clinical outcomes were analysed.

Main results and the role of chance: There was no significant difference between LH level groups in relation to patient characteristics such as mean age, body-mass index, Anti Mullerian Hormone, cycle length and cycle characteristics such as embryo grade, mean numbers of COC, MII oocyte, fertilized oocytes and the mean follicle size, e2 level and endometrial thickness on HCG day. Subgroup analyses of mNC-FET groups showed that there was no significant difference between groups in terms of implantation, clinical and ongoing pregnancy rates.

Once LH surge has been detected, triggering ovulation by hCG in patients with different LH levels undergoing mNC-FET does not have a detrimental effect on cycle outcome.

Limitations, reasons for caution: The study was a retrospective analysis.

Wider implications of the findings: mNC-FET reduces the number of hospital visits, strict ultrasonographic evaluations and blood tests required. Once LH surge has been detected, the timing of hCG can be confidently determined and patients advised accordingly.

Trial registration number: none

P-679 Comparison of patterns of endometrial receptivity biomarkers between IVF treatments performed with different gonadotrophin regimens

D. Bortolotti[1], G. Orlando[2], E. Gravotta[2], V. Gentili[1], M.G. Bafaro[3], B. Roset[3], G. Coticchio[3], A. Borini[3], R. Rizzo[4]

[1]University of Ferrara, Department of Chemical and Pharmaceutical Sciences, Ferrara, Italy ;
[2]Merck Italy, Medical Affairs Department, Rome, Italy ;
[3]9.baby family and fertility center, Reproductive Medicine IVF clinical director unit, Bologna, Italy ;
[4]University Of Ferrara, Department of Chemical and Pharmaceuticals Sciences, Ferrara, Italy

Study question: Do alternative regimens of exogenous gonadotrophins differently affect the expression of biomarkers of endometrial receptivity in IVF treatments?

Summary answer: We identified a significant difference between ART stimulation protocols (FSH+LH; FSH+HCG) in relation to the expression of selected biomarkers of endometrial receptivity.

What is known already: A highly coordinated complex sequence of biochemical and cellular events is the basis the so-called "window of uterine receptivity", during the mid-luteal phase of each menstrual cycle. However, to date, there are extremely few studies reporting on implantation biomarkers expressed in endometrial tissue following the use of different ART stimulation protocols (FSH+LH; FSH+HCG). Novel finding in this context might contribute to improve assisted reproductive technology procedures, whose rates of implantation failure remain a major problem.

Study design, size, duration: Ten endometrial biopsies and uterine flushing samples were collected during freeze-all ART treatment protocols (N=5 FSH+LH; N= 5 FSH+HCG). The endometrial receptivity status was assessed detecting molecules and immune cells implicated in immune-regulation during embryo implantation and pregnancy.

Participants/materials, setting, methods: Endometrial cells were analyzed for L-selectin ligand and Mucin-1 expression. Uterine flushing samples were analyzed for the levels of soluble molecules ((LIF (leukemia inhibitory factor); HB-EGF (heparin-binding –epidermal growth factor); Glycodelin-A; HLA (Human leukocyte antigen)-G and HLA-E; MCP-1, IP-10, IL-1β and TNF-α. Endometrial immune cells (NK cells, T cells, monocytes) were evaluated for their immune-phenotype.

Main results and the role of chance: We observed induction in Mucin-1 expression in FSH+HCG treated women. FSH+LH treated women presented a significant increase in L-selectin expression. Women treated with FSH + LH presented the highest levels of all the analyzed soluble molecules in uterine flushing samples. Interestingly, a woman with an ongoing pregnancy presented the highest levels of sHLA-G, sHLA-E, IP10, MCP1, LIF, HBGF, Glycodeln-A, IL-1beta and TNF-alpha in uterine flushing sample. The analysis of cell content in endometrial biopsies showed a lower amount of endometrial NK cells in endometrial samples of FSH+HCG-treated women compared with FSH+LH-treated women (p<0.0001; Student T test). Endometrial samples presented a low percentage of CD14+ and CD3+ cells, with no significant differences between the three cohorts of women (p=0.74; p=0.123; Student T test). When we looked at CD3+ cell subsets, we observed a decrease in $CD4^{+}CD25^{+}CD127^{dim/-}$ regulatory T cells in FSH+HCG-treated women in comparison with FSH+LH-treated women.

Limitations, reasons for caution: The main limits of this project are two: i) the small number of enrolled subjects and ii) monocentric recruitment. Validation of these data will require a larger multicentric study.

Wider implications of the findings: The present data suggest that, by influencing the expression of biomarkers of endometrial receptivity, alternative gonadotrophin regimens may differently impact on implantation. This leads to the hypothesis of the development of personalized gonadotrophins IVF treatments aimed at improving endometrial receptivity.

Trial registration number: NA

P-680 Comparable outcome using Oral dydrogesterone versus micronized vaginal progesterone (MVP) in aFET (artificial frozen embryo transfer)

Y. Atzmon[1], N. Aslih[1], M. Michaeli[1], A. Bilgory[1], E. Shalom-paz[1]

[1]Hillel - Yaffe medical center, ivf, Hadera, Israel

Study question: Does using oral dydrogesterone instead of micronized vaginal progesterone (MVP) in aFET impact pregnancy outcome
Summary answer: Oral dydrogesterone showed non-inferiority to MVP in aFET in terms of chemical and clinical pregnancy outcome
What is known already: During endometrial preparation for FET in artificial cycle the most common progesterone used is MVP in forms of vaginal suppository or as vaginal gel. Both are known for their inconvenient use, vaginal discharge and irritation. During 2017 two RCT's were conducted comparing dydrogesterone and MVP in fresh IVF cycles and oral dydrogesterone was found to have non-inferiority results in pregnancy outcome. Since then, we faced a growing demanded raised from the patients to use oral progesterone in aFET.
Study design, size, duration: Retrospective cohort study between 2018 to 2019. All patients used oestradiol 6-10 mg a day for at list 8 days as priming endometrial growth. For progesterone exposure, one of the following medications was supplemented-1. MVP 300 mg daily, 2. 8% MVP gel 90 mg daily. 3. Oral dydrogesterone (10 mg X3 TID).

Two groups were compared- **group A**- oral dydrogesterone support vs. **group B**-MVP supplementation.
Participants/materials, setting, methods: In total 238 cycles included in **group A** and 381 cycles in **group B** were analyzed. Cleavage stage embryos and blastocyst embryos were transferred after exposing to progesterone according to the established protocols. Clinical pregnancy was the primary endpoint.
Main results and the role of chance: Both groups were comparable in terms of age, BMI, and cause of infertility, gravidity and parity, maximal endometrial thickness. Although Embryo's quality scoring was significantly better in group B 2.16±0.79 vs. 2.45±0.78; P=0.02, the chemical pregnancy, and clinical pregnancy rates were similar in both groups 42.6% vs. 43.1(P=1) and 35.1% vs. 37.4% (P=0.85) respectively.
Limitations, reasons for caution: The limitation of the study are based in the retrospective nature of it and the heterogeneity of the cohort
Wider implications of the findings: Safety was shown in the use of dydrogesterone in RPL and fresh IVF cycles. Prospective studies reported non-inferiority in fresh IVF cycles (Lotus 1,2) for luteal support. This study reports, for the first time, the effectiveness of dydrogesterone in aFET cycles. More RCT's are needed to establish our results.
Trial registration number: not applicable

P-681 The relationship between the number of supplementary blastocysts available and live birth rate following single embryo transfer : analysis of 10 015 fresh IVF cycles

Y. Beebeejaun[1], T. Copeland[2], L. Polanski[3], T. El Toukhy[3]

[1]King's College London, Department of Women's Health, London, United Kingdom ;
[2]University of California Los Angeles, Department of Health Policy & Management, Los Angeles, U.S.A. ;
[3]Guy's and St Thomas' Hospital, Assisted Conception Unit, London, United Kingdom

Study question: Does the number of supplementary blastocysts available for cryo-storage affect the live birth rate in a fresh IVF cycle?
Summary answer: The present study demonstrated a non linear association between the number of supplementary blastocysts and live birth rate in different age groups.
What is known already: The ability to predict the likelihood of a live birth after single fresh embryo transfer is important for treatment planning and managing patient expectation, particularly in their first in vitro fertilisation (IVF) cycle. Cryopreservation of supernumerary embryos is often regarded as an important prognostic variable and a surrogate marker of success. Previous large studies have examined the association between the number of oocytes retrieved and cleavage-stage embryos available, and the odds of a live birth following a fresh embryo transfer, whereas the relationship between the number of supernumerary blastocysts cryopreserved following a fresh embryo transfer has not been rigorously studied.
Study design, size, duration: Anonymised data on first IVF/ICSI cycles performed at Guy's and St. Thomas' Hospital in London, were prospectively collected between July 2006 and June 2018. Cycles involving pre-implantation genetic testing (PGT), oocyte donation, transfer of cleavage-stage or more than one fresh embryo or total embryo freezing were excluded. Since age is known to be associated with lower live birth rates, sub-analysis was performed for women aged <35 years, 35-39 years and > 40 years old.
Participants/materials, setting, methods: Cycle data on women undergoing IVF/ICSI treatment between 2006-2018 were analysed to compare clinical outcomes of live birth rate based on the number of supplementary embryos obtained and stratified by the pre-defined age groups.
A multivariate logistic regression analysis was used to examine the association between livebirth ans supernumerary blastocysts after controlling for confounders. Fractional logistic regressions were modelled using a cubic polynomial transformation of the number of supernumerary blastocysts and stratified by age
Main results and the role of chance: Cycles with ≥1 supernumerary blastocysts cryopreserved had a significantly higher live birth rate compared to those without blastocyst cryopreservation (38.5%, 95% CI 36.9-40.0% vs. 24.3%, 95% CI 23.3-25.5; P<0.0001) and adjusted odds ratio (OR) 1.76, 95% confidence interval (CI) 1.61-1.92, P<0.0001).

The likelihood of having a live birth, **when < 35 years old**, increased linearly from 0.33(95% CI 0.31–0.34; P<.0001 to 0.80 (95% CI 0.74–0.86; P<.0001) between 1-6 blastocysts cryopreserved. A non-linear association was then seen up to 0.95(95% CI 0.92–0.97; P<.0001) if ≥10 blastocysts were cryopreserved.
In the 35-39 age group, the likelihood of having a live birth increased linearly from 0.30 (95% CI 0.28–0.32; P<.0001) to 0.82 (95% CI 0.73–0.91; P<.0001) for up to 6 blastocysts and non-linearly to 0.96 (95% CI 0.93–0.99; P<.0001) if ≥10 blastocyst were cryopreserved.
When aged 40 years and above, the likelihood of having a live birth increased linearly from 0.26 (95% CI 0.19–0.32; P<.0001) to 0.83 (95% CI 0.68–0.97; P<.0001) if 4 blastocysts were cryopreserved and non-linearly to 0.99 (95% CI 0.98–0.99; P<.0001) if >10 blastocysts were cryopreserved.
Limitations, reasons for caution: Limitations with observational data would apply to this study including residual confounding.
Wider implications of the findings: The predictability of a live birth with regards to the number of blastocysts available following IVF is of clinical relevance for patients and clinicians.
Trial registration number: Not applicable

P-682 Whole-genome microRNA expression profiles from single pre-ovulatory follicles of oocyte donors and polycystic ovarian syndrome (PCOS) patients

I. Rooda[1,2], M.M. Hasan[3], K. Roos[1,4], J. Viil[3], O.P. Smolander[1], A. Salumets[2,3,5,6], A. Fazeli[3,7], A. Velthut-Meikas[1]

Study question: How do miRNA expression profiles of follicular fluid (FF), extracellular vesicles (EVs) and granulosa cells from single follicles differ between polycystic and healthy ovaries?
Summary answer: It is possible to successfully sequence small RNA from low input material like FF, EVs and cells of individual follicles.
What is known already: Several miRNAs have been shown to differ between women with PCOS and control group. Moreover, miRNAs are considered as potential diagnostic markers and therefore may reveal important differences in cell-to-cell signaling in PCOS women compared to healthy individuals. miRNAs regulate gene expression in the cells where they are transcribed, but they can also be secreted into extracellular space. One mechanism to secrete miRNAs is to pack them into EVs. Analyzing cellular and extracellular miRNAs of follicles can provide information about the origin of the miRNAs and cell-to-cell signaling differences between PCOS women and oocyte donors.
Study design, size, duration: Genome-wide miRNA expression profiles were obtained by small RNA sequencing technique. miRNAs were sequenced from FFs, EVs and cells collected from the FF of individual follicles. Material for sequencing

were obtained from patients undergoing ovarian stimulation and ovarian puncture. Two patient groups were formed: women with diagnosed PCOS and oocyte donors as a control group. Eight women were recruited per group.
Participants/materials, setting, methods: FF and cellular material were collected from the first aspirated follicle visibly clear of blood contamination. Starting amount for miRNA library preparation was 500µl of FF, EVs extracted from 500µl of FF, and 10 ng of small RNA fraction from cells. RNA was extracted with miRNEASY micro kit (QIAGEN) and miRNAs libraries prepared with QIAseq miRNA Library Kit (QIAGEN). Sequencing was performed on NextSeq 500 platform (Illumina) with single-end reads of 75bp length.
Main results and the role of chance: In previous studies miRNA sequencing technique has been used for pooled FF samples. Development in the area of miRNA library preparation methods has made possible to sequence low input material like small volumes of FF and miRNAs extracted from EVs. Our preliminary sequencing results showed that five hundred µl of FF collected from a single follicle was enough to obtain sequences of over 300 different miRNAs. Principal component analysis showed that EV and FF samples from the same individual follicle clustered separately. Therefore, not all miRNAs present in whole FF are packed into EVs. To obtain more information about miRNA signalization of individual follicles we added miRNAs from granulosa cells into data analysis. Comparing miRNA profiles from follicular cells, FF and EVs provides information about miRNAs that are secreted into follicular environment by follicular cells and used for cell-to-cell signalization.
Limitations, reasons for caution: Sequencing low input material have its limitations, miRNAs with very low expression levels probably do not reach the detection levels. Only one follicle per woman was analyzed and the group size is relatively small.
Wider implications of the findings: RNA sequencing from single follicles will give an opportunity to evaluate individual follicle environment and enable to reveal differences between follicles developed in polycystic ovaries compared to healthy follicles. Moreover, this approach may provide new information about the developmental potential of oocytes from individual follicles.
Trial registration number: not applicable

P-683 Clinical outcomes after in vitro maturation (IVM) cycles in patients with polycystic ovaries before and after government legislation.

P-684 Advanced oxidation protein products induce G1/G0 phase arrest in ovarian granulosa cells via a ROS-JNK/p38 MAPK-p21 mediated pathway

Z. Xingyu[1], C. Shi-Ling[1], Z. Jun[1], L. Ying[1], C. Ying-Xue[1], Z. Jing[1], Z. Qing-yan[1]

[1]Nanfang Hospital- Southern Medical University, the Center for Reproductive Medicine- Department of Gynecology and Obstetrics, Guangzhou, China

Study question: What are the effect and mechanism of advanced oxidation protein products (AOPPs) on the cell cycle of ovarian granulosa cells.
Summary answer: AOPPs arrest ovarian granulosa cell cycle progression in G1/G0 phase by reducing cyclin E and CDK2 expression through ROS-JNK/p38 MAPK-p21 signaling.
What is known already: AOPPs, novel protein markers of oxidant-mediated protein damage, have been found to be implicated in polycystic ovarian syndrome (PCOS) and endometriosis (EMT). However, what is the role of AOPPs played on the ovarian granulosa cells is unclear. Recently, the accumulation of AOPPs has been reported to contribute to cell cycle arrest in intestinal epithelial cells and hepatocytes.
Study design, size, duration: KGN cell line was tearted with different doses of AOPPs for 24h to measure the cell cycle distribution and the protein levels of cell cycle relative proteins, and for 2h to measure the levels of ROS. KGN were also treated with 200µg/mL AOPPs for 3h to measure total and phosphorylated protein levels of JNK and p38 MAPK. Thirty-six female SD rats were randomly divided into four groups: PBS, bovine serum albumin (BSA), AOPPs, and AOPPs+NAC.
Participants/materials, setting, methods: The cell cycle distribution were measured by flow cytometry. Western blotting analysis was used to measuring the protein levels of cycle E, CDK2, p21, total and phosphorylated JNK/p38 MAPK. Intracellular ROS was detected by the probe DCFH-DA. Fluorescence intensity was measured on a SpectraMax M5 system. All experiments were repeated at least 3 times. Differences in variables between groups were determined via independent sample t-tests.
Main results and the role of chance: KGN treatment with AOPPs were arrested in G1/G0 phase, and markedly reduced the expression of cyclin E and CDK2 and increased the expression of p21, whereas native BSA had no effect. AOPPs administration significantly increased intracellular ROS generation. We also found that AOPPs induced KGN G1/G0 phase arrest by phosphorylation of JNK and p38 MAPK. Furthermore, the pretreatment of NAC (ROS scavenger), si-P21, si-JNK and si-p38 MAPK resulted in a decreased expression of p21 and increased expression of cyclin E and CDK2. AOPPs-induced G1/G0 phase arrested was also significantly blocked by the pretreatment of NAC (ROS scavenger), si-P21, si-JNK and si-p38 MAPK. In SD rats, AOPPs treatment reduced the protein expression of cyclin E and CDK2 in ovary, and increased the expression of p21, phosphorylated JNK and p38 MAPK.
Limitations, reasons for caution: This study was conducted using a cell model and rat model. Thus, this finding may not directly represent human.
Wider implications of the findings: Our findings reveal that AOPPs influence ovarian granulosa cell cycle progression by reducing cyclin E and CDK2 expression through ROS-JNK/p38 MAPK-p21 signaling. Consequently, AOPPs may represent a potential therapeutic molecule of many ovarian disease, included PCOS and EMT.
Trial registration number: not applicable

P-685 Serum progesterone level on frozen embryo transfer day is lower with hormonal therapy than with a natural cycle, a retrospective single university centre study

O. Pouget[1], M. Alsawaf[1], I. Zuna[1], M. Bonneau[1], M.L. Tailland[1], S. Ripart[1], S. Huberlant[1]

[1]CHU Nimes, Gynecology Obstetric, Nimes, France

Study question: Determine whether a difference in serum progesterone level on the transfer day exists according to the type of endometrial preparation for patients benefiting from a frozen embryo transfer
Summary answer: Serum progesterone level on frozen embryo transfer day is lower with endometrial preparation with hormonal therapy than with a natural cycle
What is known already: Live birth rate after embryo transfer with natural cycle or hormonal therapy seems to be comparable, but the pregnancy loss rate is higher with hormonal therapy. This high pregnancy loss rate may be due to luteal insufficiency with endometrial preparation with hormonal therapy, characterized by a low level of serum progesterone in the luteal phase
Study design, size, duration: We conducted a retrospective study from may to december 2019 including 115 embryo transfers (47 with a natural cycle and 68 with hormonal therapy).
All couples undergoing a frozen embryo transfer in the university centre of Nimes (France) were included
Participants/materials, setting, methods: We compared 2 endometrial preparations : natural cycle (with or without stimulation by FSH or hMG) and hormonal therapy.
The main outcome data was the level of serum progesterone (ng/mL) on the day of frozen embryo transfer, endometrial thickness, pregnancy rate, pregnancy loss rate, maternal characteristics, and embryo characteristics.
We compared quantitative measures using the Mann-Whitney-Wilcoxon test and qualitative variables using the Fisher test with the help of the Statistic software R
Main results and the role of chance: Mean serum progesterone level on embryo transfer day was 25.47 ng/mL after natural cycle versus 14.32 ng/mL after hormonal therapy (p <10-8).
There was no significant difference for demographic and fertility data (age, type of embryo, type of infertility, basal FSH, LH, Estradiol and AMH levels), endometrial thickness, number and type of embryo transferred, age of infertility, pregnancy rate and pregnancy loss rate. Body mass index was 22.9 kg/m2 in natural cycle group vs 24.8 kg/m2 in hormonal therapy group (p=0.03).
No difference was found in serum progesterone level between the progressive pregnancy and pregnancy loss (respectively 17.48 ng/mL vs 20.82 ng/mL, p=0.7)
Limitations, reasons for caution: To analyze the fetal loss rate, our workforce is small (22 progressive progressive pregnancy and 12 pregnancy loss)

Wider implications of the findings: Further research is necessary to determine if this difference on serum progesterone level has any relation with higher pregnancy loss rate with hormonal therapy
Trial registration number: not applicable

P-686 Differential gene expression in mouse oocytes from primordial and primary follicles from cultured and non-cultured ovaries

M. Amoushahi[1], K. Lykke-Hartmann[1,2,3]

[1]Aarhus University, Department of Biomedicine, Aarhus, Denmark ;
[2]Aarhus University, Department of Clinical Medicine, Aarhus C, Denmark ;
[3]Aarhus University Hospital, Department of Clinical Genetics, Aarhus, Denmark

Study question: Does comparative transcriptomic analysis on isolated oocytes from mouse primordial and primary follicles of cultured and non-cultured ovaries, prepare a better insight into molecular mechanisms involved in ovarian follicular activation?
Summary answer: Comparative transcriptomic analysis on oocytes from primordial and primary follicles from cultured and non-cultured ovaries, advanced our findings of molecular mechanisms involved in follicular activation.
What is known already: Different signaling pathways such as, PI3K/AKT are identified during ovarian primordial follicle activation.
Study design, size, duration: We compared oocytes from primordial (n= 277) and primary (n= 170) follicles in removed ovaries from 14 days old mice (*in-vivo* group) and oocytes from primordial (n= 299) and primary (n=250) follicles in cultured ovaries from 7 days old mice after 7 days (*in-vitro* group).
Participants/materials, setting, methods: ovaries from 7-days old female mice were cultured for 7 days. Non-cultured and cultured ovaries fixed, dehydrated, embedded and sectioned. Oocytes of primordial and primary follicles in both groups were isolated by Laser Capture Microdissection, and subjected to RNA extraction. Extracted RNA were sequenced using Illumina HiSeq platform. Quality filtering, trimming and removing adaptor sequences of raw data were performed. Expression value normalization and comparisons were performed using DESeq2 in software R.
Main results and the role of chance: Differential expressed gene analysis in this study, showed 1258 significant genes with 976 up-regulated genes and 282 down-regulated genes in oocytes of primordial follicles from in vitro group. Moreover, 962 and 1309 Genes were up-regulated and down-regulated respectively, in oocytes of primary follicles from in-vitro group compared to in-vivo group. *PIK3* was significantly up-regulated in oocytes of primary follicles from in-vitro group compare to in-vivo group. However, most of identified genes in primordial follicle activation were not significantly up or down-regulated in comparison between groups. Moreover, there were not significant difference between expression of oocyte specific genes such as, *NOBOX*, *SIX6*, *BSX* and *DMRTC2* in oocytes of primordial and primary follicles derived from non-cultured and cultured ovaries. Inhibitory genes in primordial follicles activation, such as *PTEN*, *P27*, *FOXO3* and *GSK* were upregulated in oocytes of primordial follicles and down-regulated in oocytes of primary follicles. These results confirmed that there is a movement in gene expression during primordial follicle activation.
Limitations, reasons for caution: This is a descriptive analysis and functional studies were not performed.
Wider implications of the findings: For the first time, we performed comparative transcriptomic analysis in mouse oocytes derived non-cultured and cultured ovaries. These descriptive results can prepare a better understanding of molecular mechanism during ovarian follicular development.
Trial registration number: not applicable

P-687 Serum luteinizing hormone level on hCG trigger day does not associate with cumulative live birth after IVF/ICSI with GnRH-agonist long protocol

R.H. Wu[1], Y.X. Wen[1], L. Luo[1], Y.B. Li[1], M.H. Chen[1]

[1]The First Affiliated Hospital of Sun Yat-sen University, Reproductive medicine center, Guangzhou-Guangdong, China

Study question: Does the serum luteinizing hormone(LH) level on hCG trigger day affect the cumulative live birth after IVF/ICSI with GnRH-agonist long protocol?
Summary answer: Serum LH level on hCG trigger day does not associate with cumulative live birth or embryo quality after IVF/ICSI with GnRH-agonist long protocol.
What is known already: Whether supplement of exogenous LH is beneficial to IVF outcome is still controversial.Serum LH level reflect the result of addition of exogenous LH on the basis of endogeneous LH level.It is unclear whether serum LH level is associated with cumulative live birth(CLBR) after IVF/ICSI.
Study design, size, duration: This is a retrospective cohort study.A total of 5734 women(6036 ovarian stimulation cycles) who underwent IVF/ICSI with GnRH-agonist long protocol at our hospital from January 2013 to December 2017 were identified and reviewed.
Participants/materials, setting, methods: The patients were assigned to three groups according to the serum LH levels on hCG trigger day: >90th, 10th-90th and <10th.CLBR was defined as the first live birth per ovarian stimulation cycle including fresh and frozen cycles and evaluated by group.Multivariable linear regression and binary logistic regression was used to assess the association between LH levels on hCG trigger day and embryo quality,CLBR after adjusting confounding factors.
Main results and the role of chance: The cumulative live birth rate was 67.6%, 63% and 58.6% with the serum LH levels on trigger day<0.39,0.39-1.54 and >1.54 mIU/ml during ovarian stimulation with GnRH-agonist long protocol respectively(P=0.043).However,the serum LH level on trigger day was not associated with cumulative live birth(OR=1.598,95%CI 0.870-2.936,P=0.13) after adjusting female age,duration of infertility,body mass index,the number of gravidity,antral follicle count,basal FSH level,total dosage of gonadotropin,addition of HMG,the thickness of endometrium and FSH,estrogen,progesterone level on the hCG trigger day,retrieved oocytes,mature oocytes,the number of viable embryo and high-quality embryo.The number of viable embryo and high-quality embryo decreased with the increase of serum LH levels on trigger day,but the serum LH level on trigger day was not associated with the number of viable embryo(B=0.032,P=0.474) and high-quality embryo(B=-0.011,P=0.802) after adjusting female age,duration of infertility,FSH and progesterone Level on day of hCG administration,total dosage of gonadotropin and the number of mature oocyte.
Limitations, reasons for caution: As a retrospective study,our analysis depended on previously recorded data.Therefore,certain variables such as complications could not be collected and conclusion is limited to achieve one live birth in each stimulation cycle.
Wider implications of the findings: The serum luteinizing hormone level on hCG trigger day does not affect the possibility to achieve one live birth per ovarian stimulation cycle,and supplement of exogenous LH may not benefit IVF/ICSI outcome.
Trial registration number: 81601239

P-688 The ratio AMH/antral follicle count an innovative tool for assessing the follicular health in young women with diminished ovarian reserve

C. Lethielleux[1], C. Sonigo[2], C. Vinolas[1], I. Cedrin-Durnerin[1], M. Grynberg[2]

[1]Jean Verdier Hospital, Reproductive Medicine and Fertility preservation, Bondy, France ;
[2]Hopital Antoine Béclère, Reproductive Medicine and Fertility preservation, Clamart, France

Study question: Does diminished ovarian reserve (DOR) and its etiology impact the AMH/AFC ratio?
Summary answer: AMH/AFC ratio varies according to the etiology of DOR in young women, suggesting different impact on the follicular health, and further oocyte quality
What is known already: Anti-Müllerian hormone and antral follicle count currently represent the two most accurate markers of the follicular ovarian status. Even though they may diagnose a reduction in the follicular stockpile, low values remain inefficient for predicting poor oocyte quality, in particular in young women. Since AMH is produced by the granulosa cells of follicles ranging from primary to small antral follicles, we hypothesized that the etiology of diminished ovarian reserve might differently impact the follicular health and their capacity of producing this peptide.

Study design, size, duration: From November 2018 to December 2019, we conducted a monocentric, retrospective study including a total of 195 infertile patients <37 years with DOR.
Participants/materials, setting, methods: All patients underwent measurement of AMH levels and AFC. DOR was diagnosed according to the Bologna criteria (AMH<1.1 ng/mL and AFC<7). AMH/AFC ratio was compared to values obtained in 53 tubal or male infertility patients matched for age and BMI, with AMH and AFC in the normal ranges. This ratio was studied according to the etiology of DOR: genetic (n=9), post-chemotherapy (n=41), idiopathic (n=87) or ovarian diseases (ovarian cyst or history of ovarian surgery, n=58).
Main results and the role of chance: Overall, median age of women with DOR was 31 (18-37.5) years. As expected, age and BMI were comparable in women with DOR and those having normal ovarian reserve tests. In addition, the AMH/AFC ratio failed to show any difference between these 2 groups (0.136 ± 0.26 vs. 0.168 ± 0.08, NS, respectively). Among women with DOR, the etiology was significantly associated with different AMH/AFC ratio. Indeed, patient with DOR of "mechanic" origin (ovarian diseases group) displayed higher mean values (0.235 ± 0.41 ng/mL/ Foll) when compared with those included in genetic (0.082 ± 0.12 ng/mL/ Foll), idiopathic (0.101 ± 0.11 ng/mL/ Foll) or post-chemotherapy (0.085 ± 0.20 ng/mL/ Foll) groups. Moreover, genetic and post-chemotherapy DOR was also associated with lower AMH/AFC ratio in comparison with idiopathic DOR.
Limitations, reasons for caution: Despite interesting results, the presents study remains retrospective on a limited number of patients. In addition, AMH/AFC ratio constitute an indirect method for assessing the follicular health.
Wider implications of the findings: AMH/AFC ratio is an innovative tool aiming to indirectly assess follicular health and possibly oocyte quality in young women with DOR. The etiology of DOR differently impacts the follicular function as reflected by AMH/AFC ratio. Therefore, data on live birth rates following natural or medically assisted pregnancies is needed.
Trial registration number: not applicable

P-689 Effect of two different doses of Vitamin D supplementation on clinical, metabolic and hormonal profiles of Insulin-resistant PCOS patients: A Randomized Controlled Trial

A. Bahadur[1], A. Yadav[1], J. Chaturvedi[1], R. Mundhra[1], R. Rajput[1], M. Naithani[2], N. Bhattacharya[1], J. Prerna[1], S. Kumari[1], N. Verma[1], M. Kumawat[1], P. Kumari[1]

[1]All India Institute of Medical Sciences, Obstetrics & Gynaecology, Rishikesh, India ; [2]All India Institute of Medical Sciences, Biochemistry, Rishikesh, India

Study question: To compare the effect of two different doses of Vitamin D Supplementation on clinical, metabolic and hormonal profiles of insulin resistant PCOS cases
Summary answer: This study supports beneficial effects of high dose vitamin D supplementation along with metformin on clinical, metabolic and hormonal status in insulin sensitive PCOS women.
What is known already: Insulin resistance plays a key role in reproductive and metabolic dysfunctions in PCOS. The rationale for vitamin D supplementation in PCOS women is based on the fact that vitamin D supplementation decreases Insulin Resistance by its role on glucose metabolism. Data on the effects of vitamin D supplementation along with metformin usage on metabolic status of patients with polycystic ovary syndrome (PCOS) are scarce.
Study design, size, duration: Prospective, open label, non-blinded randomized controlled trial conducted in department of Obstetrics and Gynecology, All India Institute of Medical Sciences, Rishikesh, India

110 women with PCOS were screened. 24 patients with BMI > 30 kg/m^2 and 14 were not willing to participate in study were excluded.

72 women with PCOS and Insulin Resistance in age group 20-35 years were included for a period of 20 months, underwent biochemical and hormonal assessment on day 2 of cycle
Participants/materials, setting, methods: Patients in Group I (n=36) received Tablet Metformin 500 mg twice a day orally along with Tablet vitamin D3 1000 IU orally for 3 months. Patients in Group II (n=36) received Metformin 500 mg twice a day orally along with Tablet vitamin D3 4000 IU orally for 3 months
Primary outcome: Change in HOMA-IR after treatment in both groups
Main results and the role of chance: Vitamin D supplementation (4000 IU) resulted in beneficial effects on HOMA-IR, mFG score, global acne score, menstrual cycle regularity, BMI. LH levels, triglyceride levels, DHEAS values, fasting and postprandial blood sugars, fasting and postprandial insulin levels as compared to 1000 IU vitamin D supplementation. ($p < 0.05$). The change in mFG score over 3 months in Group I was -1.19 ± 2.67 and in Group II was - 2.81 ± 4.15. There was statistically significant difference between the change in mFG score in the two groups (p=0.027) with the decrease in Group II being more than Group I.

Menstrual cycle irregularity in Group II was 31(86.11%) at baseline and decreased to 21(58.3%) at 3months.There was statistically significant decrease in women having menstrual irregularity between baseline and at 3 months in both the Groups with p value in Group I of 0.012 and in Group II of 0.018. The change in Vitamin D levels (ng/ml) at 3 months in Group I was 5.36 ± 2.79 and in Group II was 13.19 ± 3.26. There was statistically significant difference between rise in Vitamin D levels (ng/ml) in two groups ($p < 0.0001$) with the rise in group II being more than Group I.
Limitations, reasons for caution: Further studies with larger sample size are required before conclusion can be derived that combination of vitamin D3 4000 IU with metformin is better than vitamin D3 1000 IU with metformin in improving the clinical, hormonal and metabolic parameters in PCOS patients.
Wider implications of the findings: Hypovitaminosis D is very common in PCOS patients and exacerbates the metabolic abnormalities. It is essential to screen all the PCOS patients for
vitamin D (25OHD) deficiency and institute appropriate replacement therapy to decrease insulin resistance and thus the metabolic, hormonal and clinical profile of PCOS patients.
Trial registration number: This trial was Registered with the Clinical Trial Registry of India (CTRI) CTRI/2019/11/021926

P-690 The role of follicular Anti-Mullerian hormone in woman undergoing IVF/ICSI with regard to size, oocyte, sociodemographic parameters and other hormones and vitamins

V. Ziller[1], L. Witzke[1], M. Nesbigall[1], P. Pfefferle[2], B. Greene[3], U. Wagner[1]

[1]University Medical Center Giessen and Marburg, Department of Gyn. Endocrinology and Reproductive Medicine, Marburg, Germany ; [2]University Medical Center Giessen and Marburg, Comprehensive Biomaterial Bank Marburg CBBMR, Marburg, Germany ; [3]University Medical Center Giessen and Marburg, Biometrics, Marburg, Germany

Study question: Do levels of AMH in separately analysed follicles differ depending on size of the follicle and is it associated with steroid production and ART outcome?
Summary answer: Larger follicles do not produce more fAMH than smaller ones. The level of fAMH is correlated to steroid levels and the presence of an oocyte.
What is known already: The value of serum Anti-Mullerian hormone (AMH) as a marker for the ovarian reserve has been well established. However, the presence and actions of AMH on the follicular level has not yet been sufficiently clarified. Therefor the aim of this study was to investigate how AMH concentrations present in terms of follicle size, presence of an oocyte, demographic data and ART outcome. We also explored the association of fAMH with other hormones and vitamins such as Vitamin D, Luteinizing hormone (LH) and steroids in follicular fluid on the basis of separated follicles.
Study design, size, duration: In this prospective exploratory study, infertile women undergoing IVF between January 2018 until December 2019 were included. Written permission was required. Known illnesses of the reproductive system and infectious diseases were defined as exclusion criteria. A total of 61 female fertility patients undergoing IVF or ICSI therapy and 376 separated follicles were included.
Participants/materials, setting, methods: On the day of oocyte retrieval we collected the FF of each follicle separately and also a serum sample. The samples were individually analyzed regarding their AMH level and other hormone concentrations. The follicles were divided into a large and a small group according to their size (large (≥16mm), small<16mm)). It was also documented whether

the follicle contained an oocyte or not. Demographic data and ART outcome was added from patients records.

Main results and the role of chance: We investigated the follicular fluid AMH (fAMH) and serum AMH (sAMH) of 61 female fertility patients undergoing IVF or ICSI therapy (fAMH n= 376, sAMH n=44).

Follicles with a large diameter contained a significantly lower concentration of fAMH (mean difference around 1 ng/ml les, p=0.001). In addition, follicles that contain an oocyte showed a significantly higher fAMH level than those without one (p<0.001). There was a significant but weak correlation between fAMH and sociodemographic parameters such as patients age (r=-0.11, p<0.001) and BMI (r=0.03, p<0.006). Follicular AMH was strongly correlated to diverse other parameters such as Vitamin D (r=-0.13, p<0.001), LH (r=-0.35, p<0.001) and progesterone (r=-0.21, p<0.001) in the corresponding follicle. As expected, there is a significant positive correlation between fAMH and sAMH (r=-0.42, p<0.001)

Limitations, reasons for caution: The process of follicle separation is not 100% exact, however an in-house pre-study using predefined test solutions underlined reliability (data on file). IVF stimulated cycles may not represent the situation in natural cycles and further studies are needed.

Wider implications of the findings: As AMH and reproduction is an important part of current medical and scientific discussions correlation actual findings with clinical outcome parameters, such as fertilization rate, pregnancy rate etc. are planned to gain further insights in the mechanisms of follicular AMH and its role in assisted reproduction.

Trial registration number: n/a

P-691 The use of follitropin delta for ovarian stimulation for in vitro fertilization in patients with a low ovarian reserve: results from clinical practice.

E.C. Creutzberg[1], P. Wijngaard-Boom[2], T. Stijnen[3], J. Laven[2]

[1]Ferring BV, Gynaecology, Hoofddorp, The Netherlands ;
[2]Erasmus Medical Centre, Reproductive Medicine, Rotterdam, The Netherlands ;
[3]Leiden University Medical Centre, Biostatistics, Leiden, The Netherlands

Study question: This study describes in a real life setting the influence of a higher dose of follitropin delta in patients with a low ovarian reserve.

Summary answer: Increasing the dose of follitropin delta in patients with low ovarian reserve did not lower cancellation rates and did not result in improved clinical outcome.

What is known already: In pivotal trials performed with follitropin delta, median Anti-Mullerian Hormone (AMH) was 16.3 pmol/l. The general IVF population in the Erasmus University Medical Centre (EUMC) consists of patients with a wide range of AMH-values, including patients with low levels who are at risk for under response leading to cycle cancellation. Current evidence on ovarian response and treatment outcome in patients with low ovarian reserve shows no improvement of ongoing pregnancy rates with increased dose of FSH in women with low ovarian reserve, despite a lower cancellation rate and a higher number of oocytes retrieved.

Study design, size, duration: Since its introduction in EUMC in 2017, 148 patients with AMH lower than 7.14 pmol/L were treated with follitropin delta. Due to a relatively high percentage of cancellations, after the first half year and up to and including September 2019, patients with low to very low AMH levels were treated with a starting dose higher than calculated by the approved dosing algorithm. The outcomes of the first IVF cycle including frozen embryo transfers are described.

Participants/materials, setting, methods: AMH was measured using the automated Elecsys® AMH plus immunoassay (Roche Diagnostics International). Among the 148 consecutive patients with low ovarian reserve (AMH<7.14pmol/l), the first 47 patients were treated with 12 µg/day (as per dosing algorithm), and the next 101 patients were treated with a higher starting dose of 18 to 24 µg/day. All treatment results were collected from the clinical records. Data were described as mean (SD) and statistically analyzed using t-test.

Main results and the role of chance: The 47 patients that received a follitropin delta dose of 12 µg compared to the 101 that received a dose of 18 or 24 µg had mean (SD) age of 36.2 (4.0) vs 37.1 (4.1) years, an AMH of 4.5 (1.6) versus 3.2 (2.1) pmol/l and a body weight of 69.3 (13.7) vs 68.8 (13.3) kg. The percentage of canceled cycles due to insufficient number of follicles ≥11mm at day of last ultrasound dropped non-significantly from 34.0% in the standard-dosed group to 22.8% in the higher-dosed group (p=0.15). The number of oocytes (5.1 (3.5) vs 4.8 (2.8)) and cleavage stage embryos (2.8 (2.2) vs 2.6 (2.3)) did not change significantly. Ongoing pregnancy rate after 12 weeks including frozen embryo transfers was 17.4% in the standard-dosed group and 13.3% in the higher-dosed group (p=0.50).

Limitations, reasons for caution: This is an analysis of the use of follitropin delta in patients with low ovarian reserve on the base of AMH level in clinical practice. A heterogeneous population with different phenotypes was treated, in which the patients were not randomized and no control group was applied.

Wider implications of the findings: These preliminary results indicate that applying a dose of follitropin delta higher than calculated did not result in a lowering of cancellation rates or improvement in clinical outcome. Therefore it seems important not to deviate from the dosing algorithm and manage expectations in these patients with poor ovarian response.

Trial registration number: not applicable

P-692 The association of FSH and AMH basal levels with live birth rates after ICSI/IVF is age dependent

J. Buratini[1,2], M. Dal Canto[1], F. Brambillasca[1], C. Brigante[1], S. Gippone[1], E. De Ponti[3], M.M. Renzini[1]

[1]Biogenesi - Reproductive Medicine Centre, Istituti Clinici Zucchi, Monza, Italy ;
[2]Sao Paulo State University, Institute of Biosciences, Department of Physiology ;
[3]ASST Monza, Medical Physics, Monza, Italy

Study question: Does the association of AMH and FSH basal levels with live birth rates following ICSI/IVF change with maternal age?

Summary answer: AMH is more strongly associated with live birth than FSH in patients > 35 years, whereas the opposite is observed in patients ≤ 35 years.

What is known already: FSH and AMH have been investigated as predictors of IVF/ICSI outcomes. The literature suggests that AMH has a higher predictive value, although each alone can only weakly predict live birth. The inter-cycle variability of FSH basal levels increase with age, compromising the predictive performance of FSH in advanced maternal ages. In contrast, AMH levels are more strongly correlated with live birth in patients >35 years. Although FSH and AMH levels are often inversely correlated, 25-40% of the patients present discordant values. No study so far has assessed the impact of maternal age on AMH and FSH predictive values.

Study design, size, duration: Retrospective consecutive cohort of 2830 first ICSI/IVF cycles from 2016 to 2019. Patients were stratified according to AMH and FSH cut-offs (1 ng/mL for AMH, 10 IU/L for FSH) into four groups: A (AMH>1/FSH≤10); B (AMH>1/FSH>10); C (AMH≤1/FSH≤10) and D (AMH≤1/FSH>10). Live birth rates after the first ET were compared among groups and the correlation of AMH and FSH values with live birth rate was assessed in three populations: total, ≤35 and >35 years old.

Participants/materials, setting, methods: Women aged 20 to 45, with FSH levels measured on menstrual cycle day 2 and AMH on any day underwent COS, OPU and ICSI or IVF. One to three embryos were transferred fresh on D+3. Live birth rates (LBR) were compared among AMH/FSH groups with the Chi-square test. The correlation of AMH and FSH values with LBR was assessed by multivariate logistic regression in different maternal age populations, separately.

Main results and the role of chance: LBR differed among AMH/FSH groups in all three populations analyzed (p<0.003). In the total patient population, LBR were 24.2% (381/1573), 16.8% (40/238), 10.9% (66/606) and 11.4% (47/413), in groups A, B, C and D, respectively. When the analysis was restricted to patients > 35 years old, LBR were 17.8% (164/923), 16.0% (25/156), 8.2% (40/489) and 9.9% (33/334), respectively. In patients > 35 years old, when discordant values of AMH and FSH were present (groups B and C), a markedly higher LBR was observed in the group presenting the prognostically favorable AMH value (AMH>1, group B). Conversely, in women ≤ 35 years old, a higher LBR was observed in the group presenting the prognostically favorable FSH value (FSH≤10, group C); LBR were 33.1% (215/650), 18.3% (15/82), 22.2% (26/117) and 17.7% (14/79), respectively. Multivariate logistic analysis revealed that AMH, but not FSH, is correlated with LBR, both overall [AMH: 2.3 OR, (1.8-2.9) 95% IC, p<0.0001; FSH: 0.8 OR, (0.6-1.0) 95% IC; p=0.076] and in women > 35 years [AMH: 2.2 (1.6-3.0), p<0.0001; FSH: 1.0 (0.7-1.4), p=0.86]. In contrast, in women ≤ 35 years, FSH was more significantly correlated with LBR than AMH [AMH: 1.5 (1.0-2.3), p=0.036; FSH: 0.5 (0.4-0.9), p=0.008].

Limitations, reasons for caution: Our study is subjected to the intrinsic limitations of a retrospective analysis, the results presented could have been affected by variables that are uncontrolled for.
Wider implications of the findings: Our results suggest the possibility of developing novel prognostic strategies in ICSI/IVF practice, utilizing FSH basal levels as predictors of live birth for women younger than 35 years, and AMH levels for older patients. In addition, our findings may help in counselling patients and managing their expectations.
Trial registration number: Not applicable

P-693 Adiponectin mediates apoptotic responses in endometrial carcinoma in PCOS patients by the AMPK pathway.

S. Chen[1], X. Chen[1]

[1]Sun Yat Sen Memorial Hospital- Sun Yat Sen University, reproductive endocrinology, guangzhou, China

Study question: we hypothesize that adiponectin regulates target genes expression CYP19 through AMPK pathway, and thereby plays an important role in the tumorigenesis and tumor-development in PCOS patients.
Summary answer: We elucidate the mechanism of APN-mediated estrogen-dependent tumorigenesis and development of endometrial cancer in PCOS patients ,reveal new intervention targets for its prevention and treatment.
What is known already: Estrogen-dependent endometrial cancer is one of the most fatal long-term complications of polycystic ovary syndrome (PCOS). Our previous research confirmed that compared with age-matching health women, PCOS and endometrial cancer patients had lower adiponectin (APN) level, which showed a negative correlation with increasing expression levels of CYP19 and ERα in tumors. Our previous studies indicated that APN stimulated AMPK phosphorylation, reducing the expression of CYP19 in cancer cells, and sequentially inhibiting cancer cell proliferation and invasion. Furthermore, inhibiting AMPK pathway could block the above effect of APN.
Study design, size, duration: Human endometrial cancer cell lines Ishikawa and KLE underwent treatment with APN at various concentrations for different durations, followed by assessment of cell proliferation by methyl thiazolyl tetrazolium (MTT) assay. Real-time quantitative PCR and western blot analysis were used .Bioinformatics analysis, siRNA interference and CHIPS technology were used to detect the potential transcription factors involved in APN-stimulated AMPK pathway.
Participants/materials, setting, methods: cell culture(Human endometrial cancer cell lines Ishikawa and KLE) .Methods and endpoints used cell numbers/proliferation, Westerns, quantitative PCR, bioinformatics analysis, siRNA interference and CHIPS technology.
Main results and the role of chance: At different time points of APN treatment at different concentrations, showed by MTT assay, the proliferation rates of Ishikawa and KLE cell lines were inhibited in a dose-dependent and time-dependent manner between APN groups and the control group($P<0.5$). QT-PCR analyses showed that with the increasing concentrations of APN(0,10,30ug/ml), stimulating IK and KLE cells for 24 hours, the mRNA expression of CYP19 was markedly dose-dependent down-regulated, and the mRNA expressions of AdipoR1 and AdipoR2 were significantly increased ,compared with the control group (0ug/ml,all $P<0.05$). Western blot analysis revealed the time-dependent decreasing protein expression of the potential transcription factors CEBPA selected by bioinformatics analysis,stimulating ECC-1 at 30ug/ml for 0,5,15,30 min. RT-PCR and western blot analysis showed that the mRNA and protein expressions of CYP19 was dreseasing when detecting the ECC-1 transfected with siCEBPA for 48h($P<0.05$). Furthermore,CHIPS technology reveal there is direct combination of CEBPA and CYP19 promoter sequences.
Limitations, reasons for caution: only in vitro, cell culture.
Wider implications of the findings: reveal new intervention targets for its prevention and treatment
Trial registration number: 8140060623

P-694 Follitropin delta – first human cell line derived recombinant FSH for AMH and body weight adjusted ovarian stimulation – a real world data analysis

A. Bachmann[1], S. Kissler[2], I. Laubert[3], P. Mehrle[4], A. Mempel[5], C. Reißmann[6], D. Sauer[7], S. Tauchert[8], A.P. Bielfeld[9]

Study question: Does the first recombinant FSH with a dosing algorithm affirm efficacy data observed in pivotal trials in a real world setting?
Summary answer: A good clinical pregnancy rate and mean number of oocytes was obtained so that Follitropin delta appears as an efficient agent for daily practice.
What is known already: Follitropin delta (REKOVELLE®, Ferring Pharmaceuticals) is the first recombinant FSH (rFSH) derived from a human cell line with a dosing algorithm based on body weight and AMH. Due to different glycosylation profiles, it has a lower clearance compared to other rFSH preparations and therefore induces a higher ovarian response when administered in equal doses of biological activity. Non-inferiority of clinical pregnancy and implantation rate for controlled ovarian stimulation with conventional rFSH treatment regime could be demonstrated in the multicenter randomized pivotal trial ESTHER-1, but there is an increasing demand for daily practice data with non-selected patients.
Study design, size, duration: In a multi-center analysis comprising eight centers for reproductive medicine in Germany, observational data of 360 women who underwent ovarian stimulation with Follitropin delta have been evaluated as part of the quality control from January 2018 to June 2019. The data were analyzed retrospectively.
Participants/materials, setting, methods: Mean age was 33.53 (± 3.83) years. AMH levels ranged from 2.5% < 0.5 ng/ml to 18.6% > 5.6 ng/ml with 79.4% of all AMH measurements above 2.03 ng/ml. Patients were included when the following prerequisites were met: data on ovulation triggering available, less than six previous cycles, no additional gonadotropin medication during stimulation with Follitropin delta. No selection regarding age, serum AMH level or BMI. The data were collected retrospectively and anonymized before analysis.
Main results and the role of chance: Based on the above criteria, a total of 360 women were included in the data analysis. Downregulation was performed in 96.6% of the first Follitropin cycle in the GnRH antagonist protocol, in 3.4% in the long GnRH agonist protocol. The mean daily dose was 9.03µg with a mean total dose of 89.50µg in a mean stimulation time of 9.9 days. In the AMH ranges between 2.031 and 3.5 ng/ml 8 - 14 oocytes were obtained in 44.1% of the patients whereas in the AMH range between 3.51 and 5.6 this proportion was even 50.4%. The mean number of oocytes obtained in the first Follitropin delta cycle was therefore 11.2 (± 6.7) oocytes with 42.1% of patients having between 8 and 14 oocytes. The average clinical pregnancy rate in the first fresh cycle was 38.2% with a mean of 1.4 embryos per transfer. The cumulative pregnancy rate though was 49.4% for the first stimulation cycle including cryo cycles. Due to the descriptive character of the analysis no adjusting for multiple testing was applied.
Limitations, reasons for caution: Shortcomings of the analysis might be a selection bias of the centers. According to the daily practice setting there were no present uniform criteria on how many embryos were transferred.
Wider implications of the findings: The goal of obtaining an adequate number of oocytes (8-14) using the Follitropin delta dosing algorithm was reached in 42.1% of patients despite a wide range of AMH values, while achieving good clinical pregnancy rates. Hence, algorithm based controlled ovarian stimulation with Follitropin delta is effective in daily practice.

Trial registration number: not applicable

P-695 Individualised follitropin delta dosing for ovarian stimulation in daily practice in a Dutch IVF centre.

P. Wijngaard-Boom[1], E. Creutzberg[2], T. Stijnen[3], J.S.E. Laven[1]

[1]Erasmus University Medical Centre, Reproductive Medicine, Rotterdam, The Netherlands ;
[2]Ferring BV, Gynaecology, Hoofddorp, The Netherlands ;
[3]Leiden University Medical Centre, Biostatistics, Leiden, The Netherlands

Study question: This study investigates in a real life setting the use of follitropin delta with individualised dosing regimen in patients undergoing IVF treatment.
Summary answer: The use of follitropin delta, in real-world clinical setting with a broad and varied patient population, shows results aligned with the ESTHER-1 registration trial (NCT01956110).
What is known already: Individualised follitropin delta dosing based on anti-Müllerian Hormone (AMH) and body weight (BW) is as effective as treatment with Chinese hamster ovary (CHO) derived follitropin alfa, and leads to a more predictable ovarian response within the target of 8-14 oocytes and improved safety. Results of the ESTHER-1 trial show: similar pregnancy rates; less frequent excessive ovarian response and measures to prevent ovarian hyperstimulation syndrome (OHSS); more women with a target ovarian response (8–14 oocytes); fewer poor responses with AMH<15 pmol/L; fewer excessive responses with AMH≥15 pmol/L.
Study design, size, duration: Descriptive analysis from real-world data obtained in the Erasmus University Medical Centre. Since its introduction in 2017, 665 patients have been treated with follitropin delta in our centre up to and including September 2019. 444 of these patients had a regular ovulatory menstrual cycle and were treated with follitropin delta in a GnRH-antagonist protocol, with the dose determined by the approved dosing algorithm, based on patient's BW and AMH.
Participants/materials, setting, methods: Women are prescribed follitropin delta according to the approved dose algorithm based on the patient's BW and serum AMH levels as measured by the automated Elecsys® AMH plus immunoassay (Roche Diagnostics International). Results of the treatment were collected from the clinical records. The outcomes of the first IVF cycle including frozen embryo transfers are described. Data were described as mean (SD), median (interquartile range) or proportions and statistically analyzed using t-test and chi-square test.
Main results and the role of chance: In the 444 patients, almost all patient characteristics were significantly different compared to those of the patients in the follitropin delta arm of the ESTHER-1 trial, except age: 33.4 (4.6) and 33.4 (3.9) years, NS. Mean (SD) BW was 69.9 (13.1) and 64.7 (10.7) kg (p<0.00001), primary subfertility diagnosed in 54.3% and 70.7% of the patients (p<0.00001), and proportion of patients naive to IVF was 65.5% and 100% respectively (p<0.00001). Median AMH (interquartile range) was also significantly different: 15 (10-24.3) and 16.3 (9-24.8) pmol/l (p=0.04).

Retrieved number of oocytes was 10.2 (5.6) and 10.0 (5.6), 8-14 oocytes were retrieved in 46.6% and 43.3% of patients and the number of cleavage stage embryos was 5.6 (5.0) and 5.4 (3.7) (all not significantly different). Ongoing pregnancy rate per started cycle was 24.5 and 30.7% (p=0.04). Cumulative pregnancy rate including frozen embryo transfers was 37.3% (no data from ESTHER-1 trial). More cycles were cancelled with an insufficient number of follicles: 10.8% and 3.8% (p<0.00001) and more preventive interventions for OHSS (GnRH-agonist trigger and/or freeze all) were performed: 5.4% and 2.3% (p=0.005). Severe OHSS requiring hospitalization was reported for 3 and 2 patients.
Limitations, reasons for caution: This is an analysis of the use of follitropin delta in patients in daily clinical practice. A heterogeneous population with different phenotypes was treated, which was different from the patients treated in the clinical trials performed earlier.
Wider implications of the findings: Individualised follitropin delta treatment of a broad patient population as presented in the real-world clinical setting shows that this new dosing regimen is able to predict ovarian response in a similar way as shown in the results of a previously performed clinical trial (ESTHER-1), even though patient characteristics were different.
Trial registration number: not applicable

P-696 Addition of LH to a COS antagonist protocol is not associated with number of blastocysts or their morphology.

J.E. Schwarze[1], J. Crosby[1], G. Cavada[2]

[1]Reproductive Medicine Unit, OB/GYN Clinica Las Condes, Santiago, Chile ;
[2]Universidad de Chile, School of Public Health, Santiago, Chile

Study question: Is the addition of LH (either as hCG or rLH) to an antagonist COS protocol associated with the number and morphology of blastocysts.
Summary answer: Addition of LH is not associated with number of expanded blastocysts, nor an increase in good morphology.
What is known already: There is contradictory evidence that IVF/ICSI outcomes are improved by LH (either as hCG or rLH) supplementation during COS. Several outcomes have been analyzed with conflicting results: number of oocytes, pregnancy, abortion and delivery rates. One outcome that has not been evaluated is the morphology of blastocyst.
Study design, size, duration: We performed a hierarchical multiple to determine the impact of three different COS antagonist protocols on blastocyst morphology (expanded, cavitated, initial): rFSH (reference), rFSH/hMG and rFSH/rLH, . Confusion was accounted for by correcting for the following variables; age of female partner, number of oocytes retrieved, sperm source (donor, testicular and fresh ejaculate). The outcomes analyzed were number of expanded blastocysts, odd of having an expanded blastocyst, and odd of a blastocyst being expanded over cavitated/initial.
Participants/materials, setting, methods: 2,112 autologous IVF/ICSI cycles were performed in the Reproductive Medicine Unit at Clinica Las Condes between 2015 and 2019**.** Blastocyst morphology was classified as expanded, cavitated or initial. Multilevel regression analysis was performed to determine number of expanded blastocysts, odd of having an expanded blastocyst, odd of having an expanded blastocyst over initial blastocyst, respectively.
Main results and the role of chance: The mean age of female partner was 36 years (mode 37, SD 3.8). 20% of patients were administered rFSH, 48% hMG/rFSH and 32% rFSH/rLH. Blastocyst rate formation was 38%, 35% and 33%, respectively (Chi square, p=0.444).
Compared to rFSH alone, the addition of either hMG or rLH to an antagonist COS protocol was not associated with:

a) an increase in the number of expanded blastocysts (multilevel Poisson regression, rFSH alone (reference), hMG/rFSH IRR 1.08 (95% CI 0.93-1.26, p=0.301); rFSH/rLH IRR 0.86 (95% CI 0.73-1.92, p=0.092));
b) number of expanded blastocysts (multilevel mixed logistic regression, rFSH alone (reference), hMG/rFSH OR 1.09 (95% CI 0,76-1.40, p=0.847); rFSH/rLH OR 1.03 (95% 0,.74-5,60, p=0.162);
c) odd of a blastocyst being expanded versus cavitated/initial (rFSH alone (reference), hMG/rFSH OR 1.11 (95% CI 0.87-2.25, p=0.281); rFSH/rLH OR 1.02 (95% CI 0.93-2.00, p=0.839).

Limitations, reasons for caution: This was an observational study so there may be unknown variables that were not accounted for, as would have been in an RCT.
Wider implications of the findings: The addition of LH to a COS does not improve neither the number of blastocysts, nor the morphology of blastocysts. Therefore, the choice of hormones for COS should depend on factors like price and accessibility.
Trial registration number: NA

P-697 The individualization of the gonadotrophin starting dose in IVF/ICSI prevents OHSS in the same manner as the freeze-all strategy: a systematic review of the evidence

A.A. Marino[1], S. Gullo[2], A. Volpes[1], F. Sammartano[1], P. Scaglione[1], A. Allegra[1]

[1]ANDROS Day Surgery Clinic, Reproductive Medicine Unit, Palermo, Italy ;
[2]University of Palermo, Department of Psychology- Educational Science and Human Movement- Statistics Unit, Palermo, Italy

Study question: Is the individualization of the starting dose of gonadotrophins equivalent to the freeze-all strategy for preventing ovarian hyperstimulation syndrome (OHSS)?

Summary answer: The personalization of the gonadotrophin starting dose, in normal responders, is a valid strategy for assuring treatment safety similarly to the freeze-all policy.

What is known already: Nowadays, the freeze-all policy has gained popularity because it minimizes OHSS.

This increase was possible thanks to vitrification procedures. Consequently, "wild" ovarian stimulation seems to replace the starting dose personalization, based on female age, ovarian reserve markers, BMI, etc. Nevertheless, the freeze-all policy does not completely eliminate OHSS. Furthermore, not all clinics have adequate skills in vitrification procedures and patients may be displeased with a longer time to pregnancy

Another approach for minimizing OHSS is the tailoring of the starting gonadotrophin dose. No systematic review comparing these two different strategies, in terms of reduction of OHSS, has been yet performed.

Study design, size, duration: A systematic review, based on PubMed, Cochrane CENTRAL, EMBASE, was conducted to estimate and compare the effectiveness of the individualization of the starting dose and freeze-all strategy in the prevention of OHSS in normal responders. Following *PICOS*, inclusion criteria were: *Population*, normal responders; *Intervention*, individualization of the starting gonadotrophin dose OR freeze-all strategy; *Comparison*, no individualization OR fresh embryo transfer; *Outcome*, OHSS (primary one), clinical/ongoing pregnancy and live birth rates (secondary ones). *Study design*: RCT.

Participants/materials, setting, methods: Electronic and manual search, conducted from 1990 to 2019, yielded 184 studies. Two researches reviewed the studies independently, excluding 162 studies after the first screening and 12 studies after the second screening. Thus, 10 studies were included. The Mantel-Haenszel method was used for odds ratios (OR) and heterogeneity among studies (I^2). The results were expressed in terms of prevalence, OR, and 95% confidence intervals (CI). Standardized test and Cohen's *h* were used to compare outcomes.

Main results and the role of chance: Three studies with 2,293 participants for the freeze-all strategy (Vuong et al., 2018, Shi et al., 2018, Wei et al., 2019) and seven studies with 1,705 participants for individualized strategy (Popovic-Todorovic et al., 2003, Arce et al., 2014, Olivennes et al., 2015, Allegra et al., 2017, Nyboe-Andersen et al., 2017, Bosch et al., 2019, Peterson et al., 2019) were included in the review. None of these studies directly compared the two strategies. Preliminary analyses excluded interaction between covariates, defining intervention/control groups and outcome. In the individualization strategy, the analyses also considered cycles suspended for OHSS risk.

OHSS was significantly lower in women receiving individualized treatment [50/1,705] compared with controls [91/1,464] (OR=0.505, 95%CI 0.35-0.73, p=0.01; I^2=0%). Similarly, OHSS was significantly lower in freeze-all strategy group [14/2,293] compared with controls [35/2,296] (OR=0.403, 95%CI 0.22-0.76, p=0.01; I^2=0%). Indirect comparisons between the two strategies were carried out by calculating effect size (Cohen's *h*) on prevalence and by computing a z-test on the difference between natural log OR. The difference between the two strategies revealed a small effect size (Cohen's *h*=0.19) and yielded a non-significant z-value of 0.549 (p=0.29) suggesting that individualization of the starting dose is equivalent to the freeze-all strategy for preventing OHSS.

Limitations, reasons for caution: Comparison of the studies was indirect because no published study directly compared the freeze-all strategy with the individualization of the starting dose. In the selected studies, the definition of normal responders was not exactly the same but similar.

Randomized controlled trials comparing the two different strategies are necessary.

Wider implications of the findings: This systematic review indicates that, in normal responders, the individualization of the starting gonadotrophin dose reduces OHSS similarly to the freeze-all strategy. We believe that, albeit in the era of the freeze-all policy, the personalization of the starting gonadotrophin dose should be considered the first line of an IVF program.

Trial registration number: Not applicable

P-698 Cumulative live birth rate of poor ovarian response women won't increase after 4 complete IVF cycles

M. WANG[1], J. Guo[1], C. Fang[1], X. Liang[1]

[1]Sixth Affiliated Hospital of Sun Yat-sen University, Reproductive Medicine Center, Guangzhou, China

Study question: How does the cumulative live birth rate (CLBR) of poor ovarian response (POR) women change as oocyte retrieval cycles increase?

Summary answer: Although initiating more cycles increases the cumulative clinical pregnancy rate (CCPR) of POR women, the CLBR won't increase after 4 complete cycles.

What is known already: Women with POR went through repeated IVF/ICSI failures. Many oocyte retrieval cycles may be initiated to pursue additional success rate, but seldom can they get a live birth. Repeated trying on new oocyte retrieval cycles without promising prognosis may be a heavy burden for patients both financially and mentally.

Study design, size, duration: A retrospective cohort study of 2775 complete cycles of 1825 POR women according to the Bologna criteria were recruited at the Reproductive Medicine Center of the sixth affiliated hospital of Sun Yat-sen University from 2014 to 2018. A complete cycle defined as all fresh and frozen-thawed embryos derived from one ovarian stimulation were transferred.

Participants/materials, setting, methods: Infertile POR women who underwent their first IVF/ICSI treatment at the Reproductive Medicine Center were recruited. The optimistic and conservative estimates of CLBR and CCPR were calculated according the oocyte retrieval cycles. Cycles that had not achieved live birth but with embryos left were excluded. Cases involving oocyte thawing and donation were eliminated.

Main results and the role of chance: Basic characteristic: The mean age was 39.43 (SD=4.723) years old. 29.4% were primary infertility. The median duration of infertility was 4 (2, 7) years. The median basal serum FSH were 9.11 (7.01, 11.68) IU/L, basal AMH 0.62 (0.37, 0.93) ng/ml, and bilateral antral follicle count 4 (3, 6). 77.5% underwent IVF and the rest adopted ICSI. The proportions of ovarian stimulation protocols: mild stimulation protocol, 29.01%; Shanghai protocol, 27.6%; Antagonist protocol, 24%; long protocol 1.95%; natural cycle protocol 3.57% and others 6.92%. The median number of oocytes retrieved were 3 (2, 4).

The optimistic and conservative estimates of CCPR increased along with new cycles in the first 6 cycles (the optimistic estimates of the 1st to the 7th cycle: 25.48%, 42.38%, 59.02%, 69.78%, 73.71%, 84.19%, 84.19%; the conservative estimates of the 1st to the 7th cycle: 25.48%, 33.75%, 36.60%, 37.09%, 37.15%, 37.21%, 37.21%). But the optimistic and conservative estimates of CLBR rose as the cycles added in the first 4 cycles(the optimistic estimates of the 1st to the 7th cycle: 14.79%, 24.13%, 32.37%, 39.92%, 39.92%, 39.92%, 39.92%; the conservative estimates of the 1st to the 7th cycle: 14.79%, 18.79%, 19.95%, 20.22%, 20.22%, 20.22%, 20.22%), reached 39.99% and 20.22% respectively.

Limitations, reasons for caution: As a retrospective study, there were many cycles that had not achieved live birth but with embryos left were excluded. Thus, there were not enough cases in the 6th and 7th cycle, which may lead to deviation of the real condition.

Wider implications of the findings: It's not recommended to suggest more than 4 complete cycles for the POR women because the CLBR won't increase any more.

Trial registration number: not applicable

P-699 The use of follitropin delta for ovarian stimulation for in vitro fertilization in patients with anovulatory PCOS: results in clinical practice

J. Laven[1], P. Wijngaard-Boom[1], T. Stijnen[2], E. Creutzberg[3]

[1]Erasmus Medical Center, Reproductive Medicine, Rotterdam, The Netherlands ; [2]Leiden University Medical Centre, Biostatistics, Leiden, The Netherlands ; [3]Ferring BV, Gynaecology, Hoofddorp, The Netherlands

Study question: This study investigates in a real life setting the use of follitropin delta in patients with anovulatory Polycystic Ovary Syndrome (PCOS).

Summary answer: In patients with anovulatory PCOS, the use of follitropin delta according to the dose algorithm results in good clinical results with a favorable safety profile.

What is known already: Individualized follitropin delta dosing based on Anti-Müllerian hormone (AMH) and body weight (BW) for IVF treatment is as effective as follitropin alfa, and leads to a more predictable ovarian response within the target of 8-14 oocytes and improved safety. In pivotal trials performed with follitropin delta, only women with a regular menstrual cycle (24-35 days) were included. In our clinic, up to 40% of IVF cycles were canceled because of

hypo- or hyperresponse if patients with anovulatory PCOS were treated with other traditional stimulation protocols.
Study design, size, duration: Since its introduction in The Netherlands in 2017, 665 patients have been treated with follitropin delta in the Erasmus University Medical Centre up to and including September 2019. In total 74 of these patients had been diagnosed with PCOS prior their treatment. The real world data of their first IVF cycle including frozen embryo transfers are described.
Participants/materials, setting, methods: All patients with PCOS have been diagnosed by the Rotterdam criteria (at least 2 out of 3 features: oligo- or amenorrhea, polycystic ovarian morphology, hyperandrogenism). AMH was measured using the automated Elecsys® AMH plus immunoassay (Roche Diagnostics International) and the dose of follitropin delta was determined using its approved dosing algorithm, based on patient's BW at start of treatment and AMH. Results of the treatment were collected from the clinical records.
Main results and the role of chance: Patients with PCOS had a mean (SD) age of 31.5 (4.0) years, body weight 69.5 (10.2) kg and AMH 40.7 (22.5) pmol/L. The mean duration of subfertility was 35.8 (28.6) months. 54.1% had primary subfertility and 40.5% of patients had received IVF treatment(s) prior to the treatment cycle with follitropin delta. The mean dose of follitropin delta used was 8.4 (2.1) µg/day. The mean number of follicles ≥11mm at day of last ultrasound was 14.3 (8.5). The mean number of oocytes retrieved was 12.1 (7.0) and the mean number of cleavage stage embryos 6.9 (4.6). Target response (8-14 oocytes) was reached in 29.2% of patients; 33.8% had <8 oocytes and 36.9% >14 oocytes. Per started cycle, 44.6 % had a positive urine human chorionic gonadotropin test after the first fresh transfer and 18.9% after cryotransfer (following unsuccessful fresh transfer or cryotransfer after freeze all). Overall cumulative ongoing pregnancy rate (≥ 11 weeks) per started cycle was 39.2%. The cycle was cancelled in 12.2% of the patients (5.4% due to hyperresponse and 6.8% due to insufficient number of follicles). 21.6 % needed preventive interventions for OHSS (Gonadotropin-releasing hormone-agonist trigger and/or freeze all); no cases of severe OHSS requiring hospitalization occurred.
Limitations, reasons for caution: This is a descriptive analysis of the use of follitropin delta in PCOS patients. A heterogeneous population with different PCOS phenotypes was treated, with no control group to compare them to.
Wider implications of the findings: Clinical results as collected in routine clinical practice are promising, showing a favorable effectivity-safety profile. To conclude whether follitropin delta applied in accordance with its dosing algorithm can be used safely in PCOS patients without compromising its effectivity, further comparative investigations with larger patient groups should be conducted.
Trial registration number: not applicable

P-700 Next generation sequencing results on 18 genes are not related to phenotype in a large cohort of patients with premature ovarian

S. Eskenazi[1], A. Bachelot[2], J. Hugon Rodin[3], G. Plu-Bureau[3], A. Gompel[3], S. Catteau-Jonard[4], D. Molina-Gomes[5], D. Dewailly[6], C. Dode[7], S. Christin-Maitre[8], P. Touraine[9]

[8]Saint-Antoine Hospital, Ile de France, Paris, France ;
[9]Pitié-Salptrière Hospital, Ile de France, Paris, France

Study question: What is the prevalence of gene variants in a large prospective multicentric cohort of patients with premature ovarian insufficiency (POI) and is phenotype correlated to genotype?
Summary answer: A high percentage of patients presented gene variants detected by NGS analysis (38%) and phenotype was not correlated to genotype.
What is known already: Premature ovarian insufficiency is defined by loss of ovarian activity before the age of 40, and is characterized by menstrual disturbance (amenorrhea or oligomenorrhea) with raised gonadotropins and low estradiol. POI remains idiopathic in more than 70% of cases. However, over the past years, many candidate genes have been identified. Nevertheless their prevalence and pathogenicity are still difficult to establish.
Study design, size, duration: Cohort study on 269 patients from 2013 to 2017
Participants/materials, setting, methods: Two hundred and sixty-nine well-phenotyped POI patients were screened for variants in 18 known POI genes *(BMP15, DMC1, EIF2S2, FIGLA, FOXL2, FSHR, GDF9, GPR3, HFM1, LHX8, MSH5, NOBOX, NR5A1, PGRMC1, STAG3, XPNPEP2, BHLB and FSHB)* using next generation sequencing (NGS). Abnormalities were classified as "variant" or "variant of unknown signification" (VUS) according to functional tests if any, otherwise according to several algorithms (SIFT, Polyphen-2, mutation taster).
Main results and the role of chance: One hundred and two patients (38%) were identified with at least 1 genetic abnormality on 1 to 5 genes. Seventy-two patients (25%) presented at least 1 variant. Fifty patients presented at least 1 uncommon variant of unknown significance (VUS)(17%). Thirteen patients (4.5%) had combined abnormalities (variant and VUS). *NOBOX* variants were the most frequent autosomal gene variant implicated in POI (9% of the patients). Interestingly, previous familial history of POI, ethnicity, age at POI, primary amenorrhea or secondary menstrual disturbance occurrence was not significantly different between the different genotypes.
Limitations, reasons for caution: We possibly analyzed altogether genes with different pathogenicities, which may have influenced our results. Assessing pathogenicity for each genetic abnormality remains challenging. Moreover, it has been shown that for a single gene, different types of variants may result in variable phenotype. Non-genetic factors may also be involved in POI development.
Wider implications of the findings: NGS analysis should be proposed to every POI patient to progress in understanding gene pathogenicity. Finding a variant may help patients to accept the diagnosis of POI and improve their compliance to treatment. It can also be relevant for female relatives for whom fertility preservation could be proposed

P-701 In vitro maturation of oocytes as an (the only?) option for patients with FSH resistance or oocyte maturation failure: a case series.

F. KRIEF[1], I. Cedrin Durnerin[2], S. Sarandi[3], B. Dagher Hayeck[2], M. Peigné[2], C. Sifer[3], M. Grynberg[4]

[1]Hôpital Jean Verdier, Médecine de la Reproduction et Préservation de la Fertilité, Bondy, France ;
[2]Hôpital Jean Verdier, Service de Médecine de la Reproduction et Préservation de la Fertilité, Bondy, France ;
[3]Hôpital Jean Verdier, Biologie de la Reproduction, Bondy, France ;
[4]Hôpital Béclère, Médecine de la Reproduction et Préservation de la Fertilité, Clamart, France

Study question: How viable is *in vitro* maturation (IVM) of oocytes in patients with FSH resistance or oocyte maturation failure following ovarian stimulation?
Summary answer: IVM of oocytes provides acceptable chances of live births in patients with FSH resistance or oocyte maturation failure following ovarian stimulation.
What is known already: The concept of IVM relies on the capacity of immature oocytes to resume meiosis *in vitro* upon release from their antral follicular environment. Some patients present ovaries that are not responsive to FSH or show recurrent oocyte maturation failure after controlled ovarian stimulation. For those patients oocyte donation remains the only viable option.
Study design, size, duration: This study is a retrospective case series showing our experience with IVM for patients with resistant ovary syndrome and oocyte maturation failure from 2015 to 2019. The diagnosis of resistant ovary syndrome was considered in patients showing normal antral follicle count and serum anti-Müllerian hormone levels despite high FSH levels and absence of response to exogenous FSH administration. Oocyte maturation failure was considered when no mature oocyte was obtained after at least 2 ovarian stimulation.
Participants/materials, setting, methods: Eleven patients were included. Three patients had oocyte maturation deficiency while eight presented with ovarian resistance to FSH. All underwent at least one IVM cycle. Immature oocyte

retrieval was systematically performed 36 hours after hCG administration. After ICSI, all cleavage stage embryos were frozen and transferred during the subsequent cycle under hormonal replacement therapy.

Main results and the role of chance: Three patients with oocyte maturation deficiency, aged 34, 29 and 28 years underwent a total of 6 IVM cycles. Their antral follicle count and serum AMH (in ng/mL) levels were respectively 13 and 1.52 ; 23 and 7 ; 22 and not available.

The first 2 women had only cycle with 1 and 2 cumulus oocytes complexes recovered without metaphase 2 oocyte obtained following IVM. The third patient had 4 cycles with a mean of 8.5 immature oocytes retrieved. After a mean maturation rate of 64.7%, seven embryos were frozen, leading after the transfer of 2 embryos to one live birth.

Eight patients with resistant ovary syndrome underwent 20 IVM cycles. Mean antral follicle count and serum AMH levels were 23.7 and 5.1ng/mL respectively). An average of 23.7 ± 20 immature oocytes were collected, leading after a 40.5% maturation rate, to 30 embryos cleavage stage embryos. Five fresh embryo transfers and 12 frozen thawed embryo transfers resulted in 3 pregnancies and four live births of healthy babies. The live birth rate was 15% per IVM cycle and 37.5% per patient.

Limitations, reasons for caution: Due to the very low prevalence of oocyte maturation failure and ovarian resistance to FSH, we report results from a small population, which unable drawing strong conclusion. Further data on the use of IVM in these clinical situations are needed.

Wider implications of the findings: Patients with ovarian resistance to FSH probably represent the most interesting population for being offered IVM. Due to more uncertain results, considering IVM in oocyte maturation failure may be questionable.

Trial registration number: None

P-702 Ovarian Stimulation with rFSH+rLH vs. rFSH alone in poor/suboptimal/normal responders undergoing IVF: real life analysis of 1382 patients stratified for the number of retrieved oocytes

S. Canosa[1], N. Mercaldo[1], A.R. Carosso[1], F. Evangelista[1], C. Racca[1], A. Ruffa[1], G. Gennarelli[1], A. Revelli[1], C. Benedetto[1]

[1]Physiopathology of Reproduction and IVF Unit- S. Anna Hospital, Department of Surgical Sciences, TORINO, Italy

Study question: Is the LBR (Live Birth Rate) of expected poor/suboptimal/normal responders undergoing IVF comparable whether Controlled Ovarian Stimulation (COS) is performed using rFSH+rLH or rFSH alone?

Summary answer: In poor/suboptimal/normal responders, rFSH+rLH stimulation increases oocyte maturation rate vs. rFSH alone, and gets comparable LBR when patients with the same oocyte yield are considered.

What is known already: No large studies comparing rFSH+rLH with rFSH alone have been performed so far in IVF patients, and the usefulness of adding rLH to rFSH in this patients is still debated. Studies in unselected patients showed that rLH addition to rFSH was unable to improve IVF outcome, but some other studies showed increased success rates in some subsets of patients. A recent meta-analysis gathering a series of small studies suggested that rLH supplementation might result in a higher clinical pregnancy rate in the so-called poor responders.

Study design, size, duration: This large retrospective, real life study included 1382 expected normal/suboptimal/poor responders aged 20-43 years, with AMH≤2.5, AFC≤15, no diagnosis of polycystic ovary syndrome or history of severe ovarian hyperstimulation syndrome. These patients underwent IVF treatment at our IVF Unit between 2004 and 2019. Among them, 753 were stimulated with rFSH+rLH (rFSH+rLH group) and 629 with rFSH alone (rFSH alone group).

Participants/materials, setting, methods: The clinical characteristics and reproductive outcome of patients in the two groups were compared using t-test or chi-squared test, as appropriate. As the LBR is known to increase with the number of retrieved oocytes, a further sub-analysis was performed, in which the two different COS regimens were compared after stratification for the number of retrieved oocytes, considering patients with the same number of available oocytes.

Main results and the role of chance: The two patient groups showed significant differences in age, years of infertility, AMH, antral follicle count, that were in favour of rFSH alone, confirming how in real life, the rFSH+rLH regimen is often reserved to poor prognosis patients. Accordingly to these prognostic factors, the number of retrieved oocytes was significantly higher in rFSH alone group, but the proportion of mature, metaphase II oocytes was slightly higher in patients receiving rLH. Also the LBR/cycle (24% vs 19.5%; p<0.05) was significantly higher in patients treated with rFSH alone, having a better a priori prognosis.

Considering only the 293 poor responders according to Bologna criteria (250 of which received rFSH+rLH, 43 rFSH alone), we observed that despite having a significantly higher mean age (38.3±3.5 vs 36.2±4.4; p<0.01) patients who received rFSH+rLH produced a significantly higher proportion of mature oocytes (88.4±22.4 vs 74.6±27.6; p<0.01), and finally obtained comparable LBR/cycle (14% vs 14.4%).

The equivalence between rFSH+rLH and rFSH alone-treated patients was confirmed after stratifying patients for the number of retrieved oocytes. Although in these smaller subgroups the differences in basal characteristics were still observed (in favour of rFSH alone group), in all subgroups the LBR/cycle resulted comparable for the two regimens.

Limitations, reasons for caution: This real life, retrospective study compares two patient populations with marked differences in basal characteristics, with a selection bias in favour of rFSH-alone group. What observed should be considered as purely indicative of rLH addition effect, and should be verified in adequately powered and designed trials.

Wider implications of the findings: In poor/suboptimal/normal responders, rLH addition to rFSH results in a higher proportion of mature oocytes and in comparable LBR despite significantly worse prognostic factors. This could suggest a favorable effect of rLH on oocyte quality and/or endometrial receptivity, that should be further studied.

Trial registration number: Not applicable

P-703 No embryonic development after IVF: an analysis of the subsequent IVF cycle

A.I. Athanasiou[1], R. Setton[1], N. Shah[1], Z. Rosenwaks[1], S. Spandorfer[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine-, New York, U.S.A.

Study question: Are certain treatment modifications associated with improved embryonic development after a failed IVF cycle?

Summary answer: Following an IVF cycle with no embryonic development, longer stimulation and the use of ICSI in the subsequent cycle are associated with improved embryonic development.

What is known already: The failure of all embryos in an IVF cycle to develop normally is a challenge for clinicians. There are several factors that influence embryonic development during an IVF cycle, including the stimulation protocol, the timing of the final oocyte maturation trigger, oocyte quality, successful fertilization and embryo culture conditions. While common practice is to trigger later for poor maturation and earlier for poor embryo quality, there is little guidance for total failure or arrest of embryonic development.

Study design, size, duration: This is a retrospective cohort study in which all patients who underwent IVF at an academic medical center between 2013 and 2019 were screened for inclusion. Patients were included if they had an IVF cycle at our center that resulted in no normal embryonic development for use (index cycle) and then underwent a subsequent IVF cycle at our center.

Participants/materials, setting, methods: A total of 207 IVF cycles that resulted in no embryonic development and the subsequent cycles were included. Patients were stratified by those who had embryos suitable for use in the subsequent cycle (group A) and those who did not (group B). Comparison was made between the index cycle that had no embryos and its subsequent cycle using a t-test. Chi-square test was used to compare modifications in IVF parameters between groups A and B.

Main results and the role of chance: Compared to the index IVF cycle, group A had significant increases in: lead follicle size (19.7 vs. 20.5mm, p=0.0006), number of days past an E2 level of 400 pg/mL (3.93 vs. 4.48, p=0.0011) and a lead follicle size of 14 mm (3.28 vs. 3.61, p=0.01), days of stimulation (10.8 vs. 11.5, p=0.02), number of embryos on day 3 (2.5 vs. 4.3, p<0.0001) and average cell count per embryo (3.9 vs. 6.4, p<0.0001), peak E2 (1506 vs. 1790 pg/mL, p=0.008), and number of oocytes harvested (7.5 vs. 9.1, p=0.01), mature oocytes (5.3 vs. 7.1, p=0.0008), and normal fertilization (2.1 vs. 4.4, p<0.0001).

However, there were no significant differences in total gonadotropin use and the time from trigger to retrieval. Conversely, compared to their index IVF cycles, group B had no statistically significant differences for any of these parameters. The subsequent cycle of group A had a significant increase in the use of ICSI (96.8%) compared to group B (88.2%, p=0.002). The groups showed no statistically significant difference when comparing whether or not there was a change in protocol type, use of oocyte activation, change in starting dose, delayed stripping, use of autologous endometrial co-culture, and change or type of trigger used.

Limitations, reasons for caution: This study is limited by a relatively small sample size; thus, the impact of certain protocol modifications may have been underestimated. Furthermore, only the cycle immediately following the failed cycle was analyzed.

Wider implications of the findings: To our knowledge, this is the first study that compares IVF cycles with no embryonic development with their immediate subsequent cycles. We believe this study provides a better understanding of changes that can improve embryonic development after failed IVF cycles due to total embryonic arrest.

Trial registration number: N/A

P-704 Luteal Phase Stimulation May be Better Than Follicular Phase Stimulation in Patients with Diminished Ovarian Reserve

H.B. Zeyneloglu[1], Y.A. Tohma[2], G. Onalan[2]

[1]BASKENT UNIVERSITESI, Kadin Hastaliklari ve Dogum ABD, ANKARA, Turkey ;
[2]Baskent University, Kadin Hastaliklari ve Dogum ABD, Ankara, Turkey

Study question: Are the mean numbers of the total number of oocytes retrieved, mature MII oocytes,pronucleus,grade 1 embryos and frozen embryos after follicular phase and luteal phase stimulations (FPS and LPS) different?

Summary answer: More number of mature oocytes and frozen embryos in LPS were obtained than FPS in the group of patients with diminished ovarian reserve.

What is known already: Despite advances in assisted reproductive technologies in recent years, treatment of patients with diminished ovarian reserve is still difficult for clinicians. However, as our knowledge of the follicular development increases, this group is better understood and newer treatment modalities are being developed. Multiple follicular recruitment waves in the same menstrual cycle is the basis of this new treatment option experienced early from fertility preservation strategies including luteal phase stimulation (LPS) or dual stimulation. Although there are many studies regarding this topic, it is not clear whether (FPS) or LPS yields better outcomes in this patient group.

Study design, size, duration: This retrospective case control study was conducted with 18 patients with diminished ovarian reserve (Group 1) and 11 normoresponder infertile patients (Group 2) undergoing two ovarian stimulations (FPS and LPS) and two oocyte retrievals in two separate menstrual cycles in the Baskent University Infertility Clinic between April 2019 and December 2019.In our clinic, diagnosis of diminished ovarian reserve was made by AMH <1.2 ng/mL and a total AFC less than 5 detected with transvaginal ultrasound.

Participants/materials, setting, methods: In group 1, all embryos were frozen on day 3 or 5, whereas some patients in Group 2 had transferred embryos in FPS but did not get pregnant, their LPS embryos were frozen. Patients' data included controlled ovarian hyperstimulation performance such as peak E2 level, the total number of oocytes retrieved, mature MII oocytes, pronucleus, grade 1 embryos, good quality embryos and frozen embryos.

Main results and the role of chance: The mean age of the patients in Group 1 and 2 were 36.0 ± 4.8 and 33.4±6.0 years, respectively. In group 1, total retrieved oocyte and total MII oocyte numbers were significantly higher in LPS when compared to FPS; 4.19 vs. 2.2, (p: 0.005) and 2.67 vs. 1.72, (p:0.044), respectively. Peak E2 levels, pronucleus oocyte numbers were similar in both stimulation phases. Both Grade 1 embryo and frozen embryos numbers were higher in LPS cycle; 1.11 vs 0.55, (p:0.025) and 1.72 vs. 0.67, (p:0.009), respectively. Although Group 2 patients had better results in LPS regarding PN, grade 1 and good quality embryos, they did not reach statistical significance.

Limitations, reasons for caution: Main limitations of this study are retrospective design and small sample size. Therefore, well-designed, prospective, large-scale studies are required to improve our understanding of this topic.

Wider implications of the findings: We noticed better synchronization of follicles and recruitment of more better quality embryos in LPS. LPS may be beneficial especially in the patient with poor ovarian reserve with follicular asynchronization in the menstrual onset and in the patients who does not accept dual stimulation for psychological, economical or other reasons.

Trial registration number: Not applicable

P-705 Progesterone levels on day of ovulation trigger and ongoing pregnancy rates in fresh and frozen cycles: a secondary analysis of a randomised controlled multicenter trial

S. Stormlund[1], N. Sopa[2], A. Zedeler[1], J. Bogstad[3], L. Prætorius[1], H.S. Nielsen[3], A. Klajnbard[4], A.L. Mikkelsen[5], S. Ziebe[3], N. La Cours Freiesleben[1], C. Bergh[6], P. Humaidan[7], A. Nyboe Andersen[3], A. Pinborg[3], K. Løssl[3]

[1]Hvidovre University Hospital, The Fertility Clinic- Department of Obstetrics and Gynecology, Hvidovre, Denmark ;
[2]Hvidovre University Hospital, The Fertility Clinic- Department of Obstetrics and Gynecology, Hvidovre, Denmark ;
[3]University Hospital Rigshospitalet, Fertility Clinic, Copenhagen, Denmark ;
[4]Herlev University Hospital, The Fertility Clinic- Department of Obstetrics and Gynecology, Herlev, Denmark ;
[5]Holbæk University Hospital, The Fertility Clinic- Department of Obstetrics and Gynecology, Holbæk, Denmark ;
[6]Sahlgrenska University Hospital, Department of Obstetrics and Gynaecology, Gothenburg, Sweden ;
[7]Skive Regional Hospital, The Fertility Clinic, Skive, Denmark

Study question: What is the role of progesterone on trigger day in the decision between a freeze-all and fresh transfer strategy in IVF in regular cycling women?

Summary answer: In a clinical setting with strict trigger criteria measurement of progesterone on the day of trigger is not indicated.

What is known already: Premature progesterone elevation in the late follicular phase following controlled ovarian stimulation has been associated with decreased ongoing pregnancy and live birth rates in fresh ART cycles. The possible underlying mechanism is embryo-endometrial asynchrony leading to decreased endometrial receptivity and implantation failure. Few studies have investigated the reproductive outcomes in relation to progesterone levels on ovulation trigger day in fresh and frozen embryo transfers in a randomised controlled trial setting.

Study design, size, duration: Progesterone levels on trigger day was a secondary outcome in a multicenter, randomised trial including 460 women allocated 1:1 to either (1) GnRH agonist trigger and freeze-all strategy or (2) hCG trigger and fresh single blastocyst transfer. Recruitment was performed over a 2-year period. The aim was to investigate ongoing pregnancy rates within the two groups according to progesterone levels measured on ovulation trigger day.

Participants/materials, setting, methods: Women between 18 and 39 years with a regular menstrual cycle referred for their 1, 2 or 3rd ART treatment were included. Biobank samples were collected on trigger day in the ovarian stimulation cycle in both groups and were subsequently analysed for progesterone levels. Trigger criteria was defined as presence of three follicles ≥ 17 mm and all recruiting clinics adhered to this. Ongoing pregnancy was determined by transvaginal ultrasonography at gestational weeks 8 –10.

Main results and the role of chance: As treated analysis was applied including only those women who complied with allocated randomisation group and who reached blastocyst transfer. A total of 288 women were included in the analyses. In the present clinical setting with strict adherence to predefined trigger criteria the prevalence of progesterone elevation above 1.5 ng/ml was only 3.8% (11/288). Ongoing pregnancy was compared in women with progesterone levels below and above 1.5 ng/ml in both women undergoing fresh blastocyst transfer and women with postponed FET. In the fresh transfer group the pregnancy rate was 17% (1/6) when progesterone levels exceeded 1.5 ng/ml and 42% (55/131) when progesterone was below this cut-off level. This difference however, did not show statistical significance (p=0.4). In the freeze-all group, the ongoing pregnancy rates were 40% (2/3) when progesterone levels exceeded 1.5 ng/ml and 34% (49/146) below the cut-off level of 1.5 ng/ml (NS) indicating that progesterone levels on the trigger day in the fresh cycle do not impact results in subsequent FET cycles. Importantly however, the number of women with high progesterone levels in the present analysis was very low. Additional analyses

using different cut-off levels of high as well as low progesterone was attempted and showed similar results.
Limitations, reasons for caution: Sample size for the primary RCT was powered to detect at 13% increase in ongoing pregnancy between the two groups, however in the present secondary analysis only 288 of 460 randomised women were included. In addition, the number of women with progesterone levels above 1.5 ng/ml was very low.
Wider implications of the findings: In a clinical setting where final oocyte maturation is triggered as soon as three follicles ≥ 17 mm are present, the measurement of progesterone levels on trigger day seems of no real clinical relevance.
Trial registration number: Clinicaltrials.gov identifier: NCT02746562

P-706 Progestins vs gonadotropin releasing hormone analogues for pituitary suppression during ovarian stimulation for assisted reproductive technology, a systematic review and meta-analysis

S. Yildiz[1], P. Alexandru[1], S.G. Cekic[1], E. Turkgeldi[1], B. Ata[2]

[1]Koc University Hospital, Assisted Reproduction Unit, Istanbul, Turkey ;
[2]Koc University, Assisted Reproduction Unit, Istanbul, Turkey

Study question: Are progestins as effective as gonadotropin releasing hormone analogues for pituitary suppression in assisted reproduction ?
Summary answer: Progestins can effectively prevent premature ovulation in assisted reproductive technology (ART) cycles. However, the quality of evidence is yet low.
What is known already: GnRH antagonists have become the most commonly used agents for pituitary suppression during ovarian stimulation for over a decade. They require less injections, provide similar pregnancy rates and lower risk of ovarian hyperstimulation syndrome than the former standard of care, i.e. GnRH agonists. Progestins are also capable of suppressing endogenous luteinizing hormone (LH) secretion from the pituitary. However, early endometrial exposure to progestin preclude a fresh embryo transfer. Yet, with the advent of high-survival embryo vitrification and increasing number of oocyte cryopreservation cycles progestins are being more frequently used in ART.
Study design, size, duration: A systematic review and meta-analysis of comparative studies regardless of randomization. We searched electronic databases, trial registers, and websites from the date of inception until June 1, 2019. Seven studies involving a total of 1548 women were included.
Participants/materials, setting, methods: Three studies compared a progestin with a GnRH antagonist and four studies compared a progestin with a GnRH agonist.The primary outcome was live birth rate (LBR) per woman. Secondary outcomes were live birth or ongoing pregnancy (LB/OP) per woman and per embryo transfer (ET), ongoing pregnancy, clinical pregnancy, positive pregnancy test, numbers of oocytes and metaphase-two oocytes, duration of stimulation and gonadotropin consumption.
Main results and the role of chance: While progestins fared similar with GnRH antagonists regarding effectiveness and safety parameters, progestins were associated with significantly higher LB/OP per ET compared with the short GnRH agonist protocol (RR=1.49, 95% CI=1.16 to 1.91). Although progestin primed stimulation lasted significantly longer and required significantly more gonadotropins than the short GnRH agonist protocol, the differences were small and clinically negligible. Safety parameters were similar between progestins and GnRH agonists.
Limitations, reasons for caution: The presence of a limited number of trials/studies, most of which are not randomized nor accounts for every woman starting stimulation are drawbacks, preventing definitive conclusions on the subject.
Wider implications of the findings: If future high-quality trials confirm the findings of the present review, progestins can become the agent of choice for pituitary suppression in ovarian stimulation cycles when a fresh embryo transfer is not intended. This would be a real benefit by eliminating the need for relatively costly GnRH analogues.
Trial registration number: Not applicable

P-707 rLH supplementation during GnRh-antagonist delayed-start OPCs-syncronized IVF cycles run by Follitropin delta

A. Nazzaro[1], A. Salerno[2], M. De Martino[3], L. Di Iorio[2]

[1]Futuraivf - Reproductive Medicine Center, Human Reproduction Unit, Benevento, Italy ;
[2]Futuraivf-Reproductive Medicine Center, Human Reproduction Unit, Benevento, Italy ;
[3]Futuraivf-r Reproductive Medicine Center, Human Reproduction Unit, Benevento, Italy

Study question: May endocrine dynamics evaluation be used as a predictor of ovarian response and IVF outcome during IVF Follitropin delta driven cycles?
Summary answer: Endocrine dynamics identify women needing rLH supplementation during COS run by Follitropin delta and the threshold under which supplementation is mandatory
What is known already: Stimulation protocols, impact both oocyte quality and quantity via endocrine/paracrine signals, as oocyte quality is programmed well before ovulation. rLH supplementation increases pregnancy rate, in unselected patients, when it is supplemented as a routinary part of an IVF cycle accordingly to endocrine dynamics evaluations and during ovarian stimulation in poor responders or women of an advanced age.
Study design, size, duration: 200 unselected women were enrolled.A delayed-start protocol with individualized Follitropin delta dose,following daily 0,25 µg GnRh-antagonist administration was used.LH,E2, and Pg determinations were performed on day 3-4 of spontaneous menstruation (basal),at t0 (day of OCP stop),t1 (day of first GnRh-antagonist administration),t2 (first us scan),t3 (second us scan) to evaluate the need of rLH adding.An arbitrary cut off of 1,4 mIU/ml of circulating LH at any time was considered as the threshold for rLH tailored supplementation.
Participants/materials, setting, methods: 100 patients out of 200 (group I) received only tailored follitropin delta, whilst 100 patients (group II) received tailored rFSH plus rLH accordingly to endocrine dynamic evaluations.Primary outcomes were total number and MII retrieved oocytes,number of 2PN,top embryo quality rate.Secondary outcomes included total number of transferred embryos,BhcG/started cycle and BhcG/ET,implantation rate,clinical pregnancy rate/started cycle,-clinical pregnancy rate/ET.Data were analyzed by using the SPSS version 20.0: Mann–Whitney U-test and Z-test were used. Significance was set at $P<.05$
Main results and the role of chance: Serum E2 and P level at t2 and t3 did not show any statistical significant difference between the two groups.LH values at basal time (t0)were similar in both groups(5,60 + 2,70 vs 5,56 + 2,67 mIU/ml),whereas LH serological values at t2(2,95+3,54 vs 1,90+1,56 mIU/ml)and at t3 (2,70 + 2,15 vs 1,92+1,56 mIU/ml)were markedly reduced when COS was driven with Follitropin delta alone respect to the stimulation supplemented with rLH,reaching a statistically significant difference between the two groups (*p* value <.05 and <.002 respectively)at any time.Notably Metaphase II oocytes (6,32+3,22 vs 4,50+2,70),fertilization rate (4,18+2,16 vs 2,81+1,49;) and top scoring embryos (3,17+1,89 vs 2,16+1,25)showed a statistical significance difference in favour of women receiving and add back of rLH (*p* values <.00001;<.00001 and <.00001 respectively).Total dosage of Follitropin delta administration, total number of retrieved oocytes, total number of embryo transferred at day 2/3 were similar in the two groups.BhcG for started cycle and for embryo transfer,implantation rate and ongoing pregnancy rate for started cycle and for embryo transfer,whilst not reaching a statistically significant difference,showed a clear trend towards a better outcome in favour of the added rLH group(47,77% vs 37,96%; 50,91% vs 41,21%; 22,29% vs 16,4%; 38,50 vs 29,16%; 38,99 vs 29,6% respectively).
Limitations, reasons for caution: More robust studies are needed to have a clear comprehension of paracrine/endocrine signals regarding bidirectional cumulus-oocyte dialogue and to clarify who really needs of LH supplementation, which is the threshold under which supplementation with rLH is mandatory and, at what point of follicular stimulation we need to add rLH
Wider implications of the findings: rLH supplementation may increase pregnancy rate in Follitropin delta run IVF cycles when it is administered respecting the endocrine milieu throughout the entire length of follicular phase accordingly to endocrine dynamics. Other iatrogenic interference may further impair IVF outcome
Trial registration number: not applicable

P-708 Comparison of effects of Duphaston and Cetrotide on Oocyte and Embryo Quality in Women Undergoing Intracytoplasmic Sperm Injection

S. Jouhari[1], N. Motaref[2], A. Mohammadzadeh[2], N. Madadi[3], A. Ghoodjani[2]

[1]Avicenna Research Institute- ACECR, infertility, Tehran, Iran ;
[2]Avicenna Research Institute- ACECR, Reproductive Biotechnology Research Center, tehran, Iran ;
[3]Avicenna Research Institute- ACECR, Biotechnology Research Center, tehran, Iran

Study question: To compare the effects of Duphaston and Cetrotide on prevention of premature luteinizing hormone surge and characteristics of retrieved follicles and embryos in women undergoing intracytoplasmic sperm injection (ICSI).
Summary answer: Duphaston could be used as an appropriate medication instead of GnRH antagonists in women undergoing controlled ovarian hyperstimulation (COH).
What is known already: Premature luteinizing hormone (LH) surge is one of the causes of assisted reproductive technology (ART) cycle cancellation. GnRH antagonists are used as agents for the prevention of premature luteinizing hormone surge. It is needed to find novel approaches with improved efficacy and safety profile.
Study design, size, duration: This is a retrospective study, conducted in the Avicenna Infertility Clinic of Tehran, Iran. Women undergoing ICSI regimens for infertility treatment were recruited from September 2017 to December 2018. A total of 200 patients were assessed for eligibility, which was divided into two groups. Case group (100 patients) received Duphaston and control group (100 patients) prescribed GnRH antagonist for the prevention of premature LH surge.
Participants/materials, setting, methods: Both groups received recombinant FSH from third day of menstruation cycle. When follicular diameter reached to14 mm, Cetrotide was prescribed in control group, while Duphaston (20 mg/d) was taken orally from the third day of the cycle until the trigger day in case group.when three dominant follicles reached to17 mm, Oocyte retrieval was performed.Level of hormones in the third day of menstruation, and characteristic of follicles, oocytes, and embryos were compared between two groups
Main results and the role of chance: Results showed that Duphaston successfully inhibits a premature LH surge. There was no significant difference in the level of FSH, estradiol, and LH between the case and control groups ($p>0.05$). Results revealed also showed that Duphaston causes more oocyte retrieval in compared with Cetrotide ($p=0.04$). Although, number of follicles above 14mm, mature oocyte (MII), the total number of viable embryos, i was slightly higher n the case group, but did not reach a significant difference compared with the control group ($p > 0.05$).
Limitations, reasons for caution: . Lack of pregnancy and neonatal outcomes, reduced power of this study. Therefore a complete additional studies is needed to provide more evidence about the efficacy of the Duphaston protocol and illuminate its impact on pregnancy and children born from this novel regimen.
Wider implications of the findings: Duphaston could be used as an appropriate medication instead of GnRH antagonists in women undergoing controlled ovarian hyperstimulation (COH). Duphaston prescription not only prevents premature LH surge, but also improves number of retrieved follicles.
Trial registration number: not applicable

P-709 A comparative study of oral dydrogesterone with micronised vaginal progesterone for supporting the luteal phase in IVF-ICSI cycles

P.C. Jindal[1], M. Singh[1], R. Singh[1]

[1]Bhopal Test Tube Baby Centre, Infertility, Bhopal, India

Study question: Is oral dydrogesterone administration as effective as micronised vaginal progesterone for luteal-phase support in IVF-ICSI cycles ?
Summary answer: Yes , oral dydrogestrone is as effective as micronised vaginal progesterone for luteal-phase support in woman undergoing IVF-ICSI cycles .
What is known already: In ART cycles , there is a significant reduction in pregnancy rates without luteal-phase support . In the absence of luteal-phase support, progesterone levels are suboptimal and accompanied by premature luteolysis, short luteal phase and early bleeding. Progesterone is necessary for implantation.and early pregnancy maintenance.

Luteal phase support is mandatory in assisted reproductive technologies (ART) for optimizing outcome, so the luteal phase is supported with either progesterone, addition of estradiol to progesterone, hCG or gonadotropin releasing hormone (GnRH) agonists. Supplementation of luteal phase with progesterone is prescribed for women undergoing routine IVF-ICSI treatment.
Study design, size, duration: This is a prospective trial in Bhopal from Dec 2018 to Dec 2019. The study protocol was explained for all patients and informed written consents were given. In total 60 infertile women undergoing controlled ovarian stimulation for IVF-ICSI treatment (fresh cycle) were included in this study. Patients were divided into group A (oral dydrogesterone group) and group B (micronised vaginal progesterone group) and outcome evaluated in terms of clinical pregnancy and miscarriage rates.
Participants/materials, setting, methods: In total 60 infertile women undergoing controlled ovarian stimulation for IVF-ICSI treatment (fresh cycle) were included in this study.

Patients were divided into group A (oral dydrogesterone group) and group B (micronised vaginal progesterone group) and outcome evaluated in terms of clinical pregnancy and miscarriage rates.

Group A (n=30) received 10 mg dydrogesterone thrice a day (Duphaston; Abbott) and group B (n=30) received 400 mg micronised vaginal progesterone twice per day.
Main results and the role of chance: Clinical pregnancy rate in the micronised vaginal progesterone (group B) was higher than oral dydrogesterone (group -A) , but the difference was not significant.

Furthermore , the miscarriage rate in two groups was the same .

The difference between the two groups in the endometrial thickness and number of embryos transferred was not significant .

The clinical pregnancy rate and implantation rate were also similar in the two groups. Moreover, no discomforts following oral delivery of Duphaston have been observed during our investigation.

In summary, the use of oral dydrogesterone avoids the frequently reported and negatively perceived side effects of vaginal preparations, whereas no systemic tolerability difference from micronized vaginal progesterone has been identified.

Given the widespread preference of women for an oral compound, dydrogesterone may well become the new standard for LPS in fresh embryo transfer IVF cycles.Limitations, reasons for caution: Very few studies have compared the advantages of oral dydrogestrone with vaginal progesterone for luteal support in ART cycles.

The main limitation of our study was the relatively small sample size. Further investigations are recommended with longer follow-up and larger series to validate the findings reported here.
Wider implications of the findings: Recently, large studies have firmly establish the noninferiority in efficacy of daily 30 mg oral dydrogesterone versus daily 600 mg micronized vaginal progesterone. Despite oral administration and first pass through the liver, dydrogesterone was as well tolerated as vaginal progesterone in safety analyses with no new fetal safety concerns.
Trial registration number: not applicable

P-710 Predictors of pregnancy in women age 40 and above undergoing intrauterine insemination

G. San Roman[1], B. Abittan[1], B. Zaghi[2], R. Goldman[1], S. Brownridge[1], G. San Roman[1]

[1]Northwell Health Fertility, Obstetrics and Gynecology, Manhasset- NY, U.S.A. ;
[2]Southside Hospital- Northwell Health, Obstetrics and Gynecology, Bay Shore- NY, U.S.A.

Study question: Do follicle-stimulating hormone (FSH) and/or anti-mullerian hormone (AMH) levels predict pregnancy rates in women age 40 and older undergoing intrauterine insemination (IUI)?
Summary answer: FSH is a better prognostic indicator for the likelihood of achieving a clinical pregnancy than AMH in women age 40 and above undergoing IUI.
What is known already: IUI is widely accepted as a treatment for infertile couples. Studies have shown decreased pregnancy rates with IUI in women over the age of 40. Thus, the American Society for Reproductive Medicine (ASRM) has recommended in vitro fertilization (IVF) for this age group. However, many patients prefer IUI treatments as these cycles are less-invasive and more affordable than IVF.

Study design, size, duration: We designed a retrospective cohort study of 899 IUI cycles from 2013 to 2019.
Participants/materials, setting, methods: This study was conducted in a tertiary academic medical center. Data was collected from women age 40 and above. Women with tubal or severe male factor infertility were excluded from this study. Two-sample two-tailed t-tests assuming unequal variance were used to assess the differences in FSH and AMH levels between the pregnant and non-pregnant groups.
Main results and the role of chance: Of the 899 IUI cycles in our study, 51 (5.8%) resulted in pregnancy. No pregnancies were reported in women over the age of 45 (n=67). FSH levels among patients who achieved clinical pregnancy were significantly lower (8.7 IU/L ± 4.1) than those of patients who did not conceive (10.7 IU/L ± 6.6; *p*=0.002). AMH levels were not significantly different between the pregnant and non-pregnant patients (1.5 ng/mL ±1.7 vs. 1.5 ng/mL ± 3.2; p=0.87).
Limitations, reasons for caution: One of the limitations of our study is that this was a retrospective chart review. Given the retrospective nature of this study, specific patient indication and desires for undergoing IUI treatments as opposed to IVF were not readily available.
Wider implications of the findings: Patients age 40 and over who request infertility treatment should have detailed counseling of the likelihood of success relative to their age. Our study shows that IUI may be an option for women who do not want or cannot afford IVF.
Trial registration number: not applicable

P-711 Double stimulation protocol (DuoStim) might improve pregnancy rate in poor responders

M. Ibrahim[1]

[1]*menia university faculty of medicine, obstetrics and gynecology departement, menia, Egypt*

Study question: Is double stimulation protocol superior to short protocol in improving the pregnancy rate in poor responders?
Summary answer: Stimulation with identical protocol in the Follicular phase and Luteal Phase of the same menstrual cycle resulted in more number of blastocysts in poor responseders.
What is known already: The number of high quality oocytes retrieved in an IVF cycle is a major factor contributing to the patient pregnancy chances . While stimulation and trigger concepts have been developed successfully in normo and hyperrespoder patients the poor responder patients remains difficult to manage. However, recent advances in definitions and classifications of poor ovarian responders might enable a more accurate and clinically useful interpretation of new treatment concepts.
Study design, size, duration: Prospective cohort study done on fifty patients from December 2018 to December 2019
Participants/materials, setting, methods: Nile infertility center(NIC) and Minia Infertility Research Unit (MIRU).
Fifty poor responders planned for ICSI.
Method
1st group using the standard Long protocol for controlled ovarian hyperstimulation
2nd group using Double stimulation protocol (DuoStim) we starting from the 2nd day of the cycle with 300 IU of r- FSH + 150IU of r-LH using flexible antagonist protocol and triggering by GnRH-a then OPU after 36 hours.
Main results and the role of chance: Patients with an antimüllerian hormone level of <0.5 ng/mL, antral follicle count of <5 follicles, and/or <3 oocytes retrieved in a previous cycle were included. There are a statistically significant differences were found in the number of retrieved COCs (2.6 ± 1.8vs. 5.2 ± 3.4), MII oocytes (1.4 ± 1.2 vs. 3.9 ± 2.3) and number of transferred blastocysts(1.1 ± 0.9vs. 2.2 ± 0.8)also there is statistically significant difference in clinical pregnancy rate between the two groups (12% vs 20%) there is no statistically significant difference were found in the multiple pregnancy rate(1% vs1%) .
Limitations, reasons for caution: high cost of the treatment used limit the study
Wider implications of the findings: We recommend to implicate the study on larger sample size.
Trial registration number: not applicable

P-712 Granulosa cell signaling-based bioassay in vitro for personalized stimulation in ART: benefit of LH addition to FSH in sub-responder women

E. Paradiso[1], **C. Lazzaretti**[1], **S. Sperduti**[1], **S. Limoncella**[1], **B. Melli**[1], **M.T. Villani**[2], **A. Nicoli**[2], **J. Daolio**[2], **M. Lispi**[3], **G. Orlando**[4], **M. Simoni**[1], **L. Casarini**[1]

[1]*University of Modena and Reggio Emilia, Unit of Endocrinology- Dept. Biomedical- Metabolic and Neural Sciences, Modena, Italy ;*
[2]*Azienda Unità Sanitaria Locale – IRCCS di Reggio Emilia- Reggio Emilia- Modena, Department of Obstetrics and Gynaecology- Fertility Center- ASMN., Reggio Emilia, Italy ;*
[3]*Merck KGaA, Global Medical Affair, Darmstadt, Germany ;*
[4]*Merck Serono SpA, Medical Affair, Roma, Italy*

Study question: Can LH addition to FSH recover the difference of granulosa cell cAMP and progesterone response between sub- vs normo-responder women?
Summary answer: Co-treatment by recombinant FSH+LH may reduce, or even deplete the different cAMP and progesterone production between granulosa cells from normo- and sub-responder women.
What is known already: Granulosa cells collected from 105 normo- and 105 sub-responders women undergoing assisted reproduction (ART) feature specific FSH receptor (FSHR) expression and response to gonadotropins *in vitro*. Indeed, we demonstrated previously that normo-responders display higher sensitiveness to FSH than sub-responders, resulting in lower FSH 50% effective concentrations (EC50) required for inducing cAMP and steroid response. Moreover, normo-responders have higher basal serum estradiol levels than sub-responders.
Study design, size, duration: hGLC samples from anonymized donor women undergoing oocyte retrieval for ART are collected between 2019-2020. Cells are purified, cultured, genotyped and treated by FSH+LH *in vitro* and intracellular signaling endpoints were collected. Data obtained by cells from 42 normo-responder women are compared to those from 24 sub-responders (women who recruited a number of oocytes <70% than Follicular Output Rate). Experiments are performed under the local Ethics Committee permission (n°2018/0080377, 16/07/2018) and written consent.
Participants/materials, setting, methods: hGLC donor women undergone ART without endocrine abnormalities and diseases. hGLC samples are genotyped for FSHR polymorphisms known to modulate the response to FSH (rs6166, rs6165, rs1394205) and stimulated by increasing doses (0-100 nM) of recombinant FSH (Gonal-F, Merck KGaA, Darmstadt, Germany) + 10 nM LH (Luveris, Merck KGaA). cAMP and, as a primary endpoint, progesterone are measured by immunoassays and dose-response curves performed. Results from normo vs sub-responders were compared, considering their clinical data.
Main results and the role of chance: We found that cells of sub-responder women treated with FSH+LH produced higher cAMP levels than same cells treated by FSH alone. The presence of LH compensate for the different FSH dosage, required for increasing cAMP, between normo- and sub-responder cells (FSH EC50 2.668 ± 1.012 vs 1.486 ± 1.075 nM, respectively; p<0.01; t-test). Then progesterone synthesis was evaluated, indicating activation of the steroidogenic pathway. The 24-h basal progesterone production of cells from normo-responder women is higher than that of cells from sub-responders (p<0.01; t-test). In the presence of 10 nM LH, both unstimulated and FSH-induced, progesterone production increased in all samples. Interestingly, although progesterone produced by cells from normo-responder women is confirmed to be higher than that of cells from sub-responders (about 2-fold different progesterone levels; p<0.01; t-test). FSH (+ LH) EC50 values are similar in the two groups, revealing that the addition of LH is linked to equipotency of FSH in inducing steroidogenesis, in the two groups (t-test; p≥0.05). No different allele frequencies and FSHR expression levels between normo- versus sub-responders were found (Chi square and t-test; p>0.05), demonstrating that each of the two groups are genetically homogeneous.
Limitations, reasons for caution: In vitro data would be confirmed by translation into a clinical setting.
Wider implications of the findings: This study provides the rationale for establish an *in vitro* bioassay able of inferring and optimizing the *in vivo* response to ART treatment, evaluating steroidogenesis. The model suggests that LH addition to FSH treatment for ovarian stimulation may be beneficial in sub-responder women.
Trial registration number: not applicable

P-713 Severe haematoperitoneum after transvaginal oocyte retrieval related ovarian bleeding could be mostly managed by conservative treatment: 9577 cases of one clinician's experience in 5.5 years

M. Aygun[1], C. Pirkevi Çetinkaya[1], M. Cetinkaya[1], B. Yuksel[1], S. Kahraman[1]

[1]Sisli Memorial Hospital, IVF Andrology and Genetics Center, Istanbul, Turkey

Study question: How can we manage the severe haematoperitoneum (SHP) caused by ovarian bleeding after transvaginal oocyte retrieval (TVOR), surgical or conservative?
Summary answer: Most of the patients does not need surgery for TVOR-related intra-abdominal severe bleeding after red blood cell (RBC) transfusion and clinical observation.
What is known already: One of the most serious complications of the TVOR is intra-abdominal bleeding during in-vitro fertilization (IVF) cycles. Hospitalization is reported to be needed after this surgical procedure with an incidence between 0.06% and 0.35%. According to the literature, the rate of cases with suspected severe SHP requiring abdominal surgery is very different between 40% to 70% in large series. However, very little data on surgical versus conservative treatment for SHP caused by ovarian bleeding after transvaginal egg retrieval is currently available.
Study design, size, duration: A total of 9577 consecutive TVOR procedures performed by a single clinician were included in this retrospective study over a period of 5.5 years between June 2014 and December 2019 in one IVF center. All of the suspected SHP cases who were hospitalized were enrolled in the study group. This "complication" group was categorized according to the need for conservative or surgical treatment. General SHP rates and the treatment approaches were compared.
Participants/materials, setting, methods: The patients of suspected SHP were hospitalized and evaluated. Patients with non-ovarian bleedings were excluded. The study was grouped into two. Group I included patients in whom conservative treatment with or without RBC transfusion was performed; Group II consisted of patients who were indicated for surgical treatment. After discharge from hospital, the patients were followed up for approximately 12 weeks.
Main results and the role of chance: 9577 IVF patients who came for TVOG were performed by the same clinician between June 2014 and December 2019. A total number of 90190 oocytes were retrieved and the mean number of retrieved oocytes was 9.41±8.26. The number of SHP related ovarian bleeding complications during TVOG was 20 out of 9577 (0.20%). Whereas 17 patients (85%) needed only conservative treatment, only 3 patients (15%) needed a laparoscopic intervention. Hemostasis control method for ovarian bleeding in laparoscopy was electrocoagulation in one patient and suture in another two. None of the patients (20) had severe infections such as pelvic abscess or sepsis after the treatment. One patient was excluded from the study due to retroperitoneal bleeding.
Limitations, reasons for caution: Although all complications were treated in our institution by one surgeon, we do not know the real impact of complications and their related treatments on further infertility treatments. This could reflect a possible bias on the best solution regarding treatment methods of severe ovarian bleeding complication related to TVOR.
Wider implications of the findings: Although TVOR is a very standard procedure in IVF, the real complication rates and their treatment methods are seldom published. New international registries and databases are needed for outcomes and managements of the complications of TVOR.
Trial registration number: none

P-714 Lipid peroxidation and coenzyme Q 10 levels in follicular fluid of women undergoing IVF: a comparison between poor and normal ovarian responders

P. Sirayapiwat[1], P. Thuwanut[1], N. Orprayoon[1], R. Rungsiwiwut[2], W. Sereepapong[1]

[1]Chulalongkorn University, Obstetrics and Gynecology, Bangkok, Thailand ;
[2]Srinakharinwirot University, Department of Anatomy, Bangkok, Thailand

Study question: Is oxidative stress (lipid oxidation) in follicular fluid one of crucial factors of poor ovarian response (POR)?
Summary answer: The level of lipid peroxidation in follicular fluid showed no significant difference, whereas the antioxidant coenzyme Q10 level was significantly lower in POR group.
What is known already: Poor response to controlled ovarian hyperstimulation is one of major obstacles of successful in vitro fertilization (IVF) outcomes. In older women, age-dependent decline in ovarian reserve and oocyte quality attributes to poor ovarian response, while an underlying cause in younger women is still enigmatic. One of the possible mechanisms are oxidative stress and mitochondrial dysfunction. Coenzyme Q10 (CoQ10) is a lipid-soluble coenzyme which is an essential component of the inner mitochondrial membrane. It plays a pivotal role in intracellular antioxidant by inhibiting lipid peroxidation and DNA oxidation.
Study design, size, duration: A cross-sectional analytic study, follicular fluid from 28 women with normal ovarian response (NOR) and 28 patients with POR to controlled hyperstimulation (COH) were collected between September 2018 and January 2019 in a single academic center.
Participants/materials, setting, methods: Fifty-six infertile women, age between 25-45 years-old, without active ovarian pathology, basal FSH < 12 IU/L, AMH > 1.0 ng/ml who underwent IVF, were recruited into this study with 28 participants in POR group (1-4 retrieved oocytes) and 28 participants in NOR group (5-15 retrieved oocytes). The follicular fluid from the first punctured follicle were compared for the levels of CoQ10 and the end product of lipid peroxidation (LPO), malondialdehyde, by ELISA.
Main results and the role of chance: The mean age of participants was 39.1 year (range 32-43) in POR group and 37.1 year (range 29-42) in NOR group. The mean number of retrieved oocytes was 3.0+0.9 in POR group and 7.7+2.6 in NOR group. The levels of follicular fluid CoQ10 of women in POR group were significantly lower (0.48 + 0.31 nmol/mL) than in NOR group (1.23 + 0.85 ng/mL), $p < 0.001$, whereas the LPO levels was not significantly different between two groups, 10.34+5.88 nmol/mL in POR group and 8.25+2.82 nmol/mL in NOR group, respectively ($p = 0.09$). The clinical pregnancy rate was 17.86% and 35.71% in POR and NOR group, respectively.
Limitations, reasons for caution: The end products of lipid peroxiadation other than malondialdehyde were not analysed in this study. Other limitation of this study includes wide range of participants' ages.
Wider implications of the findings: Our results demonstrate low level of antioxidant CoQ10 in follicular fluid as a potential underlying mechanism of poor ovarian response. However, further investigation for other pathways of oxidative stress in follicular fluid and cumulus-oocyte complex are necessary to elucidate.
Trial registration number: ClinicalTrials.gov Identifier: NCT03155438

P-715 The role of vitaminD in human follicular fluid - Exploratory biochemical analysis of biomarkers: correlation of 25-hydroxyvitaminD and active 1,25-dihydroxyvitaminD between serum and follicular fluid

S. Leser[1], B. Greene[2], L. Witzke[1], M. Nesbigall[1], P.I. Pfefferle[3], U. Wagner[1], V. Ziller[1]

[1]University hospital Gießen and Marburg UKGM, Department for gynecology and obstetrics- Division of gynaecological endocrinology and reproductive medicine, Marburg, Germany ;
[2]Philipps University Marburg, Medical Biostatistics and Bioinformatics, Marburg, Germany ;
[3]University hospital Gießen and Marburg UKGM, Comprehensive Biobank Marburg, Marburg, Germany

Study question: What is the role of active Vitamin D-hormone (1,25-dihydroxyvitamin D) in human follicular fluid? Do concentrations of vitaminD differ from serum as a sign of distinct active follicular vitaminD synthesis?
Summary answer: Follicular fluid (FF) concentrations and serum concentration of 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D showed a highly significant correlation.
What is known already: Obtained as a by-product within the process of oocyte collection FF is predestined as a subject of research in assisted reproduction. In order to establish contained components as oocyte quality markers its examination is of high value. 25-hydroxyvitamin D is one of them, playing a key role in human reproduction. However, the results are conflicting and mostly pooled FF is measured so far. The scientific findings about the role of

1,25-dihydroxyvitaminD as the biologically active form of vitaminD are poor. None of the previously published studies adopted the strategy of separate collection and analysis of the FF of single follicles.
Study design, size, duration: In a prospective exploratory study, 20 infertile women undergoing IVF between January 2018 until December 2019 were included. Written permission was required. Known illnesses of the reproductive system and infectious diseases were defined as exclusion criteria. In the end a total case number of 58 follicles were analyzed.
Participants/materials, setting, methods: During the oocyte collection the sizes of follicles were measured and FF of a variable number of single follicles, according to the total number of follicles per patient and their size, was separately collected. Serum samples were obtained on the same day. After centrifugation all samples were cryopreserved at -80°C and analyzed for their 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D content after thawing.
Main results and the role of chance: The levels of 25-hydroxyvitamin D in serum and FF were significantly and strongly correlated (r=0.82, p=0.001) but hardly differed (31.00 (29.15-32.86) versus 29.62 (27.90-31.33)ng/ml, p=0.001). In addition we determined that the mean concentration of 1,25-hydroxyvitamin D is slightly but significantly higher in serum than in FF (53.53 (50.13-56.94) versus 45.51 (42.42-48.61)ng/ml, p=0.001, r=0.44). Regarding the concentration of vitamin D, significant modification of the composition of the FF as an ultra-filtrate of the serum by the follicular granulosa and theca cells does not seem to occur. There was no evidence for 1,25-dihydroxy vitamin D synthesis within the follicles.
Limitations, reasons for caution: The process of follicle separation is not 100% exact, however as other markers studied showed marked differences the gained data appears reliable. IVF stimulated cycles may not represent the situation in natural cycles, further investigations are needed.
Wider implications of the findings: As vitamin D and reproduction, as well as supplementation in fertility patients is an important part of current medical and scientific discussions the correlation of our findings with clinical outcome parameters are planned to gain further insights in the mechanisms of vitamin D and its role in the assisted reproduction.
Trial registration number: n/a

P-716 Repeat ovarian stimulation cycles in oocyte donors: Results from a cohort study

A. Zavala-Garcia[1], B. Lozano-Moreno[2], M.G. Juan Manuel[3], R. Lopez-Sanchez[4], J.J. Lopez-Galvez[1]

[1]UR Clínica Vistahermosa, Unidad de Reproducción, Alicante, Spain ; [2]UR Clínica Vistahermosa, Assisted Reproduction Medicine and Genetics Masters Program- Miguel Hernandez de Elche University, Alicante, Spain ; [3]Unidad de Reproducción UR Clínica Vistahermosa, Biology of Human Reproduction and Clinical Embryology Laboratory, Alicante, Spain ; [4]UR Clínica Vistahermosa, Biology of Human Reproduction and Clinical Embryology Laboratory, Alicante, Spain

Study question: Are there changes in total FSH dose, follicular count, retrieved meiosis metaphase II (M2) oocytes and pregnancy rates in up to 4 repeated donor cycles?
Summary answer: There are no major statistically significant changes in FSH dose, follicular count, retrieved meiosis metaphase II (M2) oocytes and pregnancy rates in repeated donor cycles.
What is known already: The number of patients requiring oocyte donation is thought to be greater than the number of eligible donors; which is a trend that will most likely keep growing within the following years. Recruiting the same donor multiple times is a way to overcome this demand, which is why the need to further investigate effects of repeated stimulation cycles of oocyte donation. Optimizing donor recruitment and understanding how their characteristics influence outcomes in recipients is essential. Even though a handful of studies have explored factors associated to pregnancy from OD cycles with contradictory results, they've studied few cycles in small populations.
Study design, size, duration: We performed a retrospective cohort study from January 2012 to October 2019. The study population consisted of women who underwent at least 4 stimulation protocols for oocyte donation, for a total of 47 women and 188 ovarian stimulation cycles. We performed mean, standard deviation, and for inferential analysis: Shapiro test, and Student's T. For categorical variables Chi Squared.
Participants/materials, setting, methods: The sample size for this study was based on the number of patients recruited at the Unit of Reproduction *UR Clínica Vistahermosa*, in Alicante, Spain; a private, tertiary reference center. Inclision criteria: (1) women 18-35 years, (2) no primary or secondary infertility, (3) seeking to become an egg donor, (4) not pregnant, (5) conventional stimulation protocol, (6) at least four stimulation cycles.
Main results and the role of chance: A total of 211 patients (525 cycles) composed our cohort with 47 women who underwent at least four consecutive stimulation cycles for egg donation, amounting to a total of 188 stimulation cycles. A total of 96 donors underwent at least one stimulation cycle, while the maximum number of repeated stimulation cycles was 12, performed on one donor. The mean age was of 24.09±3.70 years, 93.61% were of normal weight, with only 6.38% overweight and none within an obesity range BMI. Most had proven fertility or past pregnancy (71.27%) and most were active tobacco consumers, 64.89%. Donor age varied within cycles,as 22.89±3.59 in the first cycle, 23.81±3.66 in the second, 24.28±3.57 in the third, and 25.36 ±3.64 in the fourth. We compared each result aginst the baseline (first cycle) result, and only the average age in the last cycle was statistally significt (P=0.001). Total FSH dose was only statistically significant in the third vs baseline (2168.62±795.08 VS 1890±561.61, respectively, P=0.003). Total oocytes and M2 oocytes did not vary between cycles. Pregnancy rates were not statistically significant between cycles and their percentage was 59.75, 51.06, 51.06 and 53.19% for the first, second, third and fourth cycle, respectively.
Limitations, reasons for caution: The limitation of our study is a small population.
Wider implications of the findings: Optimizing donor recruitment and understanding how their characteristics influence outcomes in recipients is essential as the demographics in populations continue to trend towards a greater ageing population and fertility continues to decline, which is why the importance of understanding donor outcome is essential.
Trial registration number: NA

P-717 follicular tracking with ultrasound does not improve pregnancy rates in letrozole intrauterine insemination (IUI) cycles

K. Cho[1], J. Au[2], R. Sen-Laurenz[3], A. Albert[4], J. Havelock[1], C. Dunne[1]

[1]University of British Columbia, Department of Obstetrics and Gynecology-Division of Reproductive Endocrinology & Infertility, Vancouver, Canada ; [2]Pacific centre for Reproductive Medicine, Department of Embryology, Burnaby, Canada ; [3]University of British Columbia, Department of Sciences, vancouver, Canada ; [4]Women's Health Research Institute, Department of Biostatistics, Vancouver, Canada

Study question: In letrozole intrauterine insemination (IUI) cycles, is the probability of pregnancy associated with ultrasound monitoring or lead follicle size?
Summary answer: Ultrasound monitoring was not associated with an increased pregnancy rate; the optimal follicle size was 18-19.99mm in the unadjusted analysis.
What is known already: The worldwide shortage of clomiphene has shifted practice towards the use of letrozole for ovulation induction and unexplained infertility. However, the current protocols for letrozole IUI cycles are still largely based on the studies using clomiphene. Previous research has shown that ultrasound monitoring did not improve pregnancy outcomes with clomiphene IUI. Furthermore, a lead follicle size ≥20-23 mm has been suggested as the optimal cut-off for ovulation triggering with clomiphene. This criterion has been extended to those using letrozole.
Study design, size, duration: This retrospective cohort study includes letrozole cycles with IUI performed at a university-affiliated fertility clinic from 2016 to 2019. Exclusion criteria included: anovulatory cycles, tubal factor infertility, or total motile sperm < 1million. The patients were divided into 2 groups: ultrasound monitored and unmonitored. The associations between pregnancy rate and ultrasound use, lead follicle size at last ultrasound, endometrial thickness, or human chorionic gonadotrophin (HCG) use were determined using logistic regression and Fisher's exact test.

Participants/materials, setting, methods: Letrozole 2.5-7.5 mg was administered from cycle day 3-7 or day 1-9. In the unmonitored group, patients used ovulation predictor kits(OPK) daily starting on cycle day 10. In the ultrasound monitored group, patients presented for an ultrasound at baseline, on day 10-12, and as needed until ovulation. HCG 10,000IU was given for ovulation trigger when clinically indicated. The IUI was performed on the same day as a positive OPK or the day after HCG trigger.

Main results and the role of chance: Out of the 1196 cycles undertaken by 620 patients, 136 cycles (11.4%) were monitored with ultrasound. Overall, the pregnancy rate was 14.4% per cycle. Ultrasound monitoring was not associated with increased pregnancy rates in letrozole IUI treatments (p= 0.52).

Adjusting for age and body mass index, there was no linear relationship between lead follicle size and the odds of pregnancy (OR 1.04, 95% CI 0.86 to 1.27, p= 0.68). Multi-follicular response was also not significantly associated with an increased pregnancy rate; the presence of 2 or more lead follicles ≥18mm had 3.12 adjusted odds of pregnancy (0.85 to 10.61, p= 0.08). There was no relationship between endometrial thickness and pregnancy (OR = 1.01, 95% CI 0.79 to 1.26, p = 0.96). Similarly, the addition of HCG to trigger ovulation was not associated with increased rates of pregnancy (p= 0.58).

There was a significantly decreased pregnancy rate in those with a lead follicle measuring ≥20mm in mean diameter compared to those with lead follicle size 18-19.99mm (9.6% vs 33.7%, p= 0.005). However, there are too few pregnancies to analyze follicle size as a categorical variable for logistic regression.

Limitations, reasons for caution: While there is a statistically significant decrease in the pregnancy rate associated with lead follicles ≥20 mm, caution must be taken prior to altering clinical care. Due to the small sample size (n=22) of pregnancies in this group, these findings can also occur as a result of random sampling.

Wider implications of the findings: Overall, there is no significant relationship between ultrasound monitoring and pregnancy in letrozole IUI. However, in the subset of patients who require monitoring for accurate IUI timing, there is evidence to suggest that the optimal follicular size may be 18-19.99mm. A larger sample size is needed to confirm these findings.

Trial registration number: not applicable

P-718 Variation in luteinizing hormone levels in artificially prepared frozen-thawed embryo transfer cycles: impact on live birth rates

J. Siffain[1], A. Racca[1], P. Drakopoulos[1], B. Popovic-Todorovic[1], C. Roelens[1], S. Mackens[1], H. Tournaye[1], M. De Vos[1], H.M. Fatemi[2], C. Blockeel[1]

[1]UZ Brussel, Reproductive Medicine, Jette- Brussels, Belgium ;
[2]IVIRMA Middle East Fertility Clinic, Fertility, Abu Dhabi, United Arab Emirates

Study question: Does the variation in luteinizing hormone (LH) affect endometrial receptivity and consequently live birth rates (LBRs) in artificially prepared frozen embryo transfer cycles (FET)?

Summary answer: LBRs following artificially prepared FET cycles are not affected by variations in LH levels between the start and the end of the proliferative phase.

What is known already: Luteinizing hormone binds the LH/choriogonadotropin receptor (LHCGR) in the ovaries to promote luteinization and progesterone production. Previous studies have demonstrated the presence of LHCGR in extra-gonadal tissues, including the endometrium, where LH is thought to influence cell metabolism and growth by increasing the local production of progesterone (P). Additionally, LH may play a role in embryo implantation. As a result a positive feedback mechanism from exogenous administrated estrogens in HRT-FET cycles, increased circulating LH levels may potentially affect pregnancy outcomes.

Study design, size, duration: This is a retrospective study performed at a tertiary university-based hospital. A total of 1445 autologous HRT-FET cycles between 2010 and 2016 were included in the study. To avoid bias, we only selected patients who performed an in-house blood sample to assess LH levels across the HRT-FET cycle.

Participants/materials, setting, methods: LBRs were compared among three interquartile ranges for the difference in LH value (delta LH) at start of E2 supplementation and at the end of the proliferative phase. More specifically, we compared p<25 (delta LH<2.5 IU/L), p25-75 (delta LH 2.5- 11.3 IU/L), >p75 (delta LH >11.3 IU/L). A regression model with estimation by generalized estimating equations (GEE) was used to adjust for patients performing more than one FET cycle, as well as for known confounders.

Main results and the role of chance: Baseline demographic and clinical characteristics were comparable among the three groups except for BMI and PCOS. BMI was significantly lower in the p<75 group (25.2 kg/m2, 25.0 kg/m2 and 23.5 kg/m2 respectively for the p<25, p25-p75 and p>75 group, p<0.001), while PCOS was more common in the p<25 group (respectively, 28.5%, 22.8% and 20.6%, p=0.034), as well as the presence of irregular cycles (respectively, 59.3%, 37.8% and 32.2%, p<0.001). LBRs per started cycle were not significantly different between the investigated groups and were respectively 19.9%, 22.7% and 20.1% for the p<25, p25-75 and p>75 group (p=0.524). Miscarriage rates, on the other hand, were similar among the groups (10.83%, 10.10% and 9.76% for the p<25, p25-75 and p>75 group, respectively p=0.88). According to GEE, accounting for the following confounding factors: age, BMI, presence of irregular cycles, duration of E2 supplementation, level of serum progesterone at the end of the proliferative phase, delta LH was not significantly associated with LBR (coefficient 0.005, 95% CI- 0.02 to 0.03, p=0.72). These results were replicated in case of substantially large delta LH (p>95), as well as, when late follicular LH levels were considered as a continuous variable and failed to show any association with LBR.

Limitations, reasons for caution: Although this study included a large number of cycles and a GEE was performed to adjust for multiple cycles per patient, the results remain limited by the retrospective nature of the study and its associated bias.

Wider implications of the findings: The variation in LH between the start and the end of the proliferative phase in HRT-FET cycles has no influence on live birth rates. The estradiol-priming induced LH rise is insufficient to have any effect on the treatment outcome. Monitoring of LH levels during HRT-FET cycles is of questionable value.

Trial registration number: not applicable

P-719 Is the intravenous lipid emulsion use related to higher pregnancy and live birth rates in patients submitted to in vitro fertilization?

M. HENTSCHKE[1], L. Marquardt Burmann[1], V. Campos Dornelles[1], T. Colombo[1], V. Devens Trindade[1], A. Kira[1], R. Petracco[1], A. Petracco[1], M. Badalotti[1]

[1]Pontifícia Universidade Católica do Rio Grande do Sul PUCRS, School of Medicine, Porto Alegre, Brazil

Study question: Is the intravenous lipid emulsion (ILE) use associated with higher pregnancy rates in patients with implantation failure history after *in vitro* fertilization?

Summary answer: Patients who received more than one dose of ILE presented higher pregnancy and live birth rates than those who receive only one dose.

What is known already: Recent studies have shown benefits of using ILE in patients with repeated implantation failure, due to its ability to inhibit Natural Killers cells activity - whose exacerbated activity could be harmful in the implantation process.

Study design, size, duration: Retrospective cohort study performed at an assisted reproduction clinic in southern Brazil, that included 359 patients, with at least 2 embryo transfer failures. Data were collected from electronic record from April/2017 to February/2019.

Participants/materials, setting, methods: Samples were divided into two groups: Group 1, patients who received ILE infusion (n=64) and Group 2, who didn't receive ILE (n=295). Group 1 received 2ml of 20% ILE infusion. After pregnancy confirmation with positive hCG, some patients received a second and/or third dose of the medication. Data were presented as mean ± standard deviation or frequency and percentage. For statistical analysis, Student's test or Fisher's exact test and Pearson correlation were used, considering p<0.05.

Main results and the role of chance: Comparing ILE group *vs.* Control group, the following results were found: maternal age (36.9±4 *vs.* 36.6±3.7, p=0.711), paternal age (40.3±5.3 *vs.* 39.9±6.3, p=0.474), biochemical pregnancy (50% *vs.* 41.5%, p=0.141), clinical pregnancy (45.3% *vs.* 37.6%, p=0.158).

Regarding clinical outcomes, the rates of abortion/ectopic pregnancy were 9.3% *vs*. 2.0%, p=0.010 and live birth rate was 35.9% *vs*. 35.6%, p=0.53. When gestational age, Apgar index, birth weight and length were analyzed, no statistical differences were found. From the 45.3% clinical pregnancies in Group 1, 69% received two or more doses of ILE, leading to a positive correlation between ILE doses and clinical pregnancies variables (r=0.669, p<0.001). When comparing one dose with two or more doses, higher clinical pregnancy and birth rates were observed when more than one dose was used (p<0.001).

Limitations, reasons for caution: Retrospective study based on electronic records. Medications that could have influenced on pregnancy rates, such as aspirin and heparin were not analyzed in this study.

Wider implications of the findings: This study demonstrates that ILE could be an option for couples seeking IVF treatment with two or more implantation failures. More than one dose of the medication should be encouraged after a positive hCG in order to achieve higher clinical pregnancy and live birth rates.

Trial registration number: NOT APPLICABLE

P-720 A comparison of women's perceptions and acceptability of micronised progesterone/medroxyprogesterone acetate in combination with transdermal oestradiol in the management of young postmenopausal women <45-years

M. Mittal[1], P. Supramaniam[2], H. Hamoda[3]

[1]Imperial College Healthcare NHS Trust, Gynaecology- Reproductive Medicine, London, United Kingdom ;
[2]Oxford University Hospitals NHS Trust, Women's and Childrens, High Wycombe, United Kingdom ;
[3]King's College Hospital NHS Trust, Women's and Childrens, London, United Kingdom

Study question: To assess the acceptability and perception of young menopausal women to HRT containing micronised progesterone (MP) or medroxyprogesterone acetate (MPA), on symptom control and development of adverse effects.

Summary answer: The acceptability of both regimens was high despite adverse effects, but tolerability of MP appeared better with fewer reporting psychological concerns compared to MPA-containing regimens.

What is known already: The primary indication for HRT is symptom relief, with approximately 75% experiencing vasomotor-symptoms. Young postmenopausal women (secondary to premature ovarian insufficiency/early menopause), represent a subset population, whereby the mainstay of management is to provide physiological levels of the deficient hormones and thus, counteract the effects of the long-term sequelae of early menopause. HRT is recommended until at least the average age of the menopause. The majority of data used to counsel these women on the risk profile is extrapolated from studies conducted in older women. Furthermore, progestin is said to be responsible for some of the adverse-effects, limiting compliance.

Study design, size, duration: Prospectively recruited young menopausal women, <45 years with an intact uterus, were randomised to one of two treatment arms for 12-months duration, MP or MPA in combination with transdermal oestradiol delivered in the form of patches. A self-reported questionnaire with matrix rating scales, repeated at intervals of 3, 6 and 12-months from the commencement of the HRT regimen were compared from baseline and between the two treatment arms. A total of 190 questionnaires were returned.

Participants/materials, setting, methods: A matrix scale was used to rank the symptoms/concerns in order of priority. The scores were then grouped to signify their main symptoms (1-3), moderate symptoms (4-7) and mild symptoms (8-10) for analytical purposes.

A matrix scale was also used to rank the severity/impact of the symptom/concern on their quality of life (weighted average). The scores were grouped for analytical purposes: 1-3 signifying minimal impact; 4-7 moderate impact; and, 8-10 maximal impact.

Main results and the role of chance: The most commonly reported symptoms were low energy levels, vasomotor symptoms and sexual dysfunction. The reported symptoms did not always correlate to those that were perceived to have the greatest impact on the individual's quality of life. The prevalence of adverse effects ranged between 57.89%-87.50%. A non-significant reduction in reported adverse-effects was demonstrated in the MP treatment arm (73.91% at 3-months reducing to 57.89% at 12-months duration; p=0.33), compared to the non-significant increase seen in the MPA treatment arm (76.92% at 3-months increasing to 87.50% at 12-months duration; p=0.69). The main reported adverse effects were gastrointestinal symptoms (weight change and bloating) and psychological effects (mood swings and irritability). A significant difference in reported adverse-effects was documented between the groups after set periods, with a significantly greater proportion reporting breast tenderness after 3-months duration (p=0.01), lower numbers reporting mood swings at 6-months duration (p=0.01) as well as irritability at 12-months duration (p=0.03) in the MP treatment arm compared to the MPA treatment arm. Despite the reporting of adverse symptoms, 78.86% would continue to use HRT outside of a research setting with no reported difference in satisfaction between the HRT regimens (p=0.24).

Limitations, reasons for caution: The questionnaire was developed using the 12-points described by Burford et al., (2009). Face validity was also assessed through testing on the target population and quantitative data was obtained to reduce the Hawthorn effect.

Wider implications of the findings: Significant controversy surrounds the use of HRT. Current evidence is derived from an extrapolation of data from older menopausal women. Directed studies in the younger population will help demonstrate acceptability and tolerability in those that would benefit the most from its use.

Trial registration number: REC Number: 12/LO/1957; EudraCT Number: 2012-004511-30

P-721 Double stimulation in the same ovarian cycle might improve the number of competente oocytes and euploid embryos

T. Farias Lima[1], M. Pessoa Caldas[1], P. César Silva Matheus[2], L. Albuquerque Barros[2], C. Pessoa Caldas[3], L. Pessoa Caldas[3], C. Monteiro[1], N. Pimentel Fischer Pacheco[1], A. Eunice[1], R. Mota Paixão de Sousa[1], M. Correa Nunes[1], A. Griz[1], T. Matheus[1], L. Helena Amorim[2], M. Almeida[2]

[1]Geare Group IVF, Reproductive specialist, Recife, Brazil ;
[2]Geare Group IVF, Embriologist, Recife, Brazil ;
[3]Maurício Nassau university center, Medical Student, Recife, Brazil

Study question: Is the Double Stimulation a interesting protocol to enlarge the numbers of competent oocytes and euploid blastocysts in the group of poor responder patients?

Summary answer: The Double stimulation aproach maximizes the number of recovered oocytes and euploid embryos, possible increasing the rate of clinical pregnancy and live births.

What is known already: GnRH antagonists, estradiol priming, double stimulation, letrozole administration, DHEA, and herbal therapy supplementations are the recent modifications done to improve oocyte retrieval and subsequent embryo transfer for POR cases. The DuoStim strategy is promising to manage the chalenge population of poor responders, especially to avoid drop-out after a first failed attempt.

Study design, size, duration: We report here our 1-year experience of Duostim practice in our private IVF Center including five clinics, in january to december of 2019, in a total of 709 cases that year. Patients included were selected to the group of poor responders (POR) using the POSEIDON group definitions. The financial barrier is a problem reported by patients to perform DuoStim cycles.

Participants/materials, setting, methods: This is a retrospective analysis of forty poor prognosis patients who completed a DuoStim protocol. Thirty-three patients underwent IVF with blastocyst-stage and seven patients gone to oocyte vitrification for social preservation. The mean age was 38,6 years. The IVF cycles were followed by preimplantation genetic testing for aneuploidies.

Main results and the role of chance: The folicular phase stimulation (FPS) and luteal phase stimulation (LPS) was realized with a maximum dose of 300 IU of recombinant FSH and recombinant LH 150 IU with the same gonadotropin releasing hormone (GnRH) antagonist protocol, agonist trigger with GNRHa (leuprolide 0,2mg), and intracytoplasmic sperm injection with ejaculated sperm. Regarding the number of oocytes collected and oocyte maturation, in 20/40 cases the LPS was better, the FSP was superior in 15/40 and in 5/40 cases it

was similar in both phases. About the rate of blastocysts, it was similar in the two phase stimulations in 13/33 cases, the result of FPS was better in 10/33 cases and the LPS was in 10/33. The rate of euploidy in LPS in 4/33 cases was better, 6/33 cases were similar and in 12/33 cases the result in FPS was better. In this regard, LPS seems to contribute to conventional stimulation with more oocytes with a comparable competence as FPS, retrieved per ovarian cycle. The mean numbers of euploid blastocysts obtained from the cohorts of oocytes recruited after follicular phase and luteal phase stimulations in the same ovarian cycle were similar. Our data indicate that LPS is not correlated with a higher aneuploidy rate.

Limitations, reasons for caution: These findings are based on a small sample size of patients in a short period. More embryological and clinical data is required to confirm the benefits of DuoStim, as well as an analysis of its cost-effectiveness.

Wider implications of the findings: Many strategies have been proposed to manage poor responder patients, however, a consensus upon which is the most beneficial has not been yet reached. Double estimulation. In selected patients with low oocyte yield, DuoStim should be proposed for oocyte or embryo accumulation considering the cost-efficiency — especially in older women.

Trial registration number: not applicable

P-722 Prevalence of hyperprolactinaemia in subfertile ovulatory women and its impact on fertility treatment outcome

M. Wojcik[1], S. Amer[2], K. Jayaprakasan[3]

[1]University of Nottingham, Medicine, Nottingham, United Kingdom ; [2]Royal Derby Hospital, Gynaecology, Derby, United Kingdom ; [3]Royal Derby Hospital, Fertility Unit, Derby, United Kingdom

Study question: The objectives were to establish the prevalence of hyperprolactinaemia in subfertile ovulatory women in comparison to oligo-anovulatory women, and to evaluate whether hyperprolactinaemia influences fertility treatment outcome.

Summary answer: Prevalence of hyperprolactinaemia was 27.3% in subfertile ovulatory women, with most (86.5%) having mildly raised prolactin. Hyperprolactinaemia did not influence fertility treatment outcome.

What is known already: Prolactin has been linked to ovulation and fertility. Prolactin testing is not generally recommended for subfertile women with regular menstrual cycles, which is a surrogate marker of ovulation. However, some clinicians, particularly in general practice, still perform prolactin testing as part of baseline endocrine profile. Finding of subtle hyperprolactinemia in those women is not uncommon and this poses a dilemma whether such finding will need further evaluation. Furthermore, its impact on fertility treatment outcome is not known.

Study design, size, duration: This observational study included review of electronic hospital database of all women (n=1010), who attended a secondary level fertility clinic over a four-year period between 2015 and 2019. Data of prospectively recorded data was collected retrospectively for analysis.

Participants/materials, setting, methods: All women referred to the clinic with records of endocrine measurements were included. Women with incomplete data and patients who were already on treatment for hyperprolactinaemia were excluded. Data was collected from the hospital electronic database. Endocrine levels, clinical pregnancy outcome, and pituitary MRI, if performed, were recorded on an encrypted excel spreadsheet. Patients were identified as hyperprolactinaemic according to the hospital's norm (>496 mIU/L). Data was subsequently analysed using Chi-square Test and Risk Estimates.

Main results and the role of chance: 1010 women attended the fertility clinic during the studied period, and data from 835 women was included in the analysis. 597 women (71.5%) were in the ovulatory group and 238 (28.5%) were in the oligo-anovulatory group. Surprisingly, prevalence of hyperprolactinaemia was higher in the ovulatory women than in the oligo-anovulatory women (27.3% vs 15.5%; OR: 2.1; 95%CI: 1.4-3.1). Further investigation into the severity of hyperprolactinaemia distinguished three hyperprolactinaemia groups: mild (496-1000mIU/L), moderate (1000 – 2000mIU/L) and severe (>2000mIU/L). In the ovulatory group, mild hyperprolactinaemia was found in 141 patients (23.6%), moderate hyperprolactinaemia in 21 patients (3.5%), and severe hyperprolactinaemia in 1 patient (0.2%). In oligo-anovulatory patients, 31 (13.0%) had mild hyperprolactinaemia, 4 (1.7%) had moderate hyperprolactinaemia, and 2 (0.8%) had severe hyperprolactinaemia. Rates of clinical pregnancy (either natural or following treatment) were similar between hyperprolactinaemic and normoprolactinaemic ovulatory women.

Limitations, reasons for caution: This study was of a retrospective nature and some of the data was missing, however both of these factors would have created a minimal bias, considering the large sample size.

Wider implications of the findings: There is a high prevalence of hyperprolactinaemia among ovulatory women, however most had mildly raised levels, which may not be clinically relevant. Prolactin is responsive to minimal stress, and high levels do not influence pregnancy outcome. Prolactin measurement is not needed in regularly menstruating women, and normal ranges need redefining.

P-723 Cumulative live-birth rate over multiple cycles of in vitro fertilization in Chinese advanced-age women over 35 years old

F. Gu[1], S. Ruan[1], C. Luo[1], C. Zhou[1]

[1]The First Affiliated Hospital of Sun Yatsen university, Center for Reproductive Medicine, Guangzhou, China

Study question: How does age and ovarian response influence cumulative live birth rates (CLBRs) over multiple IVF/ICSI cycles in Chinese advanced maternal age (AMA) women?

Summary answer: The optimal and conservative CLBRs over 4 complete IVF/ICSI cycles for women over 35 years were 58.0% and 41.7%, varied by age and ovarian response.

What is known already: Traditionally, IVF success rate has been reported in terms of live birth after a single fresh embryo transfer. However, with the international shift towards single embryo transfer and cryopreservation of surplus embryos, CLBR encompassing live delivery outcomes from the fresh and all subsequent frozen embryo transfer (FET) over several complete IVF cycles is a more critical outcome. Age and ovarian response have been demonstrated to be associated with the likelihood of CLBR over multiple IVF/ICSI cycles, while how different ovarian response according to POSEIDON criteria influences the outcome within the same female age has seldom been properly investigated.

Study design, size, duration: This observational cohort study was carried out in a university-affiliated tertiary centre, including 4102 Chinese women aged ≥35 years, who initiated IVF/ICSI treatment from 1st January 2009 to 30th November 2015 and were followed until 31st May 2017. Cycles for PGT, embryo storage or with severe data missing were excluded. Overall, 3486 Chinese advanced age women undergoing 5088 IVF/ICSI cycles were included in the analysis.

Participants/materials, setting, methods: All participants were categorized into four age group: 35-37yrs, 38-39yrs, 40-42yrs and ≥43 yrs. Patients were then categorized into subgroups of non-low prognosis, POSEIDON group 2 and POSEIDON group 4 based on the ovarian response. The primary outcome was the CLBRs across all cycles in different age groups. The secondary outcome was to analyze the CLBRs in the same age group but with different ovarian response. Optimal, and conservative CLBRs were estimated.

Main results and the role of chance: The optimal and conservative estimated CLBRs over 4 IVF/ICSI treatment cycles of Chinese women aged ≥35 years were 58.0% and 41.7%, respectively. The optimal and conservative estimated CLBRs up to the fourth cycle decreased from 71.7% and 49.8% for women aged 35-37yrs (n= 2447 cycles) to 62.0% and 42.4% for women aged 38-39 years (n=1185cycles), 40.3% and 26.4% for women aged 40-42 years (n=1023 cycles) and 7.7% and 5.5% for women aged ≥43 years (n=431 cycles). In all the age groups, the LBRs of first cycle in the non-low prognosis group were higher than in the POSEIDON group 2[unexpected poor ovarian responder(POR)], followed by the POSEIDON group 4(expected poor responder). Fortunately, younger (<40 years old) unexpected POR had a 4-cycle CLBR of ~57.3% to ~70% which were comparable to those with non-low prognosis patients with a CLBR of ~74.5% to ~81%. Yet the 4-cycle CLBR of older unexpected (≥40

years old) POR was ~39.5% which was 50% lower than those with adequate ovarian reserve. The younger expected POR had a higher 4-cycle CLBR rate with 46.1%, while the CLBR was only 21.5% in the older expected POR.
Limitations, reasons for caution: High withdrawal rate due to poor prognosis of the AMA patients reduced the precision of the estimates.
Wider implications of the findings: This is the first relevant data of the CLBRs over multiple IVF cycles in Chinese women, which vary between age and ovarian response. Patients <43 years could benefit from extending IVF cycles up to three or four, whlie those over 43 should be discouraged from IVF cycles with autologous oocytes.
Trial registration number: not applicable

P-724 Paternal and Maternal Preconception Exposure to Phenol and Phthalate Mixtures in Relation to Preterm Birth Risk

V. Mustieles[1], Y. Zhang[1], P.L. Williams[2], B.J. Wylie[3], A.M. Calafat[4], R. Hauser[1], I. Souter[5], C. Messerlian[1]

[1]Harvard T.H. Chan School of Public Health, Environmental Health, Boston, U.S.A. ; [2]Harvard T.H. Chan School of Public Health, Biostatistics, Boston, U.S.A. ; [3]Beth Israel Deaconess Medical Center, Obstetrics and Gynecology, Boston, U.S.A. ; [4]National Center for Environmental Health, Centers for Disease Control and Prevention, Atlanta, U.S.A. ; [5]Massachusetts General Hospital, Obstetrics and Gynecology, Boston, U.S.A.

Study question: To what extent do paternal and maternal preconception phenol and phthalate chemical mixtures interact and contribute to preterm birth risk?
Summary answer: Couples' preconception exposure to chemical mixtures was associated with an increased risk of preterm birth, with a complex interplay between both parents.
What is known already: Humans are continuously exposed to low-doses of multiple endocrine disrupting chemicals (EDCs) and mounting evidence of heightened toxicity from mixtures exists. While maternal and paternal preconception exposures to select phenols and phthalates have been associated with increased preterm birth risk in single-chemical analyses, their joint effect in the context of complex mixtures is unknown. Emerging data highlight the potential for EDCs to exert enduring epigenetic modifications in male and female gametes, a potential mechanism related to adverse reproductive outcomes. The preconception period is thus increasingly recognized as a vulnerable window for environmental perturbation.
Study design, size, duration: Ongoing prospective preconception cohort of subfertile couples recruited between 2005 and 2018 in a large fertility center in Boston, Massachusetts, USA. A total of 384 singletons were included in the current analysis (384 mothers, 211 fathers, 203 couples) from the Environment and Reproductive Health Study. Gestational age was abstracted from medical records and validated using clinical guidelines for births following medically assisted reproduction. Preterm birth was defined as live births <37 weeks gestation.
Participants/materials, setting, methods: We used principal component analysis (PCA) with Poisson regression, and Probit Bayesian Kernel Machine Regression (BKMR) to examine maternal and paternal mean preconception urinary concentrations of EDC mixtures on preterm birth risk. Log-concentrations of bisphenol A (BPA), parabens, and eleven phthalate metabolites including those of di(2-ethylhexyl) phthalate (DEHP) were included in both maternal and paternal mixture models. Hierarchical variable selection was fit for couple-based BKMR models by dividing mixtures into maternal *vs.* paternal groups.
Main results and the role of chance: The mean (SD) gestational age among singletons was 39.3 (1.7) weeks with 8% born preterm. PCA identified four main factors, with loading scores for the DEHP-BPA factor showing associations with an increased preterm birth risk in both mothers (adjusted Risk Ratio (aRR): 1.36, 95%CI: 1.00, 1.84) and fathers (aRR: 1.47, 95%CI: 0.90, 2.42). Separate maternal and paternal BKMR models identified maternal preconception BPA and paternal preconception mono(2-ethylhexyl) phthalate concentrations were positively associated with preterm birth when the remaining mixture components were held at their median concentrations. In analyses restricted to couples, BKMR models with hierarchical variable selection showed a similar relative contribution of both paternal [Posterior Inclusion Probability (PIP): 61%] and maternal (PIP: 77%) preconception mixtures on preterm birth. Additionally, a positive cumulative joint effect of couples' preconception mixtures assessed through increasing mixture quantiles on preterm birth was also observed.
Limitations, reasons for caution: Although our mixture analysis extended information provided by previous single-chemical models, these findings may not be generalizable to fertile couples. While human populations are normally exposed to dozens of chemical families, our mixtures analyses focused on non-persistent EDCs such as those used in plastics (BPA, DEHP) and in cosmetics (parabens).
Wider implications of the findings: This study suggests a complex interplay between paternal and maternal exposures to mixtures of non-persistent chemicals, with both windows of exposure jointly and cumulatively contributing to the risk of preterm birth.
Trial registration number: Not Applicable

P-725 Refitting and adapting the van Loendersloot prognostic model for In Vitro Fertilization

J. Devroe[1], K. Peeraer[1], G. Verbeke[2], C. Spiessens[1], J. Vriens[3], E. Dancet[1]

[1]Leuven University Hospital, Gynaecology, Leuven, Belgium ; [2]Leuven Biostatistics and statistical Bioinformatics Centre, Public Health and Primary Care- KU Leuven, Leuven, Belgium ; [3]Laboratory of Endometrium- Endometriosis & Reproductive Medicine, Development and Regeneration- KU Leuven, Leuven, Belgium

Study question: What is the performance of the refitted (using previous cycle variables) and adapted (using current cycle variables) van Loendersloot prognostic model for our clinic's IVF?
Summary answer: The Refitted and the Adapted van Loendersloot model are both valuable for predicting the chance on a live birth after one complete IVF cycle.
What is known already: Prognostic models combine clinical and/or IVF-laboratory variables with different weights to predict IVF-success. The impact of informing couples about their IVF-prognosis on their expected success rates, distress and IVF-discontinuation has yet to be studied. The 'van Loendersloot model', including previous cycle IVF-laboratory variables, proved performant for two clinics and is relevant for informing couples prior to starting another cycle (Sarais, et al., 2016, van Loendersloot, et al., 2013). This model could potentially include current cycle IVF-laboratory variables, relevant for informing couples at the time of embryo transfer.
Study design, size, duration: We retrospectively studied a cohort from our clinic of 1281 IVF cycles of 591 couples (period 2010-2018). We assessed the performance of the Refitted van Loendersloot model including previous cycle IVF-laboratory variables and of the Adapted van Loendersloot model including current cycle IVF-laboratory variables.
Participants/materials, setting, methods: Eligible couples completed at least one IVF-cycle with own fresh gametes after a previous IVF-cycle with the same partner in our clinic. Binary logistic regression analysis with cumulative live birth as dependent variable identified intercept and relative weights of its variables. Performance was expressed in terms of discrimination (i.e. c-statistics) and calibration (i.e. Hosmer-Lemeshow goodness-of-fit, calibration model, Nagelkerke R^2, comparison of five disjoint groups formed by the quintiles of the IVF-prognoses and a calibration plot).
Main results and the role of chance: A total of 344 live births were obtained over 1281 oocyte aspirations (26.9%). The Refitted and Adapted van Loendersloot models showed a c-statistic respectively 0.68 (95% CI: 0.65-0.71) and 0.74 (95% CI: 0.70-0.77). The Refitted model showed no significant miscalibration (p=0.793), a good calibration model (intercept=0.00; 95%CI: -0.23–0.23 and slope=1.00; 95%CI: 0.79-1.21), good prognosis to observed ratios (0.9-1.0) and a good calibration plot. The Adapted model showed no significant miscalibration (p=0.093), a good calibration model (intercept=0.00; 95% CI: -0.18–0.18; slope=1.00; 95%CI: 0.83-1.17), good prognosis to observed ratios (0.9-1.1) and its calibration plot was even better than that of the refitted model. The calibration plots mainly differed regarding the overlap between the 95% confidence intervals of the mean observed live birth rate of the disjoint groups next to each (i.e. 4/4 for the Refitted and 1/4 for the Adapted model). These results confirm the robustness of the van Loendersloot prognostic model in both the refitted version, which can be calculated prior to an IVF-cycle, and in

the novel adapted version, which can be calculated at the time of embryo transfer.
Limitations, reasons for caution: We conducted a complete case analysis and studied an 8-year retrospective period, over which IVF-protocols changed slightly.
Wider implications of the findings: The performance of the Refitted and the Adapted van Loendersloot model in our clinic allows informing couples on their IVF-prognosis prior to an IVF-cycle or during an embryo transfer and studying the impact on couple's expected success rates, distress and IVF-discontinuation.
Trial registration number: Not applicable

P-726 The intimate vaginal hygiene practice correlates with the vaginal microbiota; an observational study of 328 in vitro fertilization (IVF) patients.

K. Rosenstand Jensen[1], P. Humaidan[1], H.O. Elbæk[1], B. Alsbjerg[1], R.J. Laursen[1], A. Mikkelsen[1], M.B. Jensen[1], L. Prætorius[2], N.L.C. Freiesleben[2], A. Pinborg[3], V. Hartvig[4], J.S. Jensen[5], T. Haahr[1]

[1]Regional Hospital Skive - Skive - Denmark -, The Fertility Clinic, Skive, Denmark ; [2]Amager-Hvidovre Hospital, Department of Gynecology and Obstetrics, Hvidovre, Denmark ; [3]Rigshospitalet, Department of Gynecology and Obstetrics, Copenhagen, Denmark ; [4]VivaNeo Stork Fertility Clinic, Copenhagen, Copenhagen, Denmark ; [5]Statens Serum Institut, Copenhagen, Copenhagen, Denmark

Study question: What is the intimate hygiene practice of women in IVF treatment and does it correlate with the vaginal microbiota?
Summary answer: Overall, 34% had an abnormal vaginal microbiota (AVM) and a total of 23% practiced vaginal douching. Of douching women, 47% had AVM.
What is known already: AVM is a molecularly defined vaginal dysbiosis dominated by anaerobic bacteria such as *Gardnerella vaginalis*. In contrast, vaginal eubiosis is considered dominated by one or more *Lactobacillus spp*. Recent independent studies have shown that AVM is significantly correlated with poor reproductive outcomes in IVF patients. Although the definitive etiology of AVM is still debated, intimate vaginal hygiene practices have been suggested as a possible etiological factor. Currently the knowledge about this issue is limited and in this study in IVF patients, we explored the impact of different vaginal hygiene practices on the presence of AVM.
Study design, size, duration: Observational cross-sectional study, including a total of 328 IVF patients from four Danish fertility centers. Patients were included from March 2019 to January 2020.
Participants/materials, setting, methods: IVF patients were eligible for inclusion if they underwent their first, second or third IVF cycle either as heterosexual couples, singles or lesbians. Besides standard gynecological work-up, patients reported intimate hygiene practices (soap, menstrual protection, douching, probiotics) in a questionnaire. Vaginal swabs were obtained prior to ovarian stimulation and subsequently subjected to quantitative PCR testing, targeting DNA of AVM bacteria.
Main results and the role of chance: From the population of 328 women, a total of 34% (112/328) were diagnosed with AVM. The largest proportion of women used water, only, (42%; 139/328) for intimate hygiene, whereas 38% (124/328) used intimate soaps of low pH and 28% (92/328) used regular soaps. Only 3% of the women (9/328) used vaginal probiotics. Interestingly, 23% (75/328) of the women reported vaginal douching, which significantly correlated with the presence of AVM (p 0.01). None of the remaining hygiene methods showed any correlation with the vaginal microbiota.

The largest proportion of women used pads for menstrual protection (42%; 137/328), followed by the use of tampons, alone (24%; 80/328) or a combination hereof (22%; 71/328). 11% used a menstrual cup (37/328). Only 1% reported use of other unspecified menstrual protection. The use of a menstrual cup significantly correlated with a normal vaginal microbiota ($p < 0.01$).

Furthermore, active smoking or the consummation of >7 units of alcohol per week significantly correlated with AVM (p 0.03 and $p < 0.01$, respectively). Finally, a fishy vaginal odor was significantly more frequently reported in AVM positive patients; 10% (11/112) in the AVM group as compared to 4% (9/216) in the normal group (p 0.04).
Limitations, reasons for caution: To the best of our knowledge, this is the first large study investigating the intimate hygiene practices and its correlation to AVM in an IVF population. As these results describe the practices of a Scandinavian IVF population, results may differ from other settings and ethnicities.
Wider implications of the findings: Exploration of the cause-and-effect relations between intimate hygiene habits and AVM is needed, requiring intervention-based prospective studies. This will lead to evidence-based advice on intimate hygiene and AVM prevention possibly increasing live birth rates in infertile patients. The high prevalence of douching in a Danish IVF population needs further investigation.
Trial registration number: NCT03420859

P-727 The InfertilScore, a couple-based machine learning model in patients with idiopathic infertility.

G. BACHELOT[1], R. Lévy[1], C. Faure[1], S. Czernichow[2], C. Dupont[1], A. Lamazière[3]

[1]Sorbonne Université- Saint Antoine Research center, INSERM équipe Lipodystrophies génétiques et acquises, PARIS, France ; [2]APHP- Hôpital européen Georges-Pompidou, Service de nutrition, Paris, France ; [3]Sorbonne Université- Saint Antoine Research center, INSERM équipe Microbiote-intestin et inflammation, Paris, France

Study question: Could unexplained infertility be diagnosed thanks to determined anthropometric, antioxidative and metabolic signature modeled using machine learning?
Summary answer: We designed a supervised multivariate model which stratify subfertile couples thanks to their anthropometric, antioxydative and metabolic signatures.
What is known already: The efficacy of traditional clinical approaches for unexplained infertility lack objective criteria to guide the medical decision for a non-surgical fertility treatment or/and assisted reproductive therapy (ART). Even if, by definition, no cause is clearly identified, the environment and lifestyle should be also considered as idiopathic infertility origins. Based on previous studies, we observed that sedentary behavior, physical inactivity, body composition and metabolic status were closely in relation to idiopathic infertility. Consequently, an algorithm on modifiable risk factors is therefore strongly needed for the management and follow-up of idiopathic infertility.
Study design, size, duration: The data of this study concerned infertile (n=96) and fertile (n=100) couples who have been recruited in the ALIFERT cross-sectional case-control study between September 2009 and December 2013 (N° P071224). The ALIFERT study has been designed to assess the association between lifestyle factors and idiopathic infertility in couples (National biomedical research Id. P071224, ethics committee approval ("Comité de Protection des Personnes") AOM 2009-A00256-51, NEudra CT 08180, clinicaltrials.gov NCT01093378).
Participants/materials, setting, methods: An accurate machine learning model was sequentially designed among 80 to 13 anthropometric, antioxidative and metabolic selected features from the ALIFERT patients.
Main results and the role of chance: Based on the ALIFERT cohort, our results showed that i) couples modeling approach was more discriminant than a model in which men and women parameters are considered separately ii) the most important variables for the projection were related to anthropometric and metabolic disorders and oxidative status iii) after reduction of our system dimensions (from 80 to 13 variables) we proposed a new algorithm to stratify fertile *vs* subfertile patients. Eventually, in order to use this tool to help the therapeutic decision, we put into perspective the InfertilScore model and the successes and failures to get pregnant after a year post ART (assisted reproductive technology). We did find some relationships between the treatment intensity (*in vitro* fertilization (IVF), artificial insemination) and the severity of idiopathic couple infertility based on our InfertilScore model. Our conclusions will be presented at ESHRE congress.
Limitations, reasons for caution: Despite a multicentric approach, these results showed a need to test the prediction strength of the InfertilScore on a future independent replication cohort.
Wider implications of the findings: In the complex situations of couples for whom, the result of the standard fertility assessment has not made it possible to highlight a clear cause of infertility, the InfertilityScore could be considered as

a useful tool for therapeutic decision-making and medical guidance in reproductive medicine.
Trial registration number: P071224

P-728 Use of Cross Border Reproductive Care in Infertile Women in Hong Kong

D. Ng[1], M.W. Lui[2], S.F. Lai[3], H.Y. Wong[4], T.S.M. Law[5], G.C.Y. Wong[6], E.H.Y. Ng[2]

[1]Pamela Youde Nethersole Eastern Hospital, Department of Obstetrics and Gynaecology, Edinburgh, United Kingdom ;
[2]Queen Mary Hospital, Department of Obstetrics and Gynaecology, Hong Kong, Hong Kong ;
[3]Kwong Wah Hospital, Department of Obstetrics and Gynaecology, Hong Kong, Hong Kong ;
[4]Princess Margaret Hospital, Department of Obstetrics and Gynaecology, Hong Kong, Hong Kong ;
[5]Prince of Wales Hospital, Department of Obstetrics and Gynaecology, Hong Kong, Hong Kong ;
[6]Family Planning Association, Family Planning Association, Hong Kong, Hong Kong

Study question: What are the incidence, demographic characteristics, attitudes and motivations of cross border reproductive care (CBRC) among women with infertility in Hong Kong?
Summary answer: Main reason for CRBC was inadequate accessibility to infertility care; Waiting lists were too long in public and the costs in private were too high.
What is known already: Cross border reproductive care (CBRC) is an escalating global trend where patients travel out of their home country for fertility treatment. It was estimated that around 5% of the fertility care involved CBRC. The reasons for CBRC in Europe included: to avoid legal restrictions at home, to avoid long waiting-lists, for less expensive treatment or the wish for donor anonymity in the context of gamete donation. There are potential advantages and disadvantages of CBRC. Safety concerns are mainly regarding the number of embryos transferred, and thus the risk of multiple pregnancies and the potential exploitation of gamete donors and surrogates.
Study design, size, duration: From 1 Feb 2017- 31 Dec 2019, a cross sectional questionnaire study was conducted in six infertility clinics in Hong Kong. A total of 1,204 questionnaires were collected and analysed.
Participants/materials, setting, methods: A questionnaire was designed to evaluate the use, attitudes and motivations of CBRC in infertile women in Hong Kong. The content of the questionnaire focused on three areas: [1] demographic information, [2] reproductive history and attitudes to fertility, [3] motivations and perspectives on CBRC. Participants completed an anonymous questionnaire, which was distributed by the clinic nurse when they attended the infertility clinic. Participation was entirely voluntary and the questionnaire took approximately 20 minutes to complete.
Main results and the role of chance: A total of 1,204 questionnaires were included. 14.7% of the respondents had used CBRC and 30.9% had plans for it or would consider it. The two main motivational factors were a long waiting time in the public sector and high treatment costs in the private sector, contributing 80.9% and 12.0% of those who had used or would consider CBRC respectively. Only 0.5% of them was motivated for CBRC for law evasion. Majority of our patients chose Taiwan as the preferred destination (69.6%); followed by mainland China (25.8%). Over half of them(55.6%) accessed information from the internet. At the point of data collection, among the patients who had used CBRC, 1.7% suffered from ovarian hyperstimulation syndrome whereas another 1.7% suffered from other types of complications. 70.2% patients believed that the authorities in Hong Kong should formulate some regulations or guidance regarding CBRC. For those participants who had used CBRC or had plans for it, 61.8% indicated that they had received local pretreatment counseling from their home country to assist them with their treatment. 70.2% patients believed that the authorities in Hong Kong should formulate some regulations or guidance regarding CBRC.
Limitations, reasons for caution: We recruited patients from infertility clinic which has a certain degree of bias. Those who had pregnancy following CBRC, single women, single men and same sex couples were not included. Furthermore, the infertility centres in our study cannot be considered as representative of all infertility centres in Hong Kong.
Wider implications of the findings: Based on the results of this study, it can be hypothesized that this CBRC trend will continue until the local health authorities can implement more effective measures to shorten the long waiting list in the public sector. Meanwhile, local reproductive care organizations should establish good practice guidelines on CBRC.
Trial registration number: not applicable

P-729 Country-specific preparation practices for the insertion of intrauterine devices: insertion procedures reported by Health Care Providers in the EURAS-LCS12 study

C. Hagemann[1], A. Bauerfeind[2], K. Heinemann[3]

[1]Berlin Center for Epidemiology and Health Research, Project Management, Berlin, Germany ;
[2]Berlin Center for Epidemiology and Health Research, Statistics, Berlin, Germany ;
[3]Berlin Center for Epidemiology and Health Research, Principal Investigator, Berlin, Germany

Study question: To identify insertion related procedures reported in the "European Active Surveillance Study on LCS12" (EURAS-LCS12) among users of intrauterine device (IUDs) in ten European countries.
Summary answer: Differences regarding insertion preparation were observed in the participating countries. They are not only related to age or parity, but also country-specific practices are relevant.
What is known already: Intrauterine contraceptive methods, such as Mirena and CU-IUDs, have a high contraceptive efficacy and are commonly used. However, the insertion procedure can be painful, and there are different procedures available to make the insertion less unpleasant, such as pain medication.
Study design, size, duration: Large, prospective, controlled, non-interventional, long-term cohort study with active surveillance of approximately 65,000 study participants in ten European countries: Austria, Czech Republic, Finland, France, Germany, UK, Poland, Spain, Italy, and Sweden. Women are enrolled by their Health Care Provider (HCP) after the IUD insertion. The study started in 2014 and the final study report is planned for 2025.
Participants/materials, setting, methods: In the EURAS-LCS12 study, a network of prescribing HCPs is enrolling women with a newly inserted IUD. HCPs and participating women complete a baseline questionnaire including information on insertion related procedures and issues. Patients receive 5 follow-up questionnaires within 3 years. All patient-reported outcomes of interest are validated with the treating physician.
Main results and the role of chance: Until end of August 2019, 55,793 women were enrolled, thereof 5,988 (11%) Jaydess, 26,183 (47%) Mirena, 3,671 (7%) Kyleena and 18,840 (34%) CU-IUD users. Users of the smaller hormonal IUDs were considerably younger (Jaydess: mean age 26,9 years, Kyleena 27.8 y) compared to Mirena (35.9 y), and 77% of Jaydess and 54% of Kyleena users were nulliparous compared to 15% of Mirena users. Pharmacological preparation (e.g. prostaglandins, painkiller) were used in 48% of Jaydess, 53% of Kyleena, 26% of Mirena and 31% of CU-IUD users, however, large differences were observed in the different countries, ranging from 7% in UK to 67% in Austria. Prostaglandins were most frequently used in Austria (44%) and Germany (33%), and painkillers in Sweden (57%), Austria (38%) and Finland (30%). This is also related to parity: of nulli-parous women, 20% received prostaglandins and 32% painkillers, compared with 9% prostaglandins and 13% painkiller used in parous women.

Use of general anesthesia was low in all countries (1 to 4%), and local anesthesia was most frequently used in the UK (43%) and Austria (31%), and less often in the other countries: Czechia (1%), Spain (2%), Finland and Italy (3%), France (6%), Poland (7%), Germany (10%) and Sweden (11%).
Limitations, reasons for caution: Age distribution differed largely among the study cohorts, and thus, also the proportion of parous women. In addition, different standard practices regarding insertion of the IUD were seen in the different countries.
Wider implications of the findings: IUDs are a comfortable contraceptive method which don't require daily intake by women. However, the insertion procedure might be unpleasant, especially for nulli-parous women. In the participating countries, different methods for preparation of the insertion were seen. Further research is necessary to assess the impact of different methods.
Trial registration number: NCT02146950

P-730 High prevalence of Mycoplasma /Ureaplasma in asymptomatic oocyte donors

P.L. Aldama González[1], M. Lacarcel[1]

[1]Eva Fertility Clinics, EvaBank, Madrid, Spain

Study question: What is the current prevalence of Sexually Transmitted Infections (STIs) in asymptomatic oocyte donors?
Summary answer: The current prevalence of STIs in asymptomatic oocyte donors is higher than expected, especially for Mycoplasma and Ureaplasma Urealyticum.
What is known already: Sexually transmitted infections (STIs) are related to infertility worldwide. The impact of STIs such as Mycoplasma hominis, Ureaplasma Urealyticum and Chlamydia Trachomatis on fertility has been debated for several decades without being able to reach definitive conclusions due to isolating difficulties and absence of symptoms.
Study design, size, duration: This is a retrospective observational study including all the asymptomatic oocyte donors with complete STIs detection report between July and December of 2019.
Participants/materials, setting, methods: A total of 72 donors (18 to 29 years old) were included in the study. Samples from each donors were cultured for Mycoplasma Hominis, Ureaplasma Urealyticum and Ureaplasma Parvum. Chlamidya Tracomatis antigen and Neisseria Gonorrhoeae antigen in cervical sample, Pallidum Antitreponema and Herpes 1/2 antibodies were analyzed. General vaginal microbiological culture was performed also for each donor. The statistical analysis was performed using measures of central tendency, and Pearson's Chi2, using the SPSS version 25
Main results and the role of chance: STIs were found in 58% of asymptomatic oocyte donors (n =42). Therewas no correlation between STIs with age, race, occupation, or marital status. However, STIs were significantly associated with low education (p=0.045). Mycoplasma hominis was founded in 39%of the cases (n=16), Ureaplasma Urealyticum in 56% (n=23), Ureaplasma Parvum 14% (n=6). Chlamydia Trachomatis 9% (n=4). Mycoplasma hominis and Ureaplasma Urealyticum was founded together in 24% (n=10), and Ureaplasma spp in 14% (n=6).
Limitations, reasons for caution: This is an small observational study based on a retrospective data analysis. Better extrapolation of the results could be validated by performing an extensive prospective study.
Wider implications of the findings: The young healthy population must be targeted with preventive educational programs. Although STI is not investigated routinely but in long run, it can might have negative impact on fertility rate in society.
Trial registration number: Not Applicable

P-731 The impact of body mass index on in vitro fertilization performance in infertile women

A. Albu[1], D. Albu[2]

[1]Carol Davila University of Medicine and Pharmacy, Endocrinology, Voluntari, Romania ;
[2]Carol Davila University of Medicine and Pharmacy, Obstetrics and Gynecology, Voluntari, Romania

Study question: Which is the relationship between the entire spectrum of body mass index (BMI) and in vitro fertilization (IVF) parameters?
Summary answer: Both low BMI and overweight BMI seem to be associated with oocytes and zygotes number and the responder type.
What is known already: The association between BMI and IVF outcome is widely debated, the results of the available studies being divergent. While higher BMI seems to have a negative impact on reproductive outcome, the data regarding the connection between low BMI and reproductive parameters are limited.
Study design, size, duration: We performed a retrospective study in the Department of Reproductive Medicine of a private hospital. The medical records of all consecutive patients who underwent IVF between January 2015 and December 2018 with all causes of infertility were reviewed.
Participants/materials, setting, methods: One thousand three hundred thirty-seven patients were included in the study (mean age 34.7±4.2 years). Patients were divided according to BMI in underweight (n=116, BMI<18.5kg/sqm), normal weight (n=971, BMI 18.5-24.99 kg/sqm), overweight (n=195, BMI 25-29.99 kg/sqm) and obese (n=55, BMI>30 kg/sqm). The number of oocytes obtained at egg collection and the zygotes number were recorded. Patients were also categorized according to the type of responder: poor responder, low responder, normal responder and hyper responder.
Main results and the role of chance: BMI was positively correlated with age (rho = 0.141, p < 0.0001) and negatively with oocytes (rho = - 0.068, p = 0.014) and zygotes number (rho = - 0.080, p = 0.004). In a multivariate regression model, after adjustment for age and AMH serum level, being underweight was positively associated with oocytes number (beta = 0.072, p = 0.002) and with zygotes number (beta = 0.059, p = 0.02) and being overweight was negatively associated with oocytes number (beta = - 0.051, p = 0.028). In a multinomial regression model, after adjustment for age and AMH serum level, underweight patients had an increased chance of being normal responder in comparison with normal weight patients (OR 1.4, CI 1.2-2), while overweight patients had decreased odds of being normal responder in comparison with normal weight patients (OR 0.56, CI 0.29-0.8)
Limitations, reasons for caution: The main limitation of the study is the relatively small number of patients included in the obese and underweight category, probably affecting the statistical analysis.
Wider implications of the findings: Our study showed the association between low and high BMI and oocytes and zygotes number, which were reported to be significant predictors of live birth, therefore offering possible ways to influence IVF outcome by modifying body weight.
Trial registration number: NA

P-732 Cumulative live birth rates among gestational carriers in altruistic surrogacy arrangements

J. Attawet[1], A. Wang[1], Z. Li[1], K. Hammarberg[2], L. Johnson[3], E. Sullivan[4]

[1]University of Technology Sydney, Public Health, Sydney, Australia ;
[2]Monash University, Public Health, Melbourne, Australia ;
[3]Victoria Assisted Reproductive Treatment Authority, varta, Melbourne, Australia ;
[4]University of Newcastle, Health and Medicine, Callaghan, Australia

Study question: What is the cumulative live birth rate (CLBR) among gestational carriers in altruistic surrogacy arrangements?
Summary answer: The CLBR among gestational carriers ranged from 23.5% after the first embryo transfer cycle to 50.6% after six consecutive embryo transfer cycles.
What is known already: CLBR is a measure of the success of assisted reproductive technology (ART) which demonstrates how each additional treatment adds to the chance of having a live birth. It is commonly used in the context of autologous treatment where women have used their own eggs.
Study design, size, duration: This was a population-based retrospective cohort study of all intended parents and gestational carriers who had at least one embryo transfer cycle in the state of Victoria, Australia between 2009 and 2016. Pregnancy and birth outcomes were followed until a live birth was achieved or until June 30, 2017, whichever came first.
Participants/materials, setting, methods: Data collected by the Victorian Assisted Reproductive Treatment Authority (VARTA) on all gestational surrogacy arrangements in Victoria between 2009 and 2017 were analysed. The primary outcome was cumulative live birth, which was defined as live deliveries with at least one live born baby resulting from initiated stimulated cycles and associated thaw cycles. Life-table was used to calculate the CLBR.
Main results and the role of chance: There were 66 intended parents and 81 gestational carriers. Of the 170 embryo transfer cycles, the majority were single embryo transfers (97.1%), using frozen/thawed embryos (97.6%) which had been fertilized by intracytoplasmic sperm injection (ICSI) (77.6%). The cumulative live birth rate was 23.5% (95% CI, 15.6-33.8%) after the first cycle and increased to 50.6% (95% CI, 40.0-61.2%) after the sixth cycle. Of the 41 deliveries, 40 were singletons and one was a twin delivery. Two of the 42 babies were preterm, two were low birthweight and one was small for gestational age.
Limitations, reasons for caution: Although this population-based study included all gestational surrogacy arrangement in Victoria, the sample size is small. The study was conducted in a setting where only altruistic surrogacy is legal, and the findings may not be generalizable to settings where commercial surrogacy is undertaken. .

Wider implications of the findings: Altruistic surrogacy arrangement is unlikely to reduce the cumulative live birth rate. Among gestational carriers, surrogacy treatment can be offered up to six consecutive embryo transfer cycles without reducing the chance of a live birth. This estimate can be used in counselling and decision-making for all parties involved in surrogacy.
Trial registration number: not applicable

P-733 Childless by circumstance – the fertility experiences of women who wanted children

J. Harper[1], D. Chauhan[1], E. Jackson[2]

[1]Institute for Women's Health, EGA Institute for Women's Health, London, United Kingdom ;
[2]London School of Economics, Law, London, United Kingdom

Study question: What reproductive experiences did childless women go through and how do they feel about being childless?
Summary answer: Women experienced social infertility, miscarriages, and if they went through IVF, they mainly stopped for emotional reasons. The majority felt negatively about being childless.
What is known already: Childlessness is increasing across many middle- and high-income countries, for a wide variety of reasons, including increasing gender equality, greater respect for reproductive autonomy, infertility and, in some cases, an inability to find a partner. Many women have postponed childbearing and the age of first birth is increasing annually. Europe has the lowest fertility rate on record, as well as a record number of women being permanently childless.
Study design, size, duration: An online survey study was developed and validated with help from childless women. The survey consisted of questions with quantitative-answer formats as well as open-text qualitative answer formats. It was promoted through social media. The survey remained open online for 15 days.
Participants/materials, setting, methods: The survey was only completed by women who were aged 46 years of age and above, who had wanted children but were childless. In total 303 survey responses were collected, 176 of which were complete surveys. The data was explored through the survey platform's data reporting function. The qualitative data was analysed with a qualitative descriptive analysis approach.
Main results and the role of chance: 16.3% (n=27) of women who wanted children reported that they did not try to have children, most commonly due to the lack of a partner (40%, n=11). Of the women who tried to have children (n=139), 70.5% (n=98) had used calendar-based menstrual cycle tracking methods to identify their fertile window and many had fertility checks including hormone tests (75.5%) and ultrasound scans (71.2%). A significant proportion of women had experienced a miscarriage (38.8%). Many women decided not to have any fertility treatments (43.2%, n=60). For those that did undergo fertility treatments, many had tried in vitro fertilization (42.4% (n=59), and this was mainly privately funded. The most common reason women gave for stopping fertility treatment was due to emotional reasons (42.4%, n=59). When asked how women felt about their childlessness, the most common emotions identified were sadness (53.1%, n=85), gradual acceptance (36.3%, n=58), and ostracism (33%, n=53).
Limitations, reasons for caution: The use of the word childless was discussed. 'Childless by circumstance' was agreed in order not to presuppose reasons for women's childlessness, or to assume that women's attitude towards their childlessness was fixed. 127 participants started but did not complete the survey. The survey was only advertised on social media.
Wider implications of the findings: This study has listened to the self-reported experiences of women who wanted children, but who are childless. Support for unsuccessful fertility patients and other childless women should be expanded, and emphasis on fertility education should be established in order to ensure that women are better informed about their fertility.
Trial registration number: Not applicable

P-734 Cost-effectiveness of medically assisted reproduction or expectant management for unexplained subfertility: when to start treatment?

R. Van Eekelen[1], M.J. Eijkemans[2], M. Mochtar[1], F. Mol[1], B.W. Mol[3], H. Groen[4], M. Van Wely[1]

[1]Amsterdam UMC- Academic Medical Centre, Centre for Reproductive Medicine, Amsterdam, The Netherlands ;
[2]University Medical Centre Utrecht- Julius Centre, Department of Biostatistics and Research Support, Utrecht, The Netherlands ;
[3]Monash Medical Centre, Department of Obstetrics and Gynaecology, Melbourne-Monash, Australia ;
[4]University Medical Centre Groningen, Department of Epidemiology, Groningen, The Netherlands

Study question: Over a time period of three years, which order of expectant management (EM), IUI-OS and IVF is the most cost-effective for couples with unexplained subfertility?
Summary answer: The most cost-effective scenario depended on the monetary value assigned to a live birth: EM-EM-IVF (if assigned <€32,000) or EM-IUIOS-IVF when assigned more.
What is known already: IUI-OS and IVF are commonly used for unexplained subfertility although these couples can still conceive naturally. Few countries have guidelines on when to proceed with medically assisted reproduction (MAR) but there is a lack of evidence to support these strategies. The increased uptake of IUI-OS and IVF over the past decades and costs related to reimbursement of these treatments are pressing concerns to health service providers. For MAR to remain affordable, sustainable and a responsible use of public funds, guidance is needed on the cost-effectiveness of treatment strategies for unexplained subfertility.
Study design, size, duration: We developed a cost-effectiveness model that follows couples with unexplained subfertility for a total of 3 years from diagnosis onwards, divided into three periods of 1 year each. The model was based on contemporary evidence i.e. the dynamic prediction model for natural conception and the network meta-analysis on RCTs in MAR for unexplained subfertility. We changed the ordering of the three options, EM, IUIOS and IVF to yield different treatment scenarios.
Participants/materials, setting, methods: The main outcomes were the probability of live birth and aveage costs. We chose the Dutch societal perspective. The probabilities of live birth after EM were taken from the dynamic prediction model for natural conception. The relative effects of IUI-OS and IVF were taken from the network meta-analysis and applied to probabilities of live birth after EM. We applied discounting. Uncertainty was taken into account using probabilistic sensitivy analyses, replicating the simulation model 20,000 times.
Main results and the role of chance: From IVF-EM-EM to EM-IUIOS-IVF, the probability of live birth varied from approximately 54% to 64% and the average costs from approximately €4000 to €9000. The scenarios IVF-EM-EM and EM-IVF-EM were dominated by EM-EM-IVF as the latter yielded a higher cumulative probability of live birth at a lower cost. The scenario IUIOS-IVF-EM was dominated by EM-IUIOS-IVF as the latter yielded a higher cumulative probability of live birth at a lower cost. After removal of scenarios that were dominated, the incremental cost-effectiveness ratio (ICER) for EM-IUIOS-IVF was approximately €31,000 compared to EM-EM-IVF. The range of ICER values between the lowest 25% and highest 75% of simulation replications was broad.

The net benefit curve showed that when we assume a live birth to be worth approximately €32,000 or less, the scenario EM-EM-IVF had the highest probability to achieve the highest net benefit. When we assume a monetary value per live birth over €32,000, the scenario with the highest probability to achieve the highest net benefit was EM-IUIOS-IVF. Results for subgroups with different baseline prognoses were similar to the primary analysis but yielded different threshold values for the assumed monetary value per live birth.
Limitations, reasons for caution: Our model was at the population level and thus based on average statistics. We also assumed certain model parameters and assessed the influence of these assumptions on our results. The change in relative effectiveness of IVF over time was found to be highly influential on results and their interpretation.
Wider implications of the findings: Two scenarios, EM-EM-IVF and EM-IUIOS-IVF, were the most cost-effective at different monetary values for a live birth with a threshold of €32,000. Our results can be used in determining sustainable MAR protocols for couples with unexplained subfertility that avoids unnecessary treatment.
Trial registration number: Not applicable

P-735 More than 40% of couples leave their supernumerary cryopreserved embryos frozen and destined for discarding

M. Stimpfel[1], B. Valentincic-Gruden[1], J. Kmecl[1], L. Bacer-Kermavner[1], J. Mivsek[1], P. Petric[1], N. Jancar[1], E. Vrtacnik-Bokal[1]

[1]Univerzitetni Klinicni Center Ljubljana, Department of Obstetrics and Gynaecology, Ljubljana, Slovenia

Study question: What is the proportion of the unused supernumerary cryopreserved embryos and couples, who don't use their cryopreserved embryos after IVF/ICSI treatment?
Summary answer: After five years of cryostorage, one third of couples still have their supernumerary embryos cryopreserved, and also one third of all embryos stay cryopreserved.
What is known already: With improvements in IVF treatments the number of cryopreserved supernumerary embryos also increased, and consequently more and more embryos are left in liquid nitrogen or discarded after certain time. The practice usually depends on legislation, if there is one; otherwise the IVF centres decide by themselves what to do. In our country, the national law stipulates that embryos can be frozen for five years, and after that discarded, although there is possibility to extend the cryopreservation time for additional five years. Despite well-defined conditions in our law, about how long to cryopreserve embryos, this still opens some ethical concerns.
Study design, size, duration: In January 2020, we retrospectively collected the data of all fresh cycles which led to embryo cryopreservation, in couples treated in our centre from January 2014 to December 2018, and analysed how many embryos are still frozen.
Participants/materials, setting, methods: We checked what the dynamic of thawing embryos was, in terms of the proportion of thawed embryos depending on cryostorage time. We also analysed what is the proportion of couples who still have frozen embryos even after five years of cryostorage, which is a legislative limit (although cryostorage is usually prolonged for additional five years and after that time the embryos are discarded).
Main results and the role of chance: The data show that after the first year of cryostorage (embryo cryopreservation in 2018) 42% of embryos were thawed, after two years (cryopreservation in 2017) 50%, after three years (cryopreservation in 2016) 54%, after four years (cryopreservation in 2015) 64%, and after five years (cryopreservation in 2014) 59%. The proportion of couples who used all their cryopreserved embryos after first year of cryostorage (embryo cryopreservation in 2018) was 42%, after two years (cryopreservation in 2017) 52%, after three years (cryopreservation in 2016) 53%, after four years (cryopreservation in 2015) 51% and after five years (cryopreservation in 2014) 59%.

We additionally tried to analyze, why so many embryos by so many couples (41%) are left frozen even after 5 years of cryostorage (cryopreservation in 2014). Our analysis indicates that one of the reasons is probably that couples conceived after fresh or frozen embryo transfer and just left other embryos frozen (28%). There is also a proportion of couples who didn't conceive through IVF, but still left their embryos frozen, sometimes even without single frozen/thawed embryo transfer (13%). They probably conceived spontaneously, or there was some other unknown reason.
Limitations, reasons for caution: The limitation of the study is retrospective design and that the proportions of thawed embryos and couples using these embryos were not followed each year separately, but for all years together.
Wider implications of the findings: The couples could be encouraged to use each and every one of their cryopreserved embryos, or to donate their embryos to other couples in the countries where this is allowed.
Trial registration number: not applicable

P-736 Import and Export of Gametes and Embryos in Italy: retrospective data realignment and implementation of a new data collection platform

G. Capelli[1], S. Bolli[2], L. Santilli[3], F. Bariani[3], V. Vigiliano[2], R. De Luca[2], L. Lombardini[3], M. Cardillo[3], G. Scaravelli[2]

[1]Italian National Health Institute - ISS / University of Cassino e Lazio Meridionale, Observatory for Medically Assisted Reproduction / Department of Human Sciences- Society and Health, Rome / Cassino FR, Italy ;
[2]Italian National Health Institute - ISS, Italian National ART Registry, Rome, Italy ;
[3]Italian National Health Institute - ISS, Italian National Transplant Centre - CNT, Rome, Italy

Study question: How many gametes and embryos travel among countries, due to reasons ranging from gamete donation supply levels to barriers in accessing specific healthcare procedures?
Summary answer: Reliable data on cross-border circulation of gametes and embryos are extremely important, also to evaluate lack of national donations.
What is known already: While some studies point out the importance of issues linked to reproductive healthcare tourism or trans-border circulation of gametes and embryos, few data are available on the matter. In Italy, since 2012, the law commits ART centers to notify any activity of Import and Export of gametes and embryos to both the Italian ART Registry in the Italian National Health Institute (ISS), which is in charge of collecting data on ART activities in Italy and the Italian National Transplant Centre (CNT), which is in charge of ensuring safety and quality of cells and tissues in Italy.
Study design, size, duration: After 2014, ART treatments with donated gametes were allowed by law in Italy, and gamete Import/Export activities started to rise. In 2017, the Italian ART Registry, the CNT, and the ART Observatory in ISS, started a retrospective cross-validation of Import/Export databases separately collected in 2016 and 2017 and planned and implemented a new common web-based system, accessible by the ~350 Italian ART centers, which came into force on 01/01/2018, to allow prospective data collection.
Participants/materials, setting, methods: Two different databases, imputed both in 2016 and 2017 on Excel files by ART Registry and CNT separately, were checked, homogenized and imported and analyzed by Stata 15. Meanwhile, the working group defined a common dataset and implemented a web-based interface for the prospective data collection, in which Single ART Establishments started to impute data prospectively on a day-by-day basis since 01/01/2018.
Main results and the role of chance: In 2016 and 2017, a total of 3040+3063 straws/vials of semen, 6239+6731 straws/vials of oocytes and 2865+2632 embryos were imported to Italian ART Centers from foreign gamete Banks and ART Centers, and a total of 3581+2937 straws/vials of semen, 16+33 straws/vials of oocytes and 55+57 embryos were exported from Italian ART Centers to foreign ART Centers. Tables, heatmaps and other data visualization tools were used to show the straws/vials imported and exported, stratified by Region for the Italian ART Centers, and by Country (both EU and extra-EU) for the International ART Centers. Many Italian ART centers work mainly importing semen and/or oocytes, while some specific centers show significant volumes of semen export followed by an import of frozen embryos. All these data were included in an Appendix of the 2018 and 2019 Annual Reports of the Italian Ministry of Health on ART activities.

Data collected from January 2018, thanks to a robust web-based data interface, will allow also to identify even better, through the analysis of SEC codes, the cross-border path followed by gametes and embryos. 2018 data will be presented in the 2020 Annual Report of the Italian Ministry of Health on ART activities, due for 30/06/2020.
Limitations, reasons for caution: In 2016 and 2017 data, some underreporting and misclassification may have occurred, since some ART Centers were regularly notifying import/export either to the Italian ART Registry or the CNT, and some misclassification of International Centers operating in the same country and belonging to the same Company may have occurred.
Wider implications of the findings: "Mapping" of the gamete and embryo cross-border exchange paths may help to identify and study international networks of co-operating ART Centers. Moreover, the need to notify import and export activities through the new web-based interface is increasing the awareness about the EU Compendium and the SEC codes.
Trial registration number: not applicable

P-737 Assessing women's preferences in a novel intrauterine device designed to monitor the womb environment in real time: A discrete choice experiment

K.Y.B. Ng[1,2], R. Evans[2], S. Wellstead[2], A. Burtt[2], E. Mentzakis[3], Y. Cheong[1,2]

[1]University of Southampton, School of Human Health and Development, Southampton, United Kingdom ;
[2]University Hospitals Southampton NHS Foundation Trust, Department of Obstetrics and Gynaecology, Southampton, United Kingdom ;
[3]University of Southampton, Department of Economics, Southampton, United Kingdom

Study question: What factors influence a woman's decision to use an intrauterine device designed to monitor the uterine environment?
Summary answer: Willingness to use a novel intrauterine device to monitor the in-vivo uterine environment is mostly influenced by its ability to guide treatment of reproductive failures.
What is known already: There is increasing evidence suggesting that the intrauterine environment is essential for successful implantation and placentation. The University of Southampton, in conjunction with an industry partner, are developing an intrauterine device which has the potential to monitor the temperature, pH and dissolved oxygen in real time in the uterus, with the aim of supporting those with reproductive failures. The device is similar in shape and size to a contraceptive coil, and has an accompanying wearable garment with an information receiver to collect data. This study aims to explore factors that are of importance to potential users of the intrauterine device.
Study design, size, duration: A discrete choice experiment (DCE) was conducted; DCE is a preference elicitation method whereby individuals reveal their preference over selected attributes of a product in a series of pair-wise choices of hypothetical alternative products. Choice sets consisted of two hypothetical intrauterine devices described via four attributes: length of use, information obtained and its use in guiding treatment, risk of complications and discreteness of the information receiver. Ethical approvals were obtained (ERGO 49115, REC 19/IEC08/0036).
Participants/materials, setting, methods: 220 women of reproductive age (18-50 years), who were wishing to achieve a pregnancy now or sometime in the future were recruited at Princess Anne Hospital in Southampton. A fractional factorial design was used to estimate effects of the four attributes, using 18 pair wise choice sets that identified all main effects and selected two-way interactions, blocked into two blocks of 9 choice sets each. Conditional and mixed logit models were used to analyse responses.
Main results and the role of chance: Analysis was performed through conditional and mixed logit models with similar results. Overall, women prefer a device which stays in the uterus for a shortest length of time, provides information that guides treatment in all cases, has the lowest risk of complications, and has an information receiver which is completely discrete. All such preferences were statistically significant ($p<0.05$). Examining relative importance attached to the attributes, women placed most importance on the information obtained from the device and its ability to guide treatment. Specifically, respondents were over 2 times more likely to choose a device if the information obtained guided treatment in all cases, compared to when information obtained guided treatment in majority of cases. Obtaining information that guided treatment in all cases had an equal importance to a drop in risk of complications by 15%. Further, the impact of a 1% increase in the risk of complications was comparable to a 7 day increase in the length of use. Finally, moving from a moderately discrete to an indiscrete information receiver reduced the device's attractiveness by a third.
Limitations, reasons for caution: Hypothetical bias may lower external validity. Although we obtained data on the 'stated' preferences within the hypothetical choice sets, we were not able to capture the 'actual' preferences of the women from this study.
Wider implications of the findings: Before the introduction of a novel fertility assessment tool, it is important to gain knowledge of the preferences of potential users. The usefulness of the device in obtaining information that will guide treatment of reproductive failures is of paramount importance to users, and appropriate counselling will support informed decision making.
Trial registration number: N/A

P-738 Age-related natural fertility outcomes in women over 35: an individual participant data meta-analysis

Study question: What is the rate of natural conception leading to livebirth over 6–12 months for infertile women of age ≥ 35 years?
Summary answer: Natural conception rates were still clinically relevant in women aged 35 and above and were significantly higher in women with unexplained infertility.
What is known already: In recent years, increasing numbers of women have attempted to conceive at a later age, resulting in a commensurate increase in the need for assisted reproductive treatment (ART). However, there is a lack of data on natural fertility outcomes (i.e. no interventions) in women with increasing age.
Study design, size, duration: Systematic review with individual patient data meta-analysis. PubMed, Medline, Embase, the Cochrane Library, clinicaltrials.gov were searched until 1st July 2018 including search terms "fertility service", "waiting list", "treatment-independent", "spontaneous conception". Language restrictions were not imposed.
Participants/materials, setting, methods: Inclusion criteria were studies reporting on infertile couples with female partner of age ≥ 35 who attended fertility services, underwent fertility work-up and were exposed to a period of expectant management. For studies that met inclusion criteria, study authors were contacted to provide individual participant data. Time to pregnancy or live birth and the effect of increasing age on fertility outcomes after adjustment for other prognostic factors were analysed.
Main results and the role of chance: We included 10 studies (7 cohort studies and 3 randomised controlled trials) (n=4415 women of at least age 35), with the observed composite primary outcome of ongoing pregnancy or live birth occurring in 436 women (9.9%) over a median follow-up of 5 months (P25-75: 2.5-8.5). Studies were of moderate to high quality. The probability of natural conception significantly decreased with any diagnosis of infertility, when compared with unexplained infertility. We found non-linear effects of female age and duration of infertility on natural conception and tabulated the predicted probabilities for unexplained infertile women of ages 35 to 42 with either primary or secondary infertility and with a duration of infertility from 1 to 6 years. For a 35-year-old woman with 2 years of primary unexplained infertility, the predicted probability of natural conception leading to live birth was 0.15 (95%CI 0.10–0.19) after 6 months and 0.23 (95%CI 0.17–0.29) after 12 months. For a 42-year-old woman, this decreased to 0.07 (95%CI 0.04–0.11) after 6 months and 0.12 (95%CI 0.07–0.17) after 12 months.
Limitations, reasons for caution: There were different study designs, recruitment strategies in different centres, protocols and countries and different methods of assessment of infertility utilised. Data was limited for women above the age of 40.
Wider implications of the findings: Women attending fertility services should be encouraged to pursue natural conception while waiting for treatment to commence and after treatment if it is unsuccessful. Our results may aid in counseling women, and, in particular, those with unexplained infertility.
Trial registration number: N/A

P-739 Dietary glycemic load and unexpected poor response to ovarian hyper-stimulation: a prospective cross-sectional study

S.A. Noli[1], E. Ricci[2], S. Ferrari[3], M. Reschini[3], F. Parazzini[4], E. Somigliana[3]

[1]Università degli Studi di Milano- Milan- Italy, Department of Clinical Sciences and Community Health, Milan, Italy ;
[2]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Department of Woman- Newborn and Child, Milan, Italy ;
[3]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Fertility Unit, Milan, Italy ;
[4]Università degli Studi di Milano, Department of Clinical Sciences and Community Health, Milan, Italy

Study question: Is there any association between dietary glycemic load and unexpected poor ovarian response to hyper-stimulation?
Summary answer: Elevated dietary glycemic load is associated with unexpected poor ovarian response.
What is known already: In recent years, increasing interest was turned to the relation between nutrition and fertility. Several studies suggested that diet in general and glycemic load in particular can affect oocytes quality, embryo development and time to pregnancy, after both natural and assisted reproduction. However, evidence is not univocal. Of relevance here is that pregnancy is the result of several factors, of whom most may not be influenced by diet. Investigations specifically focusing on particular aspects of reproduction are therefore needed. In this study, we tested the possibility that diet may cause poor response in women with normal biomarkers of ovarian reserve.
Study design, size, duration: Women eligible for in IVF at an Academic Fertility Center were invited to participate to a prospective cross-sectional study on the role of diet on IVF outcomes. Main inclusion criteria were: age between 18 and 39 years, BMI >18 and <25 Kg/m^2, preserved ovarian reserve (anti-muellerian hormone (AMH) between 2 and 5 ng/mL and/or total Antral Follicle Count (AFC) between 10 and 22 and starting dose of gonadotropins between 150-225 IU/day.
Participants/materials, setting, methods: Information on diet was obtained using a validated food frequency questionnaire (FFQ). *Unexpected poor ovarian response* was defined as the retrieval of ≤3 suitable oocytes in women expected to be normal responders based on AFC and AMH. A logistic regression model was used to adjust for confounders.
Main results and the role of chance: Out of 303 women undergoing IVF and enrolled in the study, 48 (16%) showed poor response to ovarian hyper-stimulation. Main baseline characteristics of the study groups did not significantly differ. The number of poor responsive subjects increased with glycemic load with borderline significance, both when analyzed in tertiles (p=0.054) and as continuous variable (p=0.08). However, when adjusting for age, BMI, education, smoking, occupational and leisure physical activity, endometriosis, daily calories intake, fibers intake, caffeine intake and alcohol intake, the association became statistically significant (p for trend, p=0.02). Specifically, when comparing the third to the first tertile (reference) of glycemic load, the adjusted OR was 3.91 (95% CI: 1.11-13.83).
Limitations, reasons for caution: Three main limitations should be considered: 1) findings should be referred only to women of infertile couples; 2) although we used a previously validated FFQ, information regarding dietary habits were self-reported; 3) the design of study does not allow to conclude for a causal relation.
Wider implications of the findings: If confirmed, a detrimental role of diet on ovarian response and in particular on the proportion of women with unexpected poor response may open to new therapeutic approaches. Future interventional studies should clarify whether diet modification may restore normal response to ovarian hyper-stimulation.
Trial registration number: not applicable

P-740 Overestimated? Prevalence of thrombophilia and antiphospholipid syndrome in patients with recurrent miscarriage and healthy controls

K. Vomstein[1], A. Herzog[1], P. Voss[2], K. Feil[1], T. Goeggl[2], T. Strowitzki[2], B. Toth[1], R.J. Kuon[2]

[1]Medical University Innsbruck, Department of Gynecological Endocrinology and Reproductive Medicine, Innsbruck, Austria ;
[2]Ruprecht-Karls University Heidelberg, Department of Gynecological Endocrinology and Fertility Disorders, Heidelberg, Germany

Study question: Does the prevalence of inherited and acquired thrombophilia differ between patients with recurrent miscarriage (RM) and healthy controls?
Summary answer: There is no difference in the prevalence, neither in inherited nor in acquired thrombophilia between RM patients and healthy controls.
What is known already: Although frequently performed, routine screening for inherited thrombophilia in patients with recurrent miscarriage is not recommended in clinical guidelines, whereas screening for Anti-phospholipid Antibody Syndrome (APS) is highly recommended. Further, studies on the frequency of thrombophilia in RM patients showed contradictory results. Inherited and acquired thrombophilia are associated with severe pregnancy complications like preeclampsia, fetal growth restriction and stillbirth as well as increased maternal risks of venous thromboembolism with serious long-term consequences. There is an ongoing debate on the impact of these thrombophilia on RM with the presumed mechanism of a thrombosis within the uteroplacental circulation.
Study design, size, duration: At two university-based Departments between 01/2011 and 07/2019, n=820 patients with RM (defined as ≥ 3 consecutive miscarriages) were included within a multi center case control study. The control group (n=141) consisted of young healthy women who underwent a routine screening for inherited and acquired thrombophilia. Diagnostics were performed in non-pregnant RM patients and controls.
Participants/materials, setting, methods: In non-pregnant RM patients and controls, obstetric and medical histories were obtained (including age, body mass index (BMI), gravidity, parity, number of miscarriages). The prevalence of inherited and acquired thrombophilia including deficiency of protein C/S and antithrombin (AT), elevation of factor VIII activity, APC resistance/ mutation in the factor V Leiden (FVL, G1691A) gene, mutation in the prothrombin (G20210A) gene and antiphospholipid antibodies were assessed and compared between RM patients and controls.
Main results and the role of chance: RM patients were significantly older than controls (mean age±SD, 34.24±4.59 vs 5.56±1.92, p<0.0001). The BMI in RM patients was higher than in controls (24.30±4.45 vs. 21.54±4.4, p<0.001). RM patients had a history of 3 (3/14) miscarriages (median (min/max)). There were no differences concerning the number of previous miscarriages between RM patients between the two Departments. No differences in the prevalence of protein C/S deficiency, FVL or prothrombin gene mutation were observed in RM patients and controls. However, homozygous mutations were identified only in the RM group (RM vs. controls in %: FVL heterozygous/homozygous: 7.4/0.26 vs 7.1/0.0; prothrombin heterozygous/homozygous: 3.69/0.53 vs 0.71/0.0; deficiency of protein C: 0.39 vs 0.00, protein S: 2.77 vs 3.55, AT: 0.76 vs 1.5; all p>0.05). The frequency of antiphospholipid antibodies did not differ significantly in both groups (RM vs. controls in %: anti-cardiolipin antibodies 3.66 vs. 0.0; anti-β2-glycoprotein antibodies 2.5 vs 0.7; lupus anticoagulant 0.78 vs 0.7; all p>0.05). Eleven patients in the RM group, but none of controls, fulfilled the Sydney criteria and were diagnosed with an APLS (prevalence of APLS 1.44% vs 0%, p=0.38). An elevation of factor VIII was significantly more prevalent in controls (RM vs controls in %: 5.8 vs 11.0, p=0.038).
Limitations, reasons for caution: This study is not designed to explain any possible causality between thrombophilia and RM. As our controls were of younger age and nulliparous, neither a possible influence of a future pregnancy, nor a possible development of an acquired thrombophilia or future recurrent miscarriage (prevalence of 1-3%) can be excluded.
Wider implications of the findings: The prevalence of inherited and acquired thrombophilia in RM patients has been overestimated in previous studies. While earlier studies identified an association of some inherited thrombophilia with RM, our data do not support these findings. Still, we recommend screening for APLS as it has deleterious effects on implantation and pregnancy.
Trial registration number: not applicable

P-741 The impact of smoking in 2,000 recurrent pregnancy loss patients

K. Hviid[1], A.M. Kolte[2], M.E. Issaoui[2], M.C. Krog[2], H.S. Nielsen[3]

[1]Fertility Clinic 4071- Rigshospitalet- Copenhagen University Hospital- Blegdamsvej 9- DK-2100 Copenhagen Ø- Denmark. Dept. of Obstetrics and Gynaecology- Hvidovre Hospital- Kettegaard Alle 30- DK-2650 Hvidovre- Denmark, Dept. of Obstetrics and Gynaeco, ;
[2]Fertility Clinic 4071- Rigshospitalet- Copenhagen University Hospital- Blegdamsvej 9- DK-2100 Copenhagen Ø- Denmark, Fertility Clinic, Copenhagen, Denmark ;
[3]Dept. of Obstetrics and Gynaecology- Hvidovre Hospital- Kettegaard Alle 30- DK-2650 Hvidovre- Denmark. Dept. of Clinical Medicine- University of Copenhagen, Dept. of Obstetrics and Gynaecology-, Hvidovre, Denmark

Study question: Are pregnancy history and the first outcome after referral different in smoking recurrent pregnancy loss (RPL) patients versus never-smokers?
Summary answer: Smoking RPL patients were referred younger, with more pregnancy losses and stillbirths compared to never-smokers but had no significant difference in live birth after referral.
What is known already: Smoking during pregnancy is associated with negative reproductive effects including low birthweight, placenta abruption, preterm delivery, shortened gestation, stillbirth, and sudden infant death syndrome. A recent meta-analysis examined the effect of maternal smoking on pregnancy outcomes after assisted reproductive technology and reported a decreased rate of both live birth and of clinical pregnancy respectively, and a higher pregnancy loss rate per pregnancy in the smoking group. The impact of smoking in RPL patients has not yet been elucidated.
Study design, size, duration: A cohort study including women referred to the Recurrent Pregnancy Loss Unit, the Fertility Clinic, Rigshospitalet, Copenhagen University Hospital, Denmark, between 01 January 2000 and 31 December 2017, and under the age of 42 years at referral. The cohort consists of 2,138 women with RPL. Follow-up of the first pregnancy after referral ended by December 2018.
Participants/materials, setting, methods: Pregnancy history and smoking behaviour is systematically collected at the first consultation in the RPL unit and with consent saved in a dedicated database. Patients were divided into 'smokers at time of referral' or 'never-smokers'. Former or occasional smokers were excluded. The outcome of the first pregnancy after referral was categorised as live birth versus pregnancy loss. Where appropriate the following statistical analyses were used: independent samples t-test, Pearson Chi-Square, Mann-Whitney, and multiple logistic regression.
Main results and the role of chance: Smokers at time of referral were on average 2.12 years younger than never-smokers at referral for RPL ($P < 0.0005$) and had significantly more losses prior to referral than never-smokers ($P < 0.002$). Among women with secondary RPL, smokers at time of referral's first-born children had a significantly lower birth weight and had experienced more stillbirths prior to referral ($P = 0.027$ and $P = 0.01$, respectively).

Among the 1,360 women with a pregnancy after referral in the RPL Unit 58% of smokers at time of referral had a live birth compared with 62% of never-smokers ($P = 0.289$). In an adjusted analysis no significant association was found between smoking status and chance of a live birth (OR 1.22, 95% CI: 0.88-1.68). In the first pregnancy after referral, stillbirth was significantly more common among smokers than never-smokers ($P = 0.004$). There were no statistically significant differences in birth weight or gestational age in the first pregnancy after referral between smokers at time of referral and never-smokers.
Limitations, reasons for caution: A weakness in our study is that we very strongly recommend smoking cessation at the first consultation, and our next encounter with the patient is when they report the next pregnancy. Patients who quit smoking before the first pregnancy after referral are thus erroneously categorized as active smokers.
Wider implications of the findings: Smoking RPL women are referred younger, with more pregnancy losses and stillbirths. As we lack data on smoking cessation after referral, we are uncertain if smoking reduces chances of live birth, however, the first pregnancy after referral smokers had more stillbirths. Smoking seems to be a risk factor for RPL.
Trial registration number: Not applicable

P-742 Risk factors that increase twin pregnancies following single embryo transfer with a blastocyst in relations to ART

T. Eliasen[1], A. Gabrielsen[1], B. Bay[1], U. Knudsen[1]

[1]Horsens, Fertility Clinic, Aarhus, Denmark

Study question: Which risk factors increase the risk of twin pregnancies following fertility treatment with single embryo transfer (SET) at the blastocyst stage?
Summary answer: Lower maternal age showed to be significant associated to increased risk of having twins in women following SET.
What is known already: The incidence of monozygotic (MZ) twins after fertility treatment has been reported to be higher than that following natural conception. Due to the increased maternal and fetal risk in twin pregnancies, reducing the risk of twin pregnancy, especially monochorionic, is important. Factors that have been hypothesized to increase the risk of MZ twins include fertilization method in ART, maternal age, oocyte age, embryo morphology, and culture media but studies have shown equivocal results.
Study design, size, duration: This study is a retrospective cohort study. Women who received fertility treatment from 2010-2019 at two fertility clinics in central Denmark were included. A total of 4,214 women had received 6,502 SET at the blastocyst stage with 2,196 (33.8%) subsequent pregnancies and of those 84 (3.8%) had twin pregnancies.
Participants/materials, setting, methods: Information on the women was collected from treatment start and during the pregnancy. The information included maternal age, indication for treatment, stimulation protocol, fertilisation method, BMI, blastocyst score prior to transfer, and ultrasonic findings at gestational week 8. Ultrasonic findings were confirmed by reading each patient's medical journal.
Main results and the role of chance: Twin pregnancies was identified in 84 women, and of these 43 were ultrasonically confirmed at gestational week 8 to be MC, 13 were dichorionic (DC) and 28 were of uncertain of the choriosity. This resulted in a MC twinning rate of 1.96% and a rate of 0.59% of having a DC twin. Lower maternal age was associated with an increased risk of having twins when comparing both DC and MC twins to singletons ($p=0.04$) but not when comparing only MC twins to singleton ($p=0.10$). There was no difference in the use of ICSI vs IVF. Furthermore, there was no observed difference in indication of treatment and twin rates. Finally, no difference in maternal or paternal BMI was observed.
Limitations, reasons for caution: Only ultrasonically confirmed MC pregnancies were included, which allows for a risk of underestimation, as many of the pregnancies with uncertain choriosity could be MC. Furthermore, the limited number of twin pregnancies makes unveiling significant risk factors difficult.
Wider implications of the findings: Twin rates following ART remains higher than that of natural conception. This report on twins following SET of a blastocyst found lower maternal age to be a risk factor. Assisted reproductive therapy procedure, BMI, or maternal indication was not found to be risk factors.
Trial registration number: STPS 3-3013-3234/1

P-743 Are clinical pregnancy and live birth rates comparable to evaluate the effectiveness of Assisted Reproductive Technologies?

F. Lorenzo[1], M.P. Zappacosta Villarroel[2], M.A. Armani[2], J.T. Garcia[2], S. Bouzas[3], A. Valcarcel[3]

[1]IFER, Reproduction, Buenes Aires, Argentina ;
[2]IFER, Reproduction, Ciudad Autonoma de Buenos Aires, Argentina ;
[3]IFER, Biology, Ciudad Autonoma de Buenos Aires, Argentina

Study question: Measuring outcomes: Are clinical pregnancy rate and live birth rate comparable to evaluate the effectiveness of Assisted Reproductive Technologies?
Summary answer: Conclusions on the results of a treatment based on clinical pregnancy or live birth rates as primary endpoints are comparable.
What is known already: The endpoint of an Assisted Reproductive Technology treatment is the live birth of a healthy baby. However, sometimes follow up until live birth is an additional challenge for the investigator, because couples usually return to a local obstetrician for medical care. Moreover, many studies report pregnancy rates instead of live birth rates, but this would underestimate the number of live born babies.
Study design, size, duration: This is an observational restrospective single-centre study that included 2473 women under 40 years old who underwent In Vitro Fertilization fresh embryo transfers, from January 2014 until December 2018. Statistical analysis was performed using the Chi Square test.
Participants/materials, setting, methods: Primary outcome was to compare live birth with clinical pregnancy rate. Live birth rate was defined as the birth of a living baby after embryo transfer. Clinical pregnancy rate was defined by ultrasonographic documentation of at least one fetus with a heart beat at 6-7 weeks of gestation. Secondary outcomes where miscarriage rate (intrauterine pregnancy loss before 20 weeks of gestation), implantation rate (number of gestational sacs observed at vaginal ultrasound/number of transferred embryos).

Main results and the role of chance: This study included 2473 women who underwent In vitro Fertilization fresh embryo transfers, regardless of the number of oocytes collected. Average age was 37,6 ± 2,1 years old. A total of 11351 oocytes were collected (mean 4,6 ± 2,5 SD). An average of 2.1 ± 0,4 embryos were transferred. Clinical pregnancy rate was 18% (452/2473) and live birth rate was 17% (411/2473) p: 0,13. Implantation rate was12% (570/4950). Miscarriage rate was 9 % (41/452).Conclusions on the effectiveness of a treatment based on either clinical pregnancy rate o live birth rate as endpoints are comparable.
Limitations, reasons for caution: This is a restrospective single - centre study.
Wider implications of the findings: As a large number of trials in reproductive medicine report pregnancy rates and data regarding to de future new born may be not be available, clinical pregnancy rate could be an optimal parameter to report assisted reproduction technologies results.
Trial registration number: not applicable

P-744 Setting a tariff for in-vitro fertilisation and intracytoplasmatic sperm injection (IVF/ICSI) in Scotland: a cost analysis

R. Venson[1], A. Maheshwari[2], S.M. Nelson[3], S. Corcoran[4], K.A. Boyd[1]

[1]University of Glasgow, Health Economics and Health Technology Assessment, Glasgow, United Kingdom ;
[2]National Health Service Grampian, Aberdeen Maternity Hospital, Aberdeen, United Kingdom ;
[3]University of Glasgow, School of Medicine, Glasgow, United Kingdom ;
[4]Scottish Government, Maternal & Infant Health, Glasgow, United Kingdom

Study question: What is the full economic cost of IVF/ICSI fresh and frozen cycles accounting for equipment, staff, medication, consumables, and overheads in Scotland?
Summary answer: The average full economic cost of fresh cycles was £3,334. Fresh IVF and ICSI averaged £3,185 and £3,459, respectively. Frozen cycles were cheaper, averaging £872.
What is known already: There is a need for a standardisation of price for IVF/ICSI. There is a lack of published economic studies in this field. IVF/ICSI is a very complex process that includes many different scenarios, which makes the costing process multifaceted and hinders the interpretation of the results. According to benchmarking performed for prices in NHS-England, IVF and ICSI cycles (including a fresh and a frozen cycle) cost £3,100-£3,500 and £3,500-£4,000, respectively; each subsequent frozen cycles should cost around £1,000, however, the published document was not transparent on the methods adopted to estimate these costs, or what costs were included.
Study design, size, duration: Bottom-up costs were calculated using cycle-level resource data from all Centres in Scotland during the period of 01/Jan/2015 to 31/Jul/2018. Whenever micro-costing was not possible due to the nature of the data available, aggregated macro-level data analysis was adopted.
Participants/materials, setting, methods: Anonymised cycle-level data was obtained from the four Scottish Centres that provide NHS-funded IVF/ICSI (cycles between 01/Jan/15-31/Jul/18). Costs were calculated in 2018 UK sterling prices. Resource use were assigned to individual cycles based on cycle-level data or expert-informed assumptions; when this was not available, average aggregate costs were assigned to each cycle. Cycles cancelled at early stages were also included in the analysis. Sensitivity analysis varying the ratio frozen embryo transfer:fresh cycles was performed.
Main results and the role of chance: A total of 9,442 NHS-funded cycles were included in the analysis (Ab: 1,888; Dun: 1,566; Ed: 2,224; Gla: 3,766). The average age was 34.0±4.3 years, with most of the fresh cycles (82%) being for patients below 40 years of age. Approximately 40% were IVF (14% for Gla and 50-70% for the other Centres) with the remaining being ICSI. Fresh cycles comprised 70% (62%-74%) of all cycles, whilst the rest were frozen cycles. The average cost of a fresh cycle was £3,334 (range £1,742-£4,548); with fresh IVF costing £3,185 (range £1,742-£4,000) and a fresh ICSI costing £3,459 (range £1,742-£4,548). Frozen cycles were cheaper, averaging £872 (range £207-£1,032). Cheaper cycles within the presented ranges were cycles cancelled at early stages due to various reasons. On average, 0.46 frozen ET happened for every fresh cycle. This proportion was used to estimate the average cost of a full cycle per patient, which was £3,715. The sensitivity analysis showed that, if all Centres have one frozen embryo transfer for every fresh cycle, the full cycle (1 fresh + 1 frozen) would cost, on average, £4,236.
Limitations, reasons for caution: The main challenge was finding a balance between the costing and incorporating the Centre available data and specific practices. This study was based on typical IVF/ICSI processes, and did not include specialised treatment or cost of adverse events. Assumptions were made throughout the study; these are inherent to costing studies.
Wider implications of the findings: The results presented in this study should serve as a guide to NHS-Scotland to set a tariff in the country. However, decisions made based on this study should be careful, bearing in mind the dynamicity of ART, due to constant changes in procedures and policies and new technologies being adopted.
Trial registration number: not applicable

P-745 The frozen egg's journey, does it change their efficiency?

G. Scaravelli[1], R. De Luca[1], R. Spoletini[1], V. Vigiliano[1], L. Speziale[1], S. Bolli[1], A. Bertini[1], S. Fiaccavento[1]

[1]Istituto Superiore di Sanita, National Centre for Diseases Prevention and Health Promotion, Rome, Italy

Study question: Do the female gametes transportation and cryopreservation process influence the future success or efficiency in a donor ART treatment?
Summary answer: Fresh or frozen egg donor cycles report the same results when combined respectively with FER or with fresh embryo transfer.
What is known already: The debate is still open whether fresh donor eggs are more efficient than frozen ones in an ART treatment. In Italy, since 2012 import and export of gametes and embryos is allowed as ART donor cycles from 2014. Nevertheless, due to the lack of information campaign, and to the prohibition of compensation to donors, we have no donors. Then, all the gametes utilized in Italy in donor cycles are imported from abroad and the majority of them are frozen egg cycles. Some Italian Centers, to utilize fresh eggs, send the semen abroad and import back the embryo for transfer.
Study design, size, duration: The Italian Assisted Reproduction Techniques Register(IARTR) analyzed retrospectively summary data on 11,144 oocytes donation cycles performed from 2017 to 2018 on 9,675 patients. 106 ART clinics sent data on gametes donation cycles to the IARTR and participated in the study with 97 centers (91.5%) performing at least one oocytes donation cycle. A comparison was made on the efficiency of fresh and frozen egg donor cycles also considering fresh or frozen embryo condition at transfer.
Participants/materials, setting, methods: All ART centers which have performed at least one cycle with gametes donation, that have sent data during the study period were included. Parameters regarding number of patients, number of cycles, fresh or cryopreserved ones, treatment indications, age classes, pregnancies, deliveries and live births rates were statistically analyzed using SPSS statistic 25.0. Differences between groups were compared with chi-square test and p-value <0.05 was considered to be statistically significant.
Main results and the role of chance: 97 centers with at least one donor egg cycle participated to the data collection, only 18 were public or private covered by NHS (18.6%). 9675 patients underwent 11144 cycles with egg donation, 8108 cycles (72.8%) were frozen donor eggs cycles and 3036 (27.2%) were fresh. Main indications for treatment with oocytes donation were: maternal advanced reproductive age (36.6%) and reduced ovarian reserve (36.2%). Almost all (97.9%) the oocytes used come from abroad.10414 transfer were performed (93.4% of initiated cycles) with mean age of women at transfer that was 41.6 years. The 98.4% of transfers in fresh donor eggs cycles were frozen embryo replacement (FER), while only the 23.5% in frozen donor eggs cycles. Pregnancy rates per transfer were similar if we compared treatments where only one cryopreservation take place: 35.6% with fresh eggs + FER and 36.4% with frozen eggs + fresh embryos. Cycles utilizing frozen eggs + FER show significantly lower rates 28.1% (p<0.01). Fresh eggs + FER reported significantly higher rates than the other for delivery rates (25.5%, 23.4% and 16.4% respectively) and for live birth rates (25.3%, 23.3% and 16.4% respectively). In these 2 years 2681 children were born alive with egg donation.
Limitations, reasons for caution: this is a retrospective study made with a summary data collection.

Wider implications of the findings: Our results showing slight differences in the outcomes between the group of egg donor cycles fresh or frozen, when only one cryopreservation process takes place i.e. fresh eggs plus FER and frozen egg plus fresh embryo transfer, could suggest new strategies in donor art cycles.
Trial registration number: not applicable

P-746 Probability of a live birth after fertility treatments in female cancer survivors - A Finnish population-based registry study

J. Melin[1], L. Madanat-Harjuoja[2], E. Hirvonen[3], N. Malila[4], J. Pitkäniemi[3], M. Gissler[5], A. Tiitinen[6]

[1]University of Helsinki- Helsinki University Hospital, Department of Obstetrics and Gynecology, Vantaa, Finland ;
[2]Harvard Medical School, Dana Farber Cancer Institute/Boston Children's Cancer and Blood Disorders Center- Boston, Boston- MA, U.S.A. ;
[3]Finnish Cancer Registry, Institute for Statistical and Epidemiological Cancer Research, Helsinki, Finland ;
[4]Finnish Cancer Registry, - Institute for Statistical and Epidemiological Cancer Research, Helsinki, Finland ;
[5]National Institute for Health and Welfare, Information Services Department, Helsinki, Finland ;
[6]University of Helsinki- Helsinki University Hospital, Department of Obstetrics and Gynecology, Helsinki, Finland

Study question: Does the probability of a live birth after ovulation induction (OI) and assisted reproductive technology (ART) with autologous oocytes differ in female cancer survivors compared to siblings?
Summary answer: The probability of a live birth was similar in female cancer survivors and siblings after OI, as well as ART treatments.
What is known already: As survival rates in early onset cancer survivors increase, reaching 80% in Western Europe, this comes at a cost of a risk for adverse late effects. For female cancer survivors these include diminished gonadal function and infertility, which have been reported major concerns for survivors and their family. There are, however, only a few studies available on fertility treatments and following live birth rates in female early onset cancer survivors. In one of them the likelihood of a live birth was reduced after ART with autologous oocytes in survivors compared to siblings.
Study design, size, duration: In this retrospective, register-based study, data from Finnish registers on cancer, birth and prescribed medications were merged to identify 9,092 female cancer survivors (diagnosed with cancer between 1953 and 2012 at the age of 0-39 years) and 10,030 female siblings of survivors.
Participants/materials, setting, methods: Fertility drug purchases in cancer survivors and siblings in 1993-2012, at the age of 20-41 years, were identified from the Reimbursement Register on Prescribed Medicines and live births from the Medical Birth Register. A binomial regression model with log-link function was used to calculate risk ratio (RR) for live births after fertility treatments in survivors and siblings. Fertility drugs were sub-classified into OI and ARTs and we adjusted for attained age and calendar time.
Main results and the role of chance: All in all, 198 (2.18 %) survivors and 269 (2.68 %) siblings were prescribed fertility drugs for OI, whereas for ART treatments the numbers were 173 (1.87 %) survivors and 215 (2.14 %) siblings. The cumulative live birth rate 22 to 48 weeks after fertility drug purchase was 9.1% (OI) and 14.7% (ART) among survivors and 8.2% (OI) and 14.4% (ART) among siblings. After adjusting for attained age and time period of fertility treatment, the probability of a live birth 22 to 48 weeks after fertility drug purchase was similar for survivors and siblings with OI (RR 1.07, 95% CI 0.64-1.78) and ART (RR 1.05,95% CI 0.72-1.52). The probability of a live birth occurring over 48 weeks after fertility drug purchase was also similar among survivors and siblings, for OI as well as for ART-treatments.
Limitations, reasons for caution: In this study, information on the indication for fertility treatment was unavailable and only fertility treatments with autologous oocytes were included. For live births occurring over 48 weeks after the fertility treatment, it is impossible to conclude whether they were the result of a spontaneous pregnancy or a fertility treatment.
Wider implications of the findings: For those cancer survivors, who were offered and opted for fertility treatments, the probability of live birth after OI or ART was similar compared to siblings. Today, personalized oncofertility counselling before and after gonadotoxic cancer treatments is considered standard care. This includes an evaluation of the fertility before planning pregnancy.

P-747 Laparoscopic ovarian drilling for ovulation induction in women with anovulatory polycystic ovary syndrome – a cochrane review

E. Bordewijk[1], K.Y.B. Ng[2], L. Rakic[1], B.W.J. Mol[3], J. Brown[4], T.J. Crawford[4], M. Van Wely[1]

[1]Amsterdam UMC- University of Amsterdam, Center for Reproductive Medicine, Amsterdam, The Netherlands ;
[2]University of Southampton, School of Human Development and Health, Southampton, United Kingdom ;
[3]Monash University, Department of Obstetrics and Gynaecology, Clayton, Australia ;
[4]The University of Auckland, Liggins Institute, Auckland, New Zealand

Study question: To evaluate the effectiveness and safety of laparoscopic ovarian drilling (LOD) for women with anovulatory PCOS and CC-resistance.
Summary answer: LOD may decrease live birth slightly when compared with medical ovulation induction alone.
What is known already: Polycystic ovary syndrome (PCOS) is a common condition affecting 8-13% of reproductive-aged women. Clomiphene citrate (CC) or letrozole are first line treatments. Women who are CC-resistant or do not respond on letrozole, can be treated with gonadotrophins or other medical ovulation induction agents. These medications are not always successful, can be time-consuming and can cause adverse events like multiple pregnancies. LOD is a surgical alternative to medical treatment. There are risks associated with surgery, such as complications from anaesthesia, infection, and adhesions. This review aimed to determine its benefits and risks.
Study design, size, duration: This is an Cochrane review. We searched the Cochrane Gynecology and Fertility Group trials register, CENTRAL, MEDLINE, Embase, PsycINFO, CINAHL and two trials registers in October 2019 for relevant randomised controlled trials (RCTs), and checked references and contacted study authors in the field to obtain additional data.
Participants/materials, setting, methods: Women with anovulatory PCOS who underwent LOD as secondary treatment, with or without medical ovulation induction versus medical ovulation induction alone were included. We used standard methodological procedures as recommended by Cochrane for our search, data extraction, and analyses. The primary outcomes were live birth and multiple pregnancy. Pregnancy, miscarriage, OHSS, ovulation, and costs were secondary outcomes. We conducted subgroup analyses for the different medical ovulation induction agents.
Main results and the role of chance: This review includes 41 RCTs. We found LOD may decrease live birth slightly when compared with medical ovulation induction alone (OR 0.75, 95% CI 0.59 to 0.95; 1264 women; 10 studies; I^2 = 0%, *low quality evidence*), but according to the sensitivity analysis restricted to only RCTs with low risk of selection bias there is uncertainty whether there is a difference between the treatments (OR 0.93, 95% CI 0.67 to 1.30; 675 women; 5 studies; I^2 = 0%, *low quality evidence*). In absolute terms this implies that if the chance of live birth following medical ovulation induction alone is 37%, the chance following LOD would be between 28% and 43%. For pregnancy data suggested little or no difference (OR 0.88, 95% CI 0.75 to 1.03, I^2 = 0%; *low quality evidence*).

LOD probably reduces multiple pregnancy (OR 0.30, 95% CI 0.15 to 0.59; 1519 women; 16 studies; I^2 = 0%; *moderate quality evidence*). There is uncertainty about the effect on miscarriage (OR 1.11, 95% CI 0.80 to 1.54; 2349 women; 22 studies; I^2 = 0%; *low quality evidence*)). LOD reduced OHSS (peto OR 0.24, 95% CI 0.07 to 0.86; 1262 women; 10 studies; I^2 = 0%; *low quality evidence*).
Limitations, reasons for caution: The evidence was of very low to moderate quality: the main limitation was poor reporting of study methods. The main reasons for downgrading evidence were lack of details to be able to judge risk of bias (randomisation and allocation concealment) and lack of blinding.
Wider implications of the findings: LOD is an effective alternative to medical treatment, but more evidence is required to determine the impact of

LOD on live birth in women with anovulatory PCOS and CC-resistance compared with medical ovulation induction alone. Future RCTs are advised to include adverse effects, cost analyses and consumer satisfaction.
Trial registration number: not applicable

P-748 Intrauterine infusion of platelet-rich plasma after hysteroscopic adhesiolysis is a new treatment method for patients with intrauterine adhesions after hysteroscopy

J. Peng[1], M. Li[1], Z. Zeng[1], H. Zeng[1], J. Huang[1], X. Liang[1]
[1]The Sixth Affiliated Hospital of Sun Yat-sen University, Reproductive Medicine Research Center, Guangzhou, China

Study question: To evaluate the efficacy of an intrauterine infusion of platelet-rich plasma for the prevention of recurrent adhesions and the promotion of endometrial repair after hysteroscopy in patients with intrauterine adhesions.
Summary answer: Intrauterine infusion of PRP is a new treatment method in the management of patients with IUAs after hysteroscopic adhesiolysis
What is known already: Intrauterine balloon is one of the most important methods to prevent recurrent IUAs.
Study design, size, duration: This is a retrospective study, and three groups from 2018 to 2019 were included in this study: (1) intrauterine infusion of PRP after the first operations (group A);(2) intrauterine balloon after the first operations (group B) ;(3) both intrauterine infusion of PRP and intrauterine balloon after the first operations (group C). All patients were with severe or moderate IUAs.
Participants/materials, setting, methods: Thirty-eight patients in group A, thirty-two patients in group B and twenty-four patients in group C were included. The second-look hysteroscopy and the third-look hysteroscopy were performed one week after the first operation and during the next menstrual cycle respectively. AFS scoring system was used to judge the grade of the IUAs. Embryo transfer would be performed and serum β-HCG would be tested 12 or 14 days later.
Main results and the role of chance: In our study, 28 patients in group A, 22 patients in group B and 20 patients in group C received the third-look hysteroscopy. The mean AFS score decreased from 7.93±1.60 in the first hysteroscopy to 2.75±1.40 in the third hysteroscopy in group A, from 8.09±1.86 to 3.18±1.75 in group B, and from 8.20±1.63 to 3.05±1.63 in group C, respectively. No significant differences were found among these groups neither in the first operations (P>0.05) nor in the last operations (P>0.05) . The pregnancy rates were 40.0% (6 patients with positive β-HCG among 15 patients) in group A, 38.9% (7 patients with positive β-HCG among 18 patients) in group B and 33.3% (3 patients with positive β-HCG among 9 patients) in group C (P>0.05).
Limitations, reasons for caution: This is a retrospective study, and the conclusion of the study should be proved by RCTs.
Wider implications of the findings: Intrauterine infusion of PRP is a new treatment method for IUAs and it can be a substitute for intrauterine balloon.
Trial registration number: not applicable

P-749 Tubal infertility in advanced age- Are fallopian tubes still valuable to exist?

X. Yu[1], J. Guan[1]
[1]Reproductive Center, Beijing university People's hospital, beijing, China

Study question: We explored the optimal management for tubal infertile patients in advanced age with low reproductive prognosis
Summary answer: IVF compared with surgery demonstrates higher ongoing pregnancy rate in the setting of three or more follicles, especially for those younger than 40 years.
What is known already: Women of advanced age may have mild mechanical tubal factors which are more prevalent as age increases, and the co-exist reason for their infertility is reduced oocyte quantity and quality.
Study design, size, duration: Women (≥35 years old) with diminished ovarian reserve parameters who underwent IVF or tubal repair surgery from September 2016 and September 2017 was followed prospectively 12 months to determine the proportions of women undergoing the two procedure who became pregnant and who had ongoing pregnancy live.
Participants/materials, setting, methods: Ongoing pregnancy, clinical pregnancy, miscarriage and ectopic pregnancy rates per couple were compared for patients with IVF (n=95) versus tubal operation (n =39), and were stratified based on the female age and number of follicles triggered in IVF cycle.
Main results and the role of chance: Ongoing pregnancy rate per couple after IVF or tubal laparoscopy were similar (25.3 % vs.12.8 %, respectively). Ongoing pregnancy rates for patients aged 35-40 were significantly higher in IVF treatment compared with surgery when at least 3 follicles were present (46.7 % IVF vs.11.8 % surgery, $P<0.01$). No benefit was gained by pursuing IVF in the setting of one or two follicles. In patients >40 years, once again, there was little benefit gained when proceeding IVF as opposed to tubal surgery.
Limitations, reasons for caution: The limitation of this study is its retrospective nature. With extremely low pregnancy rates in tubal infertile patients with advancing age, a prospective study could be difficult for the large size of samples.
Wider implications of the findings: Tubal stage, as the important factor in the prognosis for success after surgical repair should be considered.
Patients with severe tubal pathologies and low ovarian response are urged to proceed IVF.
Trial registration number: no

P-750 Uterine rupture during pregnancy and succeeding fertility: The URIDA (uterine rupture international data acquisition) study

I. Kosmas[1], A. Tinelli[2], J. Carugno[3], O. Mynbaev[4], A. Malvasi[5], A.S. Laganà , for the URIDA study group[6]

[6]"Filippo Del Ponte" Hospital- University of Insubria, Department of Obstetrics and Gynecology, Varese, Italy

Study question: The aim of this study is to specify the peripartum outcomes of patients with uterine rupture (UR) during pregnancy, and to estimate outcomes of subsequent pregnancies.
Summary answer: UR is a catastrophic event for mother and fetus, if the early diagnosis is missed. Otherwise, the outcomes are satisfactory even for a future pregnancy.
What is known already: Uterine rupture may take place in a healthy uterus, as in uterus that had undergone previous surgery, like myomectomy, laparoscopic salpingectomy and cesarean section (CS). This happens at 2nd and 3rd trimester of pregnancy. No data exist, except case reports about future fertility outcomes.
Study design, size, duration: This is a multi-center retrospective analysis. 270 women with complete rupture that took place at least in the last 15 years and followed for at least 5 years, was included in the analysis. Patients without a complete uterine rupture in pregnancy have been excluded.
Participants/materials, setting, methods: Women from 18 to 50 years old that diagnosed for uterine rupture during pregnancy, at 14 large gynecological centers through the world, were included. Data have been extracted and sent to the principal investigator. An independent statistician has examined the data. Demographic information, surgical history, symptoms and postoperative outcome for mother and the neonate has been recorded. Collection of the data has been performed in one year
Main results and the role of chance: 36 women had no history of surgery. Most recorded surgeries were a previous Cesarean Section (n = 113), abdominal (n = 10) or laparoscopic myomectomy (n = 9). Certain patients (n=5) had a second surgery along with the first one.

Subserosal fibroids on 25 patients with uterine rupture and 62 fibroids on the lower uterine segment are the most frequent fibroids operated. A rupture took place after resectoscopic myomectomy, in just 159 days of pregnancy. In laparotomic and laparoscopic myomectomy, rupture took place at 253 ± 52.35 and

251.22 ± 52.9 days respectively, and for patients with no previous surgery at 257.69 ± 43.15 days. Overall mean time was at 37, 32 ± 5, 09 weeks of pregnancy.

Many pregnancies delivered after 260 days (37 ± 14 weeks) of pregnancy. The birth weight was at 3106, 4 ± 653, 75 gr.

174 pregnancies conceived after uterine rupture, spontaneously in 169 women and in 5 by assisted reproductive techniques (ART). No data existed for 16 of them. 142 women delivered by CS, 13 delivered vaginally, 2 needed a vacuum extractor. The indications for CSs was twin pregnancy, cephalopelvic disproportion, emergency and placenta abruption.

Limitations, reasons for caution: This is a retrospective study, but from the other side it is a large multi-center investigation (one of the largest retrospective studies performed until now),that took place at hospital environment and by specialized personnel. The centers involved, were widespread through the world thus increasing the accuracy of the study.

Wider implications of the findings: Fertility preservation after UR is feasible with many patients to conceive spontaneously or by ART. Most of them had a CS, but a small number of them attempted and succeeded a vaginal delivery. Delivery time and birth weight in this pregnancy seems not to be affected from the previous rupture.

Trial registration number: NCT03576950

P-751 Usefulness of office hysteroscopy (OH) in patients with recurrent implantation failure (RIF)

G. Botti[1], L. Solari[1], C. Nazario[1], C. Morente[1], M.E. Mackey[2]

[1]PROAR, Videoendoscopy, Rosario, Argentina ;
[2]PROAR, Bioestatistical, Rosario, Argentina

Study question: Is OH a useful tool in the evaluation of uterine cavity in RIF patients? Does it improve the pregnancy rate in subsequent IVF/ICSI cycles?

Summary answer: OH is a useful, safe, fast tool in trained hands and well tolerated in RIF patients, with good pregnancy rates in subsequent IVF/ICSI cycles

What is known already: The success rate of IVF/ICSI remains low and many women must undergo multiple treatment cycles to achieve a pregnancy.. Several studies suggested OH could improve outcomes in women with RIF. TROPHY trial showed that OH before IVF/ICSI in women with RIF doesn´t improve the live birth rate, however in the literature there is some evidence of benefit from OH in this kind of patients showing increased pregnancy rates in subsequent IVF/ICSI cycles, both in those with normal and abnormal hysteroscopic findings.

Study design, size, duration: This is a cohort retrospective study

We performed OH in 84 RIF patients from july 2015 to june 2019

We define RIF as patients with two or more transfers of one blastocyst or two 72 hrs embryos.

A new embryo transfer cycle was done within six months afther OH.

Participants/materials, setting, methods: The procedures were done in PROAR Videoendoscopic Department, by the same operator (LS) in a vaginoscopic approach without anesthesia. We used a Bettocchi set and saline solution as a distention media.

All procedures were video recordered.

An endometrial biopsy was taken with a Pipelle cannula for anatomo-pathologic study.

OH was performed in early folicular phase or at any moment of the cycle in patients using oral contaceptives. The mean time of the procedure was 4,25 minutes (range: 2.20-8.45)

Main results and the role of chance: Four out of 84 OH were discontinued because of cervical stenosis.

In the remaining 80 patients we found 53 normal cavities (66%) and 27 abnormal (34%): 7 sinequiae, 4 adenomyosis, 2 polyps and 14 chronic endometritis (CE) confirmed with the presence of plasmocytes in the endometrial biopsy.

All patients with CE were treated with doxycycline (200mg daily for 14 days). We confirmed healing with a new biopsy in the next cycle.

Only one patient had a complication (vaso-vagal syndrome)

Pregnacy rates after OH were: 43% in normal cavities (23/53) and 52% in abnormal cavities (14/27).

Pregnancy rates in patients with pathologic findings were 28% in sinequiae (2/7), 25% in adenomyosis (1/4), 50% in polyps (1/2) and 71% in CE (10/14)

Limitations, reasons for caution: This is a retrospective study with a low number of cases.

Table 1: Diagnosis and pregnancy rates after OH

	PATIENTS	PREGNANCIES	PREGNANCY RATE	IC 95%
	n %	n	%	
NORMAL	53 66	23	43	(27.9-57.7)
ABNORMAL	27 34	14	52	(31.9-71.3)
- CE	14	10	71	(41.9-91.6)
- OTHERS	13	4	31	(9.1-61.4)
TOTAL	80	37	46	

CE was diagnosed with an anatomo-pathological criteria (plasmacytes presence in the endometrial biopsy sample). A more accurate method like flow cytometry analysis could improve CE diagnosis.

Wider implications of the findings: After OH we obtained high pregnancy rates in patients with CE and antibiotic treatment and also in patients with normal hysteroscopic findings.

Randomized controlled trials are needed before it routine use in general subfertile or RIF patients can be recommended

Trial registration number: Not applicable

P-752 what factors could predict recovery of serum anti-Mullerian hormon levels within 6 months after laparoscopic cystectomy for ovarian endometriomas

D. DAT[1], N. Ha[2], T. Phan[1], T. Anh duc[3], N.K. Toan[1]

[1]Hanoi Obstetrics and Gynecology Hospital, Gynecology Department, Hanoi, Vietnam ;
[2]Hanoi Obstetrics and Gynecology Hospital, ART center, Hanoi, Vietnam ;
[3]Hanoi Obstetrics and Gynecology Hospital, Obstetrics Department, Hanoi, Vietnam

Study question: This study aims to investigate the predictive factors that may be involved in the recovery of serum anti-mullerian hormone (AMH) levels within 6 months after laparoscopic cystectomy for ovarian endometriomas.

Summary answer: The decrease of AMH can recover after 6 months, the rate of reduction 1 month post-surgical AMH levels might predict AMH levels recovery.

What is known already: Study design, size, duration: A prospective longitudinal study was done with 104 patients undergoing laparoscopic cystectomy for unilateral endometriomas (n=77) and bilateral endometriomas (n=27). Serum AMH level was measured before surgery, at 1 month and at 6 months after surgery. Patients with serum AMH levels at 6-months higher than at 1-month after surgery were considered recovery. Many factors were assessed to find out the association with recovery of serum AMH level.

Participants/materials, setting, methods: A prospective longitudinal study

Main results and the role of chance: 52 patients (50%) showed higher AMH levels at 6 months than at 1 month after surgery (increase group) and 52 patients (50%) showed lower AMH levels (decrease group). Many factors as age of patients, the number side of ovary with endometriomas, size of endometriomas, ASRM score, duration of surgery, pre-surgical AMH level and rate of reduction AMH level (rAMH) at 1 month after surgery were analyzed and we found only statistically significant difference in rAMH at 1 month after surgery between two groups. The optimal cut-off point of rAMH at 1month for predicting AMH levels recover at 6 months after surgery was 52.77% in the patients undergoing unilateral cystectomy, 84.54% in the patients undergoing bilateral cystectomy.

Limitations, reasons for caution: no limitation

Wider implications of the findings: in the literature, there were many research in this field but still controversy

Trial registration number: not applicable

P-753 Post Implantation failure diagnostic Hysteroscopy with Endometrial Fundus Incision (FEI) might improve pregnancy outcome in oocyte recipients

E. Papanikolaou, MD- PhD[1], R. Najdecki[1], F. Chouliara[1], P. Tatsi[1], T. Chartomatsidou[1], F. Pakaki[1], S. Stamataki[1], C. Ioakeimidou[1], A. Timologou[1], C. Vlachou[1], A. Diamantopoulos[1], A. Virgiliou[2], P. Kaminski[3], A. Athanasiadis[2], E. Timotheou[1]

[1]Assisting Nature- Center of Reproduction & Genetics, Assisting Nature, Thessaloniki, Greece ;
[2]Aristotle University of Thessaloniki, 3rd Department Ob Gyn, Thessaloniki, Greece ;
[3]Military Institute of Medicine, Ob Gyn, Warsaw, Poland

Study question: To investigate whether hysteroscopic evaluation of the uterine cavity post implantation failure and FEI can improve pregnancy outcome in oocyte recipients.
Summary answer: Live Birth rate is higher in oocyte recipients, undergoing diagnostic Hysteroscopy compared to those who do not, after implantation failure, although not statistically significant.
What is known already: Implantation failure in oocyte recipients is devastating as the majority of them have previously undergone several failed IVF procedures, and therefore a new failure is difficult to be accepted. Appropriate evaluation of the uterine cavity is then of paramount importance and some advocate uterine scratching even in the presence of normal cavity.
Study design, size, duration: Between 2014-2019, 218 egg recipients underwent egg donation without hysteroscopy. Those who did not achieve live birth and had surplus embryos cryopreserved had a second chance by transferring in a subsequent frozen cycle these embryos. These patients were divided in two groups; **Hysteroscopy group (n=33)**: women who underwent hysteroscopy (Storz Bettocchi 5mm) prior to the 2nd embryo transfer (ET) and **Non- Hysteroscopy group (n=59)**: women who did not undergo hysteroscopy prior to the 2nd ET.
Participants/materials, setting, methods: The age of the studied oocyte recipients ranged from 35-50 years old. The rate of those who did not achieve a live birth at the 1st ET was 57.8% (n=126) and ninety-two of them had a second frozen-thawed ET. These patients underwent double blastocyst ET, unless only one cryopreserved blastocyst was still available. Women who had hysteroscopy before the 2nd ET all underwent FEI with endoscopic scissor irrespectively of the presence of pathology or not.
Main results and the role of chance: Among women of the Hysteroscopy group 20 were diagnosed with U2a (partial septate, arcuate uterus), whereas 13 were diagnosed with normal uterine cavity. The rest 59 recipients of the Non- Hysteroscopy group underwent a 2nd ET without hysteroscopy first. Live Birth rate was higher in the hysteroscopy group at a rate of 39,4% (n=13/33), compared to the non-hysteroscopy group 27,1% (n=16/59), although not statistically significant (p=0.087). Our current results with oocyte recipients indicate that once hysteroscopy is performed after implantation failure, a significant proportion of arcuate uterus is diagnosed and thus treated and second, that pregnancy outcome is improved after FEI irrespectively to the presence of arcuate uterus (U2a) or not (U0) with endoscopic scissor can improve pregnancy outcome
Limitations, reasons for caution: A larger sample size in both groups should provide more solid evidence regarding the impact of diagnostic hysteroscopy and FEI on the pregnancy outcome. Moreover, the interval time between the hysteroscopy and the subsequent ET, as well as the embryo quality of the 2nd choice embryos, should also be considered.
Wider implications of the findings: Although hysteroscopy with or without uterine scratching before embryo transfer, has not been universally accepted, clinical results indicate a different reality. The results of the current study indicate a potential correlation between FEI and pregnancy outcome. Further studies are required to confirm the above findings in larger groups.

POSTER VIEWING SESSION
SAFETY AND QUALITY OF ART THERAPIES

P-754 Interventional ultrasound : standardisation of ultrasound guided Embryo Transfer (ET) in Medically Assisted Reproduction (MAR) Treatment

C. Panayotidis[1], O. Amototsero[2], N. Vermeulen[3], A. D'Angelo[4]

[1]Gynaecology, Isle of Wight, Isle of Wight, United Kingdom ;
[2]Cardiff University, University Hospital of Wales, Cardiff, United Kingdom ;
[3]ESHRE, Central office, Brussels, Belgium ;
[4]Wales Fertility Institute, University Hospital of Wales-, Cardiff, United Kingdom

Study question: Identify what could be the standards for USS guided ET in MAR
Summary answer: Proposed standards of practice that the ESHRE Ultrasound working group could consider for the developing good clinical practice on how to perform Ultrasound guided ET
What is known already: There are not many papers evaluating the technical aspects of ultrasound guided ET. There is a striking heterogeneity on ET techniques and particular on the role of ultrasound settings during the procedure.
Study design, size, duration: The study design included two steps: search for existing evidence through literature search and a Delphi method survey. The Delphi survey was carried out among 12 expert specialists on embryo transfer technique , using a 73 questions questionnaire completed in two rounds achieving a consensus for recommendations on ET practice.
Participants/materials, setting, methods: Experts in MAR were selected from a database of experts created by ESHRE as a result of a survey previously circulated. Delphi survey method was used for 2 round survey fousing on the following area: patient set up , ET preparation materials, ultrasound settings, ultrasound ET technique, prevention of complications and assessment of effective ET performanceLiterature review of relevant papers with emphasis on the ET technique and optimal ultrasound settings during the ET were retrieved.
Main results and the role of chance: Recommendations on practice were formulated based on the literature review and the expert opinions. This first consensus of the expert group included recommendation on patient set up, ET preparation materials, ultrasound settings, ultrasound ET technique, prevention of complications and assessment of effective ET performance. The majority (>55%) of experts use: trans-abdominal ultrasound with the help of a trained assistant, clean the cervical plug using cotton swabs, use mostly soft catheters and if need they propose stylet catheters as an alternative. Most of the experts consider factors that negatively influence the success of the ET if intrauterine fluid is visualised prior ET, blood clot visualised during ET, uterine malformation, uterine caesarean section scar, excessive cervical mucus abnormal uterine cavity length. Experts consider complications to be associated with ET when cervical trauma occurs and least as a result of an infection. The use of bubbles to mark the embryo during the ET was predominant in their practice. Variation on ultrasound settings are analysed in regards image optimisation. These proposed standards on practice can now be presented and discussed by ESHRE aiming to be implemented in clinical practice through the publication of a clinical guideline.
Limitations, reasons for caution: Consider limitations on Delphi survey technique, consensus of expert opinions can be a starting point to discuss further what can represent the best ET practice in 2020. Further Survey rounds may be needed and the established ESHRE methodology for guideline production should be applied
Wider implications of the findings: This is the first European survey of ESHRE on USS guided ET technique aiming to formulate recommendations for good clinical practice on how to perform ET with optimal use of ultrasound technology. These recommendations will produce clinical standards in MAR enhancing the effectiveness of ET in increasing clinical pregnancy rates.

P-755 Do medical assisted reproduction and female infertility impact the risk of imprinting disorders in singletons? A longitudinal national French study

P. Fauque[1,2], G. Viot[3], D. Aviva[4], F. Pessione[5], A.W.C.H. ABM-working group[6]

[1]Centre Hospitalo-Universitaire, Laboratoire de Biologie de la Reproduction-CECOS, Dijon, France ;
[2]INSERM, Unit 1231, Dijon, France ;
[3]Clinique de La Muette, Unité de Génétique, Paris, France ;
[4]Centre Hospitalo-Universitaire, Centre d'assistance médicale à la procréation, Amiens, France ;
[5]Agence de la biomédecine, Direction médicale et scientifique, Paris, France ;
[6]Agence de la biomédecine, Groupe de travail: suivi des femmes et des enfants en AMP, Paris, France

Study question: Do medical assisted reproduction and female infertility (i.e. endometriosis, polycystic ovary syndrome [PCOS] and primary ovarian insufficiency [POI]) increase the risk of imprinting disorders in singletons?
Summary answer: The risk of imprinting disorders was increased in children conceived after fresh embryo transfers or from mothers with endometriosis, especially for neonatal diabetes mellitus (NDM).
What is known already: Epidemiological studies suggest that singletons born from assisted reproductive technologies (ART) have a higher risk of adverse perinatal outcomes, specifically for imprinting disorders. Because ART manipulations and processes take place at times when epigenetic reprogramming and imprinting are occurring (i.e. during female gametogenesis and preimplantation embryo development), there is concern that ART can induce adverse epigenetic effects and affect the establishment/maintenance of genomic imprints. However, little is currently known about the risk of imprinting defects according to the type of ART or the type of underlying female infertility.
Study design, size, duration: Using data from the French National System database (SNDS), we conducted a comparative analysis of all singleton births (deliveries ≥22 weeks of gestation and/or >500g of birthweight) that occurred in France over a 5-year period (2013-2017) resulting from fresh embryo or frozen embryo transfers (fresh-ET or FET from IVF/ICSI cycles), intrauterine insemination (IUI) and natural conceptions (NC). Data was available for this cohort of children at least up to early childhood (mean 2.5 years old).
Participants/materials, setting, methods: A total of 3,501,496 singleton births were included (including 20,218 from IUI, 45,303 from fresh-ET; 18,885 from FET). Data were extracted from national health databases. We monitored syndromes/diseases involving imprinted genes: Beckwith-Wiedemann's, Silver-Russell's, Prader-Willi's and Angelman's syndromes, pseudohypoparathyroidism, NDM, syndromes affecting the imprinted region of chromosome 14q32, neuroblastoma and retinoblastoma. Univariate and multivariate analyses were performed with multiple logistic regression models to analyse the effect of ART conception and the effect of female infertility (endometriosis/PCOS/POI).
Main results and the role of chance: In our cohort of children, the prevalence of imprinting-related diseases was 0.10% after NC, 0.16% after fresh-ET, 0.12% after FET, and 0.11% after IUI. Compared with infants conceived naturally, children born after fresh-ET had a significantly higher prevalence of imprinting diseases, with an aOR of 1.43 [95%CI 1.13–1.81, p=0.003]. In particular, in univariate analysis, we observed a significant increase in the number of cases of NDM in the fresh-ET group compared with the NC group. This increased risk of NDM was confirmed in multivariate analysis (1.96 aOR [95%CI 1.43–2.70], p<0.0001), even when the type of female infertility was taken into account (1.58 aOR [95%CI 1.13–2.21], p=0.008). The overall risk of imprinting disorders was similar in the IUI group, the FET group and the NC group, as well as for specific imprinting-related diseases. There was an overall independent increase in risk of imprinting diseases for children with mothers diagnosed with endometriosis (1.38 aOR [95%CI 1.06–1.80], p=0.017). Specifically, whatever the mode of conception, the NDM risk tended to be higher for children conceived by women with endometriosis (1.47 aOR [95%CI 1.00–2.16], p=0.051). On the contrary, the children of women with POI and PCOS had no particular significant epigenetic risk.
Limitations, reasons for caution: For some extremely rare syndromes, the sample size may be too small reliably conclude that there was no difference between groups. The underlying molecular mechanisms were not known.
Wider implications of the findings: The increased perturbations in genomic imprinting could be caused by controlled ovarian hyperstimulation (and potentially endometriosis) through the impairment of endometrial receptivity and placentation, leading to epigenetic feto-placental changes. These novel findings highlight the importance of considering the mode/process of conception and the infertility context in children health follow-up.
Trial registration number: Not applicable

P-756 Preparing the endometrium with natural cycles protects patients from an increased risk of adverse obstetric and neonatal outcomes after frozen-thawed embryo transfer

C. Li[1], X. Jing-Jing[1], W. Yan-Ting[1], H. He-Feng[1]

[1]International Peace Maternity and Child Health Hospital- School of Medicine-Shanghai Jiao Tong University, Department of Reproductive Medicine, Shanghai, China

Study question: To explore the association between different endometrial preparation protocols and adverse obstetric and perinatal complications in patients after frozen embryo transfer (FET).
Summary answer: Preparing the endometrium with natural cycles could prevent the increased risk of pregnancy-related complications and the increased risk of adverse neonatal outcomes after FET.
What is known already: Previous studies have focused on pregnancy outcomes after FET performed using different endometrial preparation protocols. Few studies in the literature have evaluated the effect of endometrial preparation on pregnancy-related complications, especially in ovarian stimulation protocols.
Study design, size, duration: This retrospective cohort study included all FET cycles (n=12,950) performed between 2010 and 2017 in our hospital.
Participants/materials, setting, methods: All FET cycles were categorized into three groups according to the endometrial preparation protocol. Pregnancy-related complications and subsequent neonatal outcomes were compared among groups using multilevel logistic regression.
Main results and the role of chance: Among all 12,951 FET cycles, the live birth rate was slightly lower for HRT cycles than for natural cycles (28.15 vs. 31.16%, p<0.001). The pregnancy loss rate was significantly higher in ovarian stimulation (OS) or hormone replacement therapy (HRT) cycles than in natural cycles (NC vs. OS vs. HRT: 10.89% vs. 16.44% vs. 17.14%). Among women with live birth, preparing the endometrium using OS or HRT protocols increased the risk of preeclampsia, and ICP was found in both singleton and multiple deliveries. Additionally, OS and HRT protocols increased the risk of LBW and SGA in both singletons and multiples after FET.
Limitations, reasons for caution: As a hospital-based study, several confounders related to medical procedures have been taken into consideration. However, it is not possible to rule out unknown confounders. Bias induced by patients' favor for different endometrial preparation protocols is another inevitable limitation due to the retrospective design.
Wider implications of the findings: Caution is warranted when using OS or HRT protocols due to the increased risk of gestational hypertension, preeclampsia, and ICP as well as the risk of LBW and SGA.
Trial registration number: Not applicable

P-757 Relationship between number of oocytes retrieved and multiple pregnancies

"Abstract withdrawn by the authors"

P-758 How to reduce risk of genetic disease in gamete donor children

H. Hjalgrim[1], S. Timshel[2]

[1]Amplexa, Amplexa Genetics, Odense, Denmark ;
[2]European Sperm Bank, Copenhagen, Denmark

Study question: Can we prevent the birth of donor children with autosomal recessive disorders by genetically matching the donor and recipient, prior to fertility treatment?
Summary answer: It is possible to reduce the risk of genetic diseases in gamete donor children by routinely offering genetic matching.
What is known already: Every individual carries a number of abnormal variants in genes associated with autosomal recessive diseases. Even if most sperm banks screen their donors for the most common of these, donor children are still born with autosomal recessive diseases. This will only happen if both donor and recipient carry variants in the same genes. Screening of gamete donors varies highly in both extent and quality of the genetic tests. Only a few sperm banks recommend genetic testing of the recipient and even fewer offer matching of donor and recipient.
Study design, size, duration: A case report and series study based on genetic reports of children born with autosomal recessive diseases from European Sperm Bank (ESB) donors January 1st, 2012- December 31st, 2019. Furthermore, results of all donor-recipient genetic matches performed for a consecutive 15 months period (September 1st, 2018 – December 31st, 2019).
Participants/materials, setting, methods: Genetic reports from ESB donor children with autosomal recessive diseases diagnosed in the mentioned period. Carrier status subsequently confirmed in donor.

Recipients of donor sperm from ESB are screened at Amplexa Genetics with GeneXmatch, a customized targeted NGS gene panel, including app. 400 autosomal recessive genes. The recipients are matched against similar genetic data from their chosen donor. A no-match is reported as such when donor and recipient carry variants in the same genes.

Main results and the role of chance: *Main results:*

During the observation period sperm from ESB donors gave rise to app. 30.000 reported births. ESB received genetic reports from 23 children born with documented autosomal recessive diseases, where the sperm donor subsequently proved to be a carrier of the variant in question. GeneXmatch has been an option from September 1st, 2018; 17% of matches were no-matches, prompting the recipient to choose another donor. If GeneXmatch had been an option from 2012, the birth of 17 of the 23 reported children with autosomal recessive disease could have been prevented.

Role of chance: In all the reported 23 cases, the donors were proved to be carriers of pathogenic variants found in the donor children. The number of no-matches would probably have been higher had the donors not been screened for and excluded if carriers of cystic fibrosis, congenital deafness and spinal muscular atrophy.

Limitations, reasons for caution: The findings represent a minimum – not all children born with a genetic disease are reported to the respective sperm banks. Furthermore, not all children with a congenital disease are offered genetic testing.

Wider implications of the findings: To reduce the number of children born with autosomal recessive disorders from gamete donors, genetic matching between donor and recipient should be offered routinely. Genepanels for this should be high quality, cover autosomal recessive disorders with carrier frequencies above 1/100, well recognized geno-phenotype correlation with high penetrance and early onset.

Trial registration number: not applicable

P-759 Associations between meteorological perturbation, ambient air pollution and outcomes during ART treatment

J. Liu[1], M. Zhao[2], H. Zhang[3], J. Zhao[1], H. Kong[1], M. Zhou[1], Y. Guan[1], T.C. Li[2], X. Wang[1], D.Y.L. Chan[2]

[1]Third Affiliated Hospital of Zhengzhou University, Reproductive Medicine Center, Zhengzhou, China ;
[2]Faculty of Medicine- The Chinese University of Hong Kong, Assisted Reproductive Technology Unit- Department of Obstetrics and Gynaecology-, Hong Kong, China ;
[3]School of Sun Yat-sen University, Data and Computer Science, Guangzhou, China

Study question: Are meteorological perturbation and air pollution related to the outcome of IVF?

Summary answer: The implantation and clinical pregnancy is affected by temperature perturbation, however, not affected by air pollution during ART treatment in the reported area.

What is known already: Meteorology may affect IVF pregnancy rate. Air pollution may reduce IVF pregnancy rates and live births and increase miscarriage rates. At the same time, the risk of adverse obstetrics may be increased. However, the impact of meteorological perturbation and air pollution on IVF treatment outcomes is inconclusive in a few published articles.

Study design, size, duration: Retrospective cohort study of 6967 fresh, autologous IVF cycles for the first time at the Reproductive Medicine Center of the Third Affiliated Hospital of Zhengzhou University was performed between 2015.10 and 2018.12.

Participants/materials, setting, methods: Meteorological and air pollutant data came from China's relevant official website (http://data.cma.cn/) (http://106.37.208.233:20035/). The exposure was divided into 4 periods: gonadotropin (Gn) injection to oocyte retrieval (OR) (P1), OR to embryo transfer(ET) (P2), one day after ET to ET +14 days (P3), Gn injection to ET +14 days (P4). Multivariate logistic regressions were used to estimate the association between interquartile increases in variables and reproductive outcomes. Adjust other parameters that affect IVF treatment outcomes.

Main results and the role of chance: The mean age and BMI were 31.52±4.92 years and 23.30±3.23kg/cm^2. Meteorological parameters included average surface temperature, daily highest surface temperature, daily lowest surface temperature, average pressure, average relative humidity, sunshine hours and average temperature. Air pollutant parameters included CO, NO2, OPM10, PM2.5 and SO2. The effect of daily lowest surface temperature on implantation and clinical pregnancy was confirmed by multivariate analysis. Compared with women exposed to Q1 of daily lowest surface temperature, women exposed to Q4 period had highest probability of implantation and clinical pregnancy rates during P1 (a OR 1.26, 95% CI 1.08–1.46 for implantation; a OR 1.26, 95% CI 1.08–1.47 for pregnancy) and P2 periods (a OR 1.25, 95% CI 1.07–1.45 for implantation; a OR 1.27, 95% CI 1.09–1.47 for pregnancy), followed by Q3(a OR 1.14 for implantation and 1.04 for pregnancy) and Q2 (a OR 1.03for implantation and 1.16 for pregnancy) during P1, followed by Q3(a OR 1.12 for implantation and 1.01 for pregnancy) and Q2 (a OR 1.02 for implantation and 1.11 for pregnancy) during P2. There was no significant correlation between clinical outcomes and air pollution variables.

Limitations, reasons for caution: Meteorology and ambient air pollution level in specific areas may not represent the actual level of air pollution that every woman is exposed to. There may be a correlation between climate and air pollution parameters, which may lead to biased results.

Wider implications of the findings: More accurate instruments are needed to timely measure the various meteorological and air pollution parameters of the patients' environment, in order to more accurately assess their impact on the outcome of IVF treatment.

Trial registration number: processing

P-760 Comparison of perinatal outcomes between day 5 and 6 blastocyst transfers in both fresh and frozen cycles

C. Cheung[1], J. Kasraie[1], I. Solis-Trapala[2], A. Sizer[1]

[1]Shrewsbury and Telford Hospital NHS Trust, Shropshire and Mid Wales Fertility Centre, Shrewsbury, United Kingdom ;
[2]Keele University, School of Primary- Community and Social Care, Staffordshire, United Kingdom

Study question: Does extended culture to day 6 (D6) blastocysts increase adverse neonatal outcomes in both fresh and frozen cycles compared to standard day 5 (D5) blastocysts?

Summary answer: The mean birthweight, gestation, congenital anomalies and other neonatal morbidity did not differ between D5 and 6 transfers in both fresh and frozen groups.

What is known already: Previous studies have demonstrated that the type of culture medium and duration of culture have impact on birth weights. Many studies have shown that blastocyst transfers are associated with higher birth weights when compared to cleavage stage embryos. There are also reports of increased risk of adverse neonatal outcomes such as preterm birth and congenital anomalies with prolonged culture. D6 blastocysts are slower developing and have also spent longer in culture medium. There are very few studies, with controversial results, examining whether D6 blastocysts are associated with adverse neonatal outcomes when compared against normally developing D5 blastocysts.

Study design, size, duration: This is a retrospective cohort study conducted in a single unit. 637 fresh blastocyst transfer cycles (481 D5 and 156 D6 cycles) and 446 frozen cycles (291 D5 and 155 D6 cycles) from January 2013 to December 2018 included. Perinatal outcomes from singleton births were compared between D5 and 6 groups. Fresh and frozen cycles were analysed separately. 223 live births from the fresh group and 79 from the frozen group were available for analysis.

Participants/materials, setting, methods: In the fresh treatment group, all patients underwent fresh autologous cycles and fulfilled our unit's single blastocyst transfer criteria. All blastocysts in the frozen group were exclusively vitrified either from surplus embryos in a preceding fresh cycle or from a 'freeze all cycle'. D5 and 6 blastocysts were transferred after the same duration and dose of progesterone supplement. Mixed D5 and 6 transfers were excluded. Data were analysed using multiple logistic regression model.

Main results and the role of chance: In the fresh cycles, patients' age, BMI and number of previous treatment cycles between the D5 and 6 groups were similar. D5 transfers resulted in higher live birth rates compared to D6 group (D5=43.9%, D6=31.4%, $p<0.05$). Miscarriage, ectopic rates and multiple pregnancies resulting from monozygotic twinning were comparable.

184 live births from the D5 group were compared against 39 births from the D6 group. There were no significant differences in mean birthweight (D5= 3305g, D6= 3346g, P=0.65) and gestation (D5= 38.8, D6=38.9, P=0.82). The rates of large and small for gestational age, preterm births, congenital anomalies and stillbirths did not differ between the groups.

In the frozen cycles, there were no significant differences between the mean age at freeze and treatment, BMI, previous number of treatment cycles and number of blastocysts transferred. Live birth rates were not significantly different (D5=22.7%, D6=24.9%, p=0.77). Miscarriage, ectopic and multiple pregnancy rates were similar.

49 live births from D5 were compared against 30 births from D6 group. There were no significant differences in mean birthweight (D5=3533g, D6=3456g, p=0.59) and gestation (D5=38.8, D6=38.7 p=0.90). The rates of large and small for gestational age, preterm births, congenital anomalies and stillbirths did not differ between the groups.

Limitations, reasons for caution: A relatively small number of livebirths were analysed in our study, particularly from D6 groups. Some data were missing from patients who delivered out of area. Other potential factors such as maternal hypertension, pre-eclampsia and diabetes that can also influence birth outcomes were not taken into account in this study.

Wider implications of the findings: We demonstrated from our data that D6 blastocyst transfers did not result in an increased rate of adverse perinatal outcomes. Larger studies including day 7 transfers with long term follow up on children born from prolonged culture should be undertaken to clarify the safety of transferring D6 and D7 blastocysts.

Trial registration number: not applicable

P-761 Impact of endometriosis on maternal and perinatal morbidity in IVF versus spontaneous conception: a national 6-years observational study

S. Epelboin[1], R. Levy[2], M. Valentin[3], F. Pessione[4]

[1]Assistance Publique Hôpitaux de Paris Hôpital Bichat-Claude Bernard, Gynecology Obstetrics Reproductive Medecine, Paris, France ;
[2]Assistance Publique Hôpitaux de Paris Hôpital Tenon Université de Paris, Embryology, Paris, France ;
[3]Assistance Publique Hôpitaux de Paris Hôpital Bichat-Claude Bernard, Obsterics, Paris, France ;
[4]Agence de la Biomédecine, Epidemiology Biostatistics, Saint Denis, France

Study question: Which role of endometriosis and which additional risk of In Vitro Fertilisation(IVF) in maternal or fetal morbidity when comparing single deliveries of populations with/without endometriosis, after spontaneous or IVF conception?

Summary answer: There is an independent role of endometriosis in the increased adjusted risk of most maternal and perinatal morbidities in spontaneous deliveries, further increased by IVF

What is known already: Large observational studies identified that IVF pregnancies are associated with a significant risk of complications, even if single, as compared with pregnancies after spontaneous conception (SC) . These complications include preterm delivery, gestational diabetes, pre-eclampsia and placental anomalies, leading to increased fetal loss, intrauterine growth restriction, all events being a significant concern (Pinborg, 2013, Ombelet, 2016, Wang, 2016, Luke, 2017, Vermey, 2018). Moreover, several recent studies identified that compared with women without endometriosis, women with endometriosis had higher odds of maternal morbidities as hypertensive disorders, diabetes, placenta previa, placental abruption, preterm birth (Zullo, 2017, Lalali, 2018, Porpora,2020). Which respective responsibility?

Study design, size, duration: This is an observational national cohort study comparing maternal (MM) and perinatal (PM) morbidities in 3 groups of single pregnancies registered between 2013 and 2018 in France. The first group was SC without endometriosis (SC-non-endo), the second was SC with endometriosis (SC-endo), the third included IVF standard or using intracytoplasmic injection and fresh transfers with endometriosis (IVF-endo). Births were considered when > 22 weeks of gestation (WG), and term birth was defined > 37 WG.

Participants/materials, setting, methods: Pregnancies and deliveries were analyzed by extracting the Information Systems Medicalization Program (PMSI) French database. The main identified morbidity indicators were: venous thrombosis, gestational diabetes, hypertensive disorders (gestational hypertension or pre-eclampsia), placenta previa, placental abruption, premature birth, small for gestational age (SGA), major congenital malformations. The risks of MM and PM were estimated in multivariate analysis after adjustment for maternal age, smoking and obesity, primiparity and history of diabetes and hypertension.

Main results and the role of chance: The study included all 4,170,780 national single deliveries, among which 38035 (0.9%) with endometriosis. In the SC group, endometriosis was diagnosed in 31,101 mothers (0.76%). In the IVF group (55,947), endometriosis was diagnosed in 6,934 (12.4%).

Mean maternal ages were 30.0 (std=5.3), 31.7 (std=4.8) and 33.1 (std=4.0), for SC, SC-endo and IVF-endo groups.

Compared to control group, SC-endo and IVF-endo groups showed respectively lower rates for obesity (3.9% and 3.1% versus 4.9%), and smoking (3.7% and 2.4% vs 4.7%) (p< 0. 0001). Respective rates in SC-endo and IVF-endo were higher for primiparity (47.4% and 76.7% versus 39.6%), and history of hypertension (1.14% and 1% vs 0.85%). There was no difference for history of diabetes mellitus.

In SC group, endometriosis was associated with increased risks of venous thrombosis, hypertensive disorders, placenta previa, placenta abruption, premature birth (all p<.0001), congenital malformation (p= .049) and SGA (p<.0003) . In the endometriosis group, the comparison of highlighted aOR of SC-endo and IVF-endo populations, versus SC-non-endo , provided evidence that IVF techniques increased the risk of placenta previa (aOR 2.62 vs 6.51, p <.0001), premature birth (aOR 1.37 vs 1.92, p<.0001), and SGA (aOR 1.05 vs 1.25, p<.0001), respectively, No other significant difference was found (thombosis, diabetes...).

Limitations, reasons for caution: While the strength of this study lies in the number and completeness of subjects studied, its limitations are its register-based nature, not allowing to refine the risk evaluation, mainly according to the type of endometriosis (peritoneal, deep, associated adenomyosis), which can determine complications of variable importance (vascular, placentation).

Wider implications of the findings: These data demonstrating an independent role of endometriosis in the increased adjusted risk of most maternal and perinatal morbidities in spontaneous and IVF deliveries may improve the vigilance of practitioners in monitoring pregnancies when endometriosis, and be considered in the debate on the place of surgery for infertile endometriotic women.

Trial registration number: not applicable

P-762 Impact of subchorionic haematoma in early pregnancy on obstetric complications: A retrospective cohort study in women who had live births after frozen-thawed embryo transfer

O. Mochizuki[1], S. So[2], N. Murabayashi[2], W. Yamaguchi[1], N. Miyano[1], F. Tawara[1]

[1]Tawara IVF clinic, Reproductive medicine, Shizuoka, Japan ;
[2]Hamamatsu University School of Medicine, Department of Reproductive and Perinatal Medicine, Hamamatsu, Japan

Study question: We investigated whether subchorionic haematoma (SCH) in early pregnancy is involved in the development of obstetric complications in women who underwent frozen-thawed embryo transfer.

Summary answer: SCH in early pregnancy may contribute to the development of placenta previa and a clinically adherent placenta.

What is known already: SCH is known to contribute to abortion and premature birth. It has also been reported that taking aspirin during pregnancy contributes to the development of SCH. Pregnancy following assisted reproductive technology (ART) has been reported to have a high frequency of obstetric complications, but its association with the presence of SCH is not known.

Study design, size, duration: This study was approved by the Ethics Committee of Tawara IVF Clinic. Of the 5139 patients who underwent frozen -thawed embryo transfer between March 2015 and September 2018, 1426 women who had live births were included in this study.

Participants/materials, setting, methods: SCH was usually assessed at pregnancy weeks 7–9. Obstetric complications data were obtained from delivery hospital records. Multivariate analysis controlled for potential confounding effects: maternal age, body mass index, history of pregnancy and miscarriage, embryo stage at transfer, number of embryos transferred, use of assisted hatching, endometrial preparation method, aspirin use during pregnancy, and infertility cause (male infertility, polycystic ovary syndrome,

leiomyoma, endometrial polyps, adenomyosis, fallopian tube obstruction, endometriosis).

Main results and the role of chance: Of 1426 women who had live births, 343 women (24.1%) had SCH in early pregnancy. There was no difference in the frequency of SCH between the hormone replacement cycle and natural ovulatory cycle. There was also no difference in endometrial thickness (SCH group 9.9±1.8 mm vs. non-SCH group 10.0±1.7 mm) and aspirin use during pregnancy (7.6% vs. 9.4%). SCH was more frequent in women who had infertility due to endometrial polyps (SCH 9.4% vs. non-SCH 5.0%, p<0.001). Women with SCH in early pregnancy had a significantly higher risk of placenta previa (odds ratio (OR) 3.67 [1.21–11.60]) and a clinically adherent placenta (7.18 [3.04–18.41]) compared with that of non-SCH women. No differences were found in the development of hypertensive disorders of pregnancy (0.91 [0.49–1.60]), non-reassuring foetal status (1.56 [0.87–2.74]), foetal growth restriction (1.86 [0.61–5.24]), chorioamnionitis (2.42 [0.68–8.06]), premature rupture of the membranes (1.14 [0.65–1.95]), caesarean section (1.07 [0.75–1.51]), and preterm-delivery (1.24 [0.68–2.19]).

Limitations, reasons for caution: The size and location of the SCH was unknown. It is not known whether SCH was continuously present during pregnancy.

Wider implications of the findings: The group that developed SCH in early pregnancy had a significantly higher frequency of placenta previa and a clinically adherent placenta than that in the non-SCH group. Attention should be paid to the presence of SCH during early pregnancy after frozen -thawed embryo transfer.

P-763 Is the information on endometrial scratching provided by IVF clinics' websites biased?

V. Galiano[1,2], R. Orvieto[2,3], R. Machtinger[2,3], R. Nahum[2,3], E. Garzia[4], P. Sulpizio[4], A.M. Marconi[1], D. Seidman[2,3]

[1]ASST Santi Paolo e Carlo - San Paolo University Hospital, Department of Obstetrics and Gynecology, Milan, Italy ;
[2]The Chaim Sheba Medical Center, Infertility and IVF Unit - Department of Obstetrics and Gynecology, Ramat Gan, Israel ;
[3]Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel ;
[4]ASST Santi Paolo e Carlo - San Paolo University Hospital, Reproductive Medicine Unit, Milan, Italy

Study question: How accurate is the information about endometrial scratching presented on fertility clinics websites, considering the conflicting evidence on the effectiveness of this procedure?

Summary answer: The information about endometrial scratching available to the public from IVF-clinics' websites is often inaccurate.This could perpetuate false myths among infertile patients about the procedure.

What is known already: The impact of endometrial scratch on live birth rates remains inconclusive. Yet, this procedure is actively promoted by some fertility clinics as a proven means to improve IVF success rates, especially in couples with repeated implantation failure. Little information is currently available on the type and quality of information provided on IVF clinic's websites in regard to the merits of endometrial scratch.

Study design, size, duration: A systematic evaluation of fertility clinics websites**.** We developed a 10-criteria structured questionnaire to evaluate the quality of information about endometrial scratching available through the internet. The search and review were performed in January 2020 by a single investigator.

Participants/materials, setting, methods: We included in the study all websites of fertility clinics that presented in the first 30 pages of the Google.com search engine after typing "endometrial scratching" as the key word.

Main results and the role of chance: Our search identified 55 websites that all belonged to private IVF clinics. Almost half of the clinics were from the UK (23/55, 41.8%). Only 22 of 55 (40%) websites reported an accurate description of the procedure and how it is performed, and only 8 of 55 (14.5%) websites reported on the undetermined effectiveness of the procedure. Furthermore, 13 (23.6%) websites bluntly encouraged its use. The cost of the procedure was clearly displayed in only 5 (9.1%) cases and in only 7 (12.7%) websites a bibliography on the procedure was provided, mostly studies supporting the procedure. Less than half of the websites clearly noted (23/55, 41.8%) associated risks, such as infection, endometrial injury or uterine perforation. However, the possibility of pain during and after the scratch was often (34/55, 61.8%) described. Many of the reviewed websites were not updated, and data was often presented (20/55, 36.4%) with no date of entry. None of the websites reported the clinic's pregnancy rate following the procedure.

Limitations, reasons for caution: Our limited sample size may not be fully representative and was limited to English language websites.

Wider implications of the findings: Much of the information available to the public regarding new fertility enhancing "add-on" treatments is currently provided through fertility clinic's websites.ESHRE,as well as other leading professional organizations,should deliver better guidelines for fertility clinic websites, as there is an urgent need to improve the type and quality of information currently provided.

Trial registration number: Not applicable

P-764 Impact of frozen-thawed embryo transfers and hormone substitution on thrombotic risk markers

T. Dalsgaard[1], K. Kirkegaard[2], A.M. Hvas[3], U. Knudsen[1]

[1]Clinical Medicine, Gynaecology and Obstetrics, Horsens, Denmark ;
[2]Clinical Medicine, Gynaecology and Obstetrics, Aarhus, Denmark ;
[3]Clinical Medicine, Clinical Biochemistry, Aarhus, Denmark

Study question: Is there a difference in thrombotic risk markers between women receiving artificial cycle frozen embryo transfer (AC-FET) compared to natural cycle frozen embryo transfer (NC-FET)?

Summary answer: Women receiving AC-FET have an activated coagulation indicated by increased thrombin generation while being estrogen substituted. Such coagulation activation might induce an increased thromboembolic risk.

What is known already: Fertility treatment with frozen embryo transfer (FET) is used widely. Women treated with AC-FET receive high doses of estrogen in contrast to women treated with NC-FET. Estrogen substitution is likely to be associated with an increased risk of thromboembolism based on previous research on hormone replacement therapy in other contexts. Additionally, an increased risk of thrombosis has been shown in pregnant women following assisted reproductive technology treatment as compared to natural fertilization. However, the knowledge of how the coagulation is activated in women undergoing estrogen substitution during treatment with AC-FET remains unknown.

Study design, size, duration: Prospective cohort study of women receiving AC-FET with estrogen/progesterone substitution or NC-FET. Blood samples were obtained four times: 1) prior to hormone substitution (baseline), 2) confirmation of biochemical pregnancy, 3) gestational week 8 and 4) gestational week 13 (5 weeks after cessation of hormone substitution). Inclusion criteria: women aged >18 years assigned for FET. Exclusion criteria: egg donor recipients, known bleeding disorders, indication for thromboprophylaxis and treatment with anti-platelet medication or non-steroid-anti-inflammatory drugs.

Participants/materials, setting, methods: Women were recruited at the Department of Obstetrics and Gynaecology, Horsens Fertility Clinic, Denmark, August 2019 – June 2020. In total, 18 participants have been included: 10 women treated with AC-FET and 8 women receiving NC-FET. We examined alterations in surrogate markers of thromboembolic risk: primary outcome was the difference in thrombin generation expressed as endogenous thrombin potential before, during and after hormone stimulation. Secondary endpoint was platelet aggregation assessed by whole blood impedance aggregometry.

Main results and the role of chance: We found an increased thrombin generation after hormone substitution within the group treated with AC-FET compared to NC-FET indicated by a significantly shorter time to peak (3 ± 0.1 min versus 6.4 ± 0.4 min) ($p < 0.0001$), a significantly higher mean peak (329 ± 13 nM versus 259 ± 13 nM) ($p = 0.002$) and higher endogenous thrombin potential (1827 ± 480 nM min versus 1544 ± 131 nM min) ($p=0.02$). When compared to the NC-FET group, women receiving AC-FET had significantly higher thrombin generation shown by a shorter mean time to peak (5.6 ± 0.2 min versus 8.3 ± 0.7 min) ($p = 0.0006$), higher mean peak (329 ± 13 nM vs 174 ± 15 nM) ($p < 0.0001$) and a larger endogenous thrombin potential (1827 ± 160 nM min vs 1375 ± 82 nM min) ($p < 0.05$). We found no significantly increase in platelet aggregation from baseline till after hormone substitution in the AC-FET group (p-values > 0.16). Likewise, when comparing platelet aggregation with unstimulated controls, no significant changes were found (p-values > 0.51). With data being preliminary, we expect these findings to be more pronounced when investigated in a larger cohort.

Limitations, reasons for caution: We had no wash out period and with a half-life of estrogen on 13-20h, we cannot exclude coagulation parameters to be affected by estrogen before study enrollment. A larger study is required, to confirm our results and to further examine the clinical impact of coagulation changes in women receiving AC-FET.
Wider implications of the findings: Our findings show an increased thrombin generation during estrogen substitution, which might increase the risk of thromboembolism. It is relevant to individually consider the indication for AC-FET and restrict the use of unnecessary hormone exposure.
Trial registration number: 1-10-72-101-19

P-765 Time-related treatment outcomes in infertility studies: a systematic mapping review and evidence-based definition

S.K. Sunkara[1], W. Zheng[2], T. D'Hooghe[2], S. Longobardi[3], J. Boivin[4]

[1]King's College London, Division of Women's Health, London, United Kingdom ;
[2]Merck KGaA, Global Medical Affairs Fertility, Darmstadt, Germany ;
[3]Merck KGaA, Global Clinical Development Fertility, Darmstadt, Germany ;
[4]Cardiff University, School of Psychology, Cardiff, United Kingdom

Study question: How have time-related treatment outcome measures been assessed and reported in clinical studies evaluating infertility treatments and how best to define them?
Summary answer: There is inconsistency amongst studies in reporting time-related treatment outcomes; a robust clinically meaningful contextual definition should be incorporated into all fertility-related clinical studies.
What is known already: Time taken to achieve a healthy live birth is an important consideration when planning fertility treatments. Longer treatment is stressful to patients and increases costs. The ability to compare the effectiveness of interventions with respect to a time-related measure would enable treatment selection aimed at reducing the time to achieve a live birth. The comparison of a time-related measure between possible treatments may also be beneficial for patient counselling with regards to setting expectations. It is, therefore, important to explore how such outcomes have been defined in fertility-related clinical studies with the aim of setting justified and evidence-based definitions.
Study design, size, duration: This is a systematic review of clinical studies in the context of infertility that reported time-related treatment outcomes. PubMed, MEDLINE and Embase were searched for studies published up to 16th August 2019. The search strategy comprised key words/MESH terms: assisted reproductive technologies, fertility treatment, ovarian stimulation, ovulation induction, IVF, intracytoplasmic sperm injection, infertility, subfertility, intrauterine insemination, time, duration, and birth. Results were filtered to include studies in humans and publications in English.
Participants/materials, setting, methods: The screening criteria for inclusion were: a clinical study in the context of infertility (population is infertile or had clinical risk factors for infertility, e.g. fibroids, polycystic ovary syndrome, etc.) and/or a population undergoing fertility management or treatment, which had a treatment outcome measure that contained duration of time (e.g. time to pregnancy or time to live birth). Non-clinical studies, including epidemiological incidence and prevalence studies were excluded.
Main results and the role of chance: 42 out of 5730 captured studies were included in the systematic review after independent assessment for eligibility by two reviewers. The most frequent end time-points for time-related outcome measures were "time to pregnancy" (25/42; 59.5%) and "time to conception" (15/42; 35.7%); 5/42 (11.9%) studies evaluated "time to live birth". There were inconsistencies with regards to the start time-point and no consistent time-related treatment measures reported by majority of studies. We propose time-related treatment measures that build on existing definitions of reproductive outcomes: · Start time-point should be randomization or, for non-randomized studies, the point at which randomization would have occurred if it had been a randomised controlled trial (RCT).

–Kaplan–Meier plot or cumulative incidence plot could be presented to illustrate the likelihood of achieving a clinical pregnancy with a foetal heartbeat that results in a live birth over time (days, weeks, months) or over the number of menstrual or treatment cycles. Medial survival time model could be adapted for example to calculate the time for 25% of the patients to become pregnant (i.e. time to Quartile Pregnancy).

–Data for time-related treatment measures should be reported for all RCTs, regardless of live birth occurrence, and should be adjusted for prognostic covariates.
Limitations, reasons for caution: The review only included studies published in English and authors were not contacted for more details of endpoints evaluated; therefore, some of the time-related treatment measures used in the literature may have been missed.
Wider implications of the findings: Our research provides the basis for a consensus definition of a time-related treatment measure for studies of fertility treatment. We anticipate that our review and justified suggestions will facilitate discussion around appropriate time-related treatment outcome measures for studies evaluating fertility treatments that is relevant to healthcare professionals and patients.
Trial registration number: Not applicable

P-766 Elective transfer of one embryo is associated with higher cumulative live birth rate and improved perinatal outcomes compared to transfer of two embryos with IVF

R. Mejia[1], E. Capper[2], K. Summers[1], P. Ten Eyck[3], B. Van Voorhis[1]

[1]University of Iowa Hospitals and Clinics, Department of Ob-Gyn- Division of REI, Iowa City, U.S.A. ;
[2]University of Iowa Carver College of Medicine, Department of Ob-Gyn, Iowa City, U.S.A. ;
[3]University of Iowa, Department of Biostatistics, Iowa City, U.S.A.

Study question: Are cumulative live birth rate, time to pregnancy and perinatal outcomes similar with initial elective single embryo transfer (eSET) versus double embryo transfer (DET)?
Summary answer: An initial eSET transfer is associated with a higher cumulative live birth rate, a minor increase in time to pregnancy, and markedly improved perinatal outcomes.
What is known already: Compared to DET, eSET is associated with a marked reduction in multiple gestations but has a lower delivery rate per initial embryo transfer. Changes in the Society for Assisted Reproductive Technology (SART) database since 2014 allow linkage of all transfers of both fresh and cryopreserved embryos to their stimulation cycle of origin. This allows for calculation of the cumulative delivery rate per initiated IVF retrieval cycle in a United States national IVF database- a better measure of the total reproductive outcome for patients.
Study design, size, duration: Retrospective cohort study, dataset included a total of 49,333 patients who had their first oocyte retrieval between January 2014 and December 2015. Subsequent frozen transfer cycles linked to the initial retrieval cycle occurring through December 2016 were included for cumulative outcome assessment. The primary outcome was cumulative live birth rate. Secondary outcomes were time to pregnancy resulting in delivery (measured in days and embryo transfer cycles), multifetal pregnancy rate, infant birthweight and perinatal mortality rate.
Participants/materials, setting, methods: Participants included women aged 21 to 45 from a national database of IVF outcomes from SART- reporting fertility clinics. Generalized linear mixed models were used to control for significant clinical and demographic variables when assessing both primary and secondary outcomes between those who received eSET versus DET in the initial embryo transfer.
Main results and the role of chance: As compared to DET, eSET in the initial transfer was associated with a significantly higher cumulative live birth rate (74% vs 57%, AOR 1.32, 95% CI 1.26- 1.38) after controlling for confounding variables. When categorized by the woman's age, a higher cumulative live birth rate with initial eSET was seen in all age categories but only remained statistically significant for women under age 38. In the full sample, initial eSET was associated with a significantly lower cumulative multifetal pregnancy rate (8 % VS 34 %, AOR 0.13, 95% CI 0.12-0.14), a higher birthweight (mean difference of 406 grams, 95% CI 387-425 grams), a lower rate of pre-term births below 28 weeks (1.2% versus 2.8%, p< 0.001) and a lower perinatal mortality rate (0.5% versus 1.2%, p<0.001). Compared to DET, initial eSET was associated with a slightly longer time (82 days versus 51 days, AOR 1.47, 95% CI 1.44- 1.50) and more embryo transfer cycles (1.7 versus 1.4 cycles, AOR 1.19, 95% CI 1.16-1.21) to achieve a pregnancy resulting in delivery.
Limitations, reasons for caution: Categorization of eSET was based on the initial transfer; findings from this study are not generalizable to application of

eSET in subsequent cycles. Despite controlling for many known variables between the eSET and DET groups, other unmeasured differences in patient and cycle characteristics may confound these findings.
Wider implications of the findings: eSET is associated with a higher cumulative delivery rate, especially in younger patients. This combined with the marked reduction in multifetal pregnancies and improved perinatal outcomes suggests that, despite the slightly longer time to pregnancy, a strategy of initial eSET is preferred over DET in the first IVF cycle.
Trial registration number: not applicable

P-767 The prevalence of blood-borne viral infections (BBVI) among roughly 184 00 people seeking fertility services in Ontario, Canada

H. Shapiro[1], M. Neal[2], E. Candido[3], B. Rachlis[3], J. Kwong[4]

[1]University of Toronto, Mount Sinai Fertility, Toronto, Canada ;
[2]Montreal Fertility Centre, Montreal Fertility Centre, Montreal, Canada ;
[3]Institute for Clinical Evaluative Sciences, Primary Care and Health Systems Research Program, Toronto, Canada ;
[4]Institute for Clinical Evaluative Sciences, Populations and Public Health Research Program, Toronto, Canada

Study question: How often is HIV or viral hepatitis diagnosed in first or subsequent testing of people whose testing is solely for the purposes of ART laboratory requirements?
Summary answer: The 5-year cumulative incidence of hepatitis and HIV were 522 (489-556) and 31.4 (23.7-40.6) /100,000.We estimate 80% of HIV cases were identified from initial testing.
What is known already: The incidence and sero-conversion rates of blood-borne viral infections (BBVI) in the fertility-seeking population is though to be very low. Studies to date have not documented any new cases of HIV after initial testing. However, small sample sizes and short duration of follow-up preclude definitive conclusions of incidence or sero-conversion rates. Thus recommendations for testing frequency have been instituted without adequate supportive evidence.
Study design, size, duration: This is an administrative database cohort study of 184 328 individuals who had a consultation for infertility followed by testing for BBVI within one year of that consultation. Data for ongoing testing and consultation for management of BBVI was extracted for up to five years from the first test. The study period was April 1 2002-March 31 2013 for cohort entry and to March 2018 for follow-up.
Participants/materials, setting, methods: The databases used contain coded patient and physician identifiers, service provided, date of service, and diagnosis for Ontario residents in publicly funded healthcare. They do not provide test results. BBVI diagnosis was defined from consultation with a diagnostic code for hepatitis or HIV. This was set as the diagnosis date. The index date was set as the first BBVI test that occurred within one year of the first consultation for infertility.
Main results and the role of chance: 184,328 people had BBVI testing within one year of consultation for infertility. 2491 were found to have pre-existing disease. There were 949 new diagnoses of hepatitis and 57 new diagnoses of HIV in the 5-year follow-up. The cumulative incidence of diagnosis was 522 (95%CI 489-556) per 100,000 for viral hepatitis and 31.4 (95%CI 23.7-40.6) per 100,000 for HIV. The median time from first test to management was 13.0 months (IQR 2.33-32.2) and 2.95 months (IQR 1.34-20.0) for hepatitis and HIV respectively. Thirty nine of the fifty-seven people with HIV were seen in consultation for their BBVI within one year of the first test. The interval from first test to management for women with HIV was much shorter than for men. Forty-four percent of patients had one BBVI test prior to management. The majority who had two tests before BBVI consultation had the second test less than one year from the first. The median time from last test to management was 2.39 (<1-9.28) and 1.51 (<1-5.41) months. Sixty-two individuals had five or more BBVI tests prior to a diagnosis of hepatitis. The incidence of HIV after multiple BBVI tests was too small to be reliably calculated.
Limitations, reasons for caution: Every positive test may not have resulted in consultation, underestimating the incidence of BBVIs. Testing for clinical indications could not be separated from testing as ART routine practices, which would overestimate the incidence. Consultation more than one year from initial testing may reflect either delay to care or interim sero-conversion.
Wider implications of the findings: *This is the largest population-based study describing BBVI testing and disease incidence in the infertility population. The* majority (but not all) of HIV diagnoses were made with the first test. These results can be used to develop evidence-based, cost-effective guidelines for BBVI test frequency in ART.
Trial registration number: not applicable

P-768 Endometrial thickness before embryo transfer is associated with placenta accreta at delivery.

O. Rosenbluh[1], A. Peretz[1], D. Lasry[2], A. Solnica[3], E. Esh-Broder[1], D. Hochner-Celnikier[1]

[1]Hadassah Medical Center, Obstetrics & Gynecology, Jerusalem, Israel ;
[2]Shaare Zedek Medical Center, Obstetrics & Gynecology-, Jerusalem, Israel ;
[3]Hadassah Hebrew University, Henrietta Szold School of Nursing, Jerusalem, Israel

Study question: Our objective was to explore the correlation between endometrial thickness before embryo transfer and the finding of placenta accreta at delivery among patients utilizing in-vitro fertilization (IVF) treatments.
Summary answer: Thinner endometrial thickness before embryo transfer is an independent risk factor for developing placenta accreta during pregnancy among IVF patients.
What is known already: It has been shown that besides prior cesarean section, placenta previa and advanced maternal age, in-vitro fertilization (IVF) is an independent risk factor for placenta accreta.

Recently, it has been suggested that a correlation exists between the endometrial thickness at time of embryonic transfer and the risk of placenta accreta, claiming that the thinner the endometrium is at time of transfer the more prominent the finding of placenta accreta at birth.
Study design, size, duration: This is a case-control study where we retrospectively analyzed the medical records of 29 cases of placenta accreta occurring in IVF patients, who were treated and gave birth at our Medical Center between the years 2007-2017. We then created a control group of IVF patients matched by age, date of embryo transfer and prior cesarean section (1:2) without accreta and compared the endometrial thickness before transfer between the two groups.
Participants/materials, setting, methods: All patients, who delivered a live-born fetus at 24 weeks of gestation or greater at our Center from 2007 to 2017, were reviewed for placenta accreta. Of those, we designated a subset of women undergoing fertility treatments who were both clinically adherent and showed invasive pathology (n=29).

Cases of accreta were matched to controls (1:2) without accreta, and multivariable logistic regression model was performed, while controlling for potential confounders.
Main results and the role of chance: Among patients with placenta accreta who were both clinically adherent and reported as having invasive pathology, higher rates of thinner (under 7 mm) endometrial linings were observed as compared to patients who did not develop placenta accreta (21.4% vs. 5.2% respectively, p<0.05). While performing sub-analysis we observed that lower endometrial thickness was significant only when comparing the transfer of fresh embryos (33.3% vs. 5.0%, p<0.05). However, when comparing cryopreserved embryo transfer no significant association was observed (7.7% vs 5.5%, p=0.81). In multivariate analysis, lower endometrial thickness is an independent risk factor for placenta accreta while controlling for maternal age, prior cesarean section and fresh vs. frozen (odds ratio 4.07, 95% confidence interval 1.1-16.5)
Limitations, reasons for caution: The limitation of the study is the retrospective case-control nature of the study.
Wider implications of the findings: We have determined that patients who developed accreta had thinner endometrial linings compared to patients without accreta in fresh embryo transfers. A threshold value of 7 mm or less was shown to be significantly higher in accreta cases requiring special attention be paid to endometrial thickness during fresh IVF cycles.
Trial registration number: N\A

P-769 Maternal outcomes of IVF twins versus spontaneous twins

T. Nguyen[1], D. Tran[2], T. Phan[3], D. Do[4], M. Nguyen[5], H. Nguyen[5], A. Salumets[6]

[1]Ha Noi Obstetric and Gynecology Hospital, Department of High risk Pregnancy, Ha Noi, Vietnam ;

[2]Ha Noi Obstetrics and Gynecology Hospital, Department of High risk Pregnancy, Ha Noi, Vietnam ;
[3]Ha Noi Obstetrics and Gynecology Hospital, Delivery Department, Ha Noi, Vietnam ;
[4]Ha Noi Obstetrics and Gynecology Hospital, Gynecology Department, Ha Noi, Vietnam ;
[5]Ha Noi Obstetrics and Gynecology Hospital, Assisted Reproductive Center, Ha Noi, Vietnam ;
[6]University of Tartu, Women's Clinic and Institute of Genomics, Tartu, Estonia

Study question: Investigate the potential differences in maternal outcomes between IVF and spontaneous twins in the context of a low-middle income country
Summary answer: Our study shows that although there are some differences in perinatal complications, pregnancy overall outcomes were not significantly different between IVF and spontaneous twins.
What is known already: Assisted reproductive technologies have been used widely in obstetrics, especially invitro fertilization (IVF). One of the main concerns of both patients as well as doctors is how IVF techniques affect the maternal outcomes of the pregnancy. Many studies were conducted to address this question but few have been done in the context of a low-income country like Vietnam where multiple embryo transfer remains popular and the demand of multiple pregnancies is still high.
Study design, size, duration: Size: 733 women with twin pregnancy were included in the study (344 IVF twins and 389 spontaneous twins).
Duration: 6 months from 1 Jan 2019 to 30 June 2019
Participants/materials, setting, methods: A retrospective cohort study was performed on women with twin pregnancy delivered at a large public women's hospital in the North of Vietnam in 6 months from 1 Jan 2019 to 30 June 2019. Two groups of twin pregnancies were investigated: IVF and spontaneous ones. Anonymous maternal outcome information was extracted from the hospital database.
Main results and the role of chance: 733 women with twin pregnancy were included in the study (344 IVF twins and 389 spontaneous twins). When it comes to maternal prenatal complications, higher rates of first-trimester bleeding (5.8% vs 1.8%, p<0.01), gestational diabetes (12.79% vs 7.2%, p<0.01) and pre-eclampsia (8.72% vs 2.83%, p<0.001) were seen in IVF group, compared to control group, respectively. No HELLP syndrome, abruptio placentae or placenta accreta cases were reported. Despite the percentage of threaten preterm birth was higher (38.7% vs 14.4%, p<0.001, respectively) and the gestational ages at delivery were lower in the IVF group (36.2 ± 2.5 weeks vs 36.5 ± 2.4 weeks, p<0.05), the actual rates of preterm birth and birthweight were not different between the two groups (65.7% vs 66.3%, p>0.05 and 2372.8 ± 467.0 grams vs 2323.3 ± 493.1 grams, respectively). IVF women tended to have more C-section than those who conceived twins naturally (84.01% vs 74.29%, p<0.001, respectively). The proportions of postpartum uterine atony and bleeding were higher in IVF group (20.6% vs 14.4%, p<0.05 and 28.2% vs 17.7%, p<0.01, respectively) but those of blood transfusion or perinatal infection were similar between the two groups.
Limitations, reasons for caution: Our study is a retrospective cohort study
Wider implications of the findings: With careful monitor and follow-up, despite higher risk of antenatal complication, IVF twin pregnancies may achieve similar outcomes as spontaneous twins.
Trial registration number: not applicable

P-770 Long-term follow-up of children conceived with assisted reproductive techniques – attention-deficit hyperactivity disorder and 9th-grade performance in the Swedish population.

C. Wang[1], A.L.V. Johansson[1], C. Almqvist Malmros[1,2], S. Hernández-Díaz[3], A.S. Öberg[1,3]

[1]Karolinska Institutet, Medical epidemiology and Biostatistics, Stockholm, Sweden ;
[2]Karolinska University Hospital, Astrid Lindgren Children's Hospital, Stockholm, Sweden ;
[3]Harvard University, Harvard T.H. Chan School of Public Health, Boston, U.S.A.

Study question: Could use of assisted reproductive techniques (ART) affect offspring risk of attention-deficit hyperactivity disorder (ADHD) or 9th grade school performance?
Summary answer: We found no evidence of a negative influence of ART on children's risk of ADHD or their academic achievement in lower secondary school.
What is known already: Early neurodevelopmental assessments of children conceived with in-vitro fertilization (IVF) have been largely reassuring, though a reported link between use of intra-cytoplasmic sperm injection (ICSI) and risk of autism warrants further attention. Some deficiencies may not become manifest or of significance until school-age (ADHD) or adolescence (academic achievement), and larger studies with longer follow-up are needed to understand the long-term consequences of IVF (and ICSI), independent of infertility.
Study design, size, duration: Linkage of national registers allowed prospective follow-up of all live births in Sweden up to the end of 2012. To allow the outcomes to be captured, school performance was evaluated in the cohort born 1983 to 1996 ((N=1,493,903) whereas ADHD was evaluated in the cohort born 1997 to 2006 (N=926,198).
Participants/materials, setting, methods: Use of ART (IVF/ICSI) was reported by IVF-clinics, medical records, and mothers at the first antenatal visit. Cases of ADHD were identified via specialist diagnosis (outpatient register) and/or use of ADHD medication (prescribed drug register). The school register provided total grade score and eligibility for upper secondary school. Children conceived with ART were compared to spontaneously conceived children (1) from the population, and (2) from couples with known trouble conceiving, while adjusting for background factors.
Main results and the role of chance: The study included a total of 2,420,101 children. Overall, children conceived with ART were at lower risk of ADHD (Hazard Ratio (HR)=0.81 [95% CI 0.75-0.88]) and did slightly better in lower secondary school (mean difference in the grade average (scale 0-20) (MD)=1,10 [95% CI 1.01-1.20]; eligibility Odds Ratio (OR)=1.45 [95% CI 1.31-1.61]), but once maternal characteristics were taken into account they rather appeared at a slight disadvantage (with no difference in risk of ADHD). In the comparison to children of couples with known trouble conceiving, a similar overall advantage was simply attenuated toward the null (HR=0.94 [95% CI 0.86-1.02]; MD=0.05 [95% CI -0.04-0.25]; OR=1.01 [95% CI 0.90-1.10]). Further comparison of children conceived with IVF alone versus with IVF and ICSI showed no differences in risk of ADHD.
Limitations, reasons for caution: The study concerns all children born in Sweden across two decades. Variation in clinical practice between countries is expected but may concern access to and indications for IVF/ICSI more than the medical procedures themselves. Treatment strategies have also changed over time, with single-embryo transfer policy e.g., reducing multiple gestations.
Wider implications of the findings: This study provides additional reassurance concerning offspring neurodevelopment following ART, finding no indication for concern about children's risk of ADHD or overall performance in school.
Trial registration number: not applicable

P-771 Artificial intelligence (AI) is an emerging topic in the fertility field: it is time to discuss standards of reporting AI outcomes

J. CHAMBOST[1], C. Jacques[1], C.A. Pena[1], M. Kotrotsou[2], C. Hickman[3]

[1]Apricity, AI team, Paris, France ;
[2]Apricity, Medical team, London, United Kingdom ;
[3]Apricity, AI team, London, United Kingdom

Study question: How has the reporting of AI evolved in the last two years at the annual conferences of ASRM, ESHRE and Fertility?
Summary answer: Volume of AI studies in fertility is increasing, but the quantity and quality of data remains low compared to AI in other healthcare fields
What is known already: AI has become a mainstream topic in various healthcare industries, including oncology, radiology and genetics. In fertility, Curchoe and Bormann (2019) demonstrated that AI publications at ESHRE (the largest worldwide conference in fertility, based in Europe) and ASRM (the second largest worldwide conference in fertility, based in America) increased sharply from 2017 to 2018. At ESHRE, from one to seven, and at ASRM, from one to nine. The

authors observed wide variability in how AI methods were described as well as size of datasets (from 3 to 11,898) and concluded that there was a need for applying reporting standards.
Study design, size, duration: Systematic review of conferences ASRM 2018 vs 2019, ESHRE 2018 vs 2019 and Fertility (largest UK conference in fertility) 2019 vs 2020. Program, abstract books and conference applications, as well as attendance to all six conferences, were used to collect information on all relevant abstracts, whether presented as poster or oral.
Participants/materials, setting, methods: 4986 abstracts were analysed: 1064 for ASRM 2018, 1089 for ASRM 2019, 1104 for ESHRE 2018, 1116 for ESHRE 2019, 293 for Fertility 2019 and 320 for Fertility 2020. Using PRISMA method, the abstracts were searched using the following keywords: artificial intelligence, deep learning, machine learning.
Main results and the role of chance: All three conferences reported an increase in AI publications over time: an overall increase of 1.7 fold from one year to the next (19 to 32). ASRM increased by 1.8 fold (from 9 in 2018 to 16 in 2019), ESHRE increased by 1.4 fold (from 7 in 2018 to 10 in 2019), Fertility increased by two fold (from 3 in 2019 to 6 in 2020). AI still represents a minor proportion (1%) of all abstracts. Many areas of assisted reproduction were represented, with embryo quality assessment, ploidy or viability prediction, sperm motility or quality assessment, IVF stimulation protocols and recipient-donor matching. Most studies were focused on deep learning analysis on images (81%) to improve embryo selection (69%). As described in Curchoe and Bormann (2019), high variability in data sample size continues to be the case (from 50 to 20,000 images for embryo selection topics using deep learning) with most studies analyzing a few thousands of images, which is insufficient for deep learning standards. Variability was also observed in algorithm prediction results (from 50% to 82% for classification accuracy) and all abstracts lacked sufficient details on the algorithm structure to allow for suitable scrutiny as to the validity of the claims.
Limitations, reasons for caution: This study assessed conference abstracts and associated presentations rather than publications. Of all AI abstracts identified in Fertility 2020, two were published, neither of which reached the recommended standards for AI publication seen in other fields. Studies and datasets could overlap, reducing the actual number of independent studies on AI
Wider implications of the findings: Results further emphasize the importance of setting standards for AI studies reporting and comparison. The relatively small sample sizes suggest a need for a secure data sharing infrastructure that would enable effective and high quality collaborative AI studies on sensitive data that will ultimately benefit patients.
Trial registration number: not applicable

P-772 Human error measurement and human error reduction with electronic witnessing system (EWS)

B. Aydin[1]

[1]*Ivmed Clinic Fertility Center, Embryology, Kiev, Ukraine*

Study question: Is human error during routine IVF process measurable? At what stages can human error occur most, and how can it be minimized?
Summary answer: Human error in routine IVF can be measured with EWS. With our RFID chip EWS, human error can be reduced to very low levels.
What is known already: Existing studies show that electronic witnessing system works very successfully in all stages of IVF applications, but it is still insufficient in terms of cryopreservation and software. EWSs should secure all stages of IVF process from the time patient enters the clinic to the completion of all laboratory procedures. Our study is designed to ensure biological material safety with EWS and is intended to reveal statistical data of a system that can be actively used in all laboratory processes. We also determined the cryopreservation process and the performance of all IVF personnel with the system.
Study design, size, duration: 15000 IVF cycles covering the years 2016-2020 were recorded with IVFID Electronic Witnessing system. Error warning received from 36 different IVF clinics were calculated and error distributions at each IVF stage were determined. Normal IVF patients, patient group for egg donation and surrogacy were registered, and IVF stages affected by human error were determined by calculating records of possible errors for each patient group.
Participants/materials, setting, methods: RFID electronic chip, electronic wristband and barcode system were used in every stage of patient groups. Thus, biological materials were secured throughout the entire laboratory process. The system recorded the data received via electronic chip through software and calculated it statistically. Human errors from each procedure in the embryology and andrology laboratories were recorded. In addition, the system was supported with personal witnessing patient software, and the error rate was reduced to zero.
Main results and the role of chance: In our study where 15,000 IVF cycles were evaluated, human error data received from 36 different clinics were evaluated and statistically calculated. Human error warnings were received 169 times out of 15,000 IVF cycles at different stages. Accordingly, error warnings were received 14 times during the oocyte pick up phase, 17 times during the denudation phase, 26 times during the ICSI phase, 8 times during the dish change phase, 68 times during the embryo transfer phase (17 of these were received during the fresh embryo transfer phase and 51 times during the frozen embryo transfer phase) and 36 times during the sperm preparation phase. When the error distribution according to different clinics were evaluated, error warnings were received from 23 out of 36 different clinics at different stages. Human errors were prevented by RFID electronic chip system and embryologist was warned visually and audibly on screens during the procedure. During the cryo phase of the IVFID Witnessing system with the vitrification straw chip system, no error warnings were received. Looking at individual embryologist performances, it is seen that error warnings were received from 32 different embryologists.
Limitations, reasons for caution: EWS's purpose is reducing human error and ensuring biological materials' safety. The use of system is important at every stage in Embryology/Andrology Laboratories. System can only send alerts regarding certain human errors, so 100% biological material safety isn't guaranteed. Human factor will always exist, and individual witnesses should support EWS.
Wider implications of the findings: Regular use of EWSs in IVF laboratories is very important to avoid human error-based interferences in biological materials, and they should be used regularly in IVF laboratories. In addition, EWSs can be actively used in genetic laboratories during the IVF process and clinical laboratories.
Trial registration number: not applicable

P-773 A new tool to evaluate the performance of IVF Centres

P. Arvis[1], **M. Benchaib**[2]

[1]*Clinique La Sagesse, ART, RENNES, France ;*
[2]*Hôpital Femme Mère Enfant, Laboratoire Biologie de la Reproduction, Lyon, France*

Study question: Our objective was to develop an indicator to evaluate the performance in ART, based on a very large database, and using artificial intelligence.
Summary answer: The segmentation of the treated population into 4 different prognostic classes allows a much more precise evaluation of the actual performance than the overall result.
What is known already: The overall performance of IVF Centers ,, based on Cumulative Live Birth Rate (CLBR), depends on multiple factors, including setting criteria for measuring the success, initial patient selection, practitioner competence, choice of protocols, quality of laboratory and equipment, and completeness of data collected. As a result, it is very difficult to compare performance among IVF Centers on objective and homogeneous criteria. However, the main question is to determine up to what extent the success rate depends on the skill of practitioners and laboratories, or on the initial selection of good prognosis patients. A tool is needed to answer this question.
Study design, size, duration: This non-interventional retrospective controlled study included a total of 113,253 unselected consecutive cycles (81.268 Controlled Ovarian Stimulation [COS], and 31985 Frozen embryo transfer [FET]), collected from 12 IVF French centres during 2007–2016 period. No exclusion criteria were applied, excepted for oocyte donation or preservation. This database contains complete and detailed information on patients' history and characteristics, protocols used, ovulation monitoring, oocyte collection, embryo production, transfer and freezing, and pregnancy outcome.
Participants/materials, setting, methods: The primary endpoint was the CLBR. The model was developed using the machine learning on a training set

(n=56993). Simple and multiple logistic regressions were used. From the odds ratios a selection indicator was calculated with a geometric mean, this value was divided into 4 classes. The best prognosis modality, of each selected covariates has been chosen as reference, the geometric mean cannot exceed 1. The results obtained were validated on a setting set (n=24426).

Main results and the role of chance: The multivariate analysis on the training set shows 7 baseline covariates linked to CLBR, both highly significant and independent: female age, BMI, AMH level, uterine abnormality, rank of attempt, previous abortion, parity. The combination of these indicators and their influence on the CLBR allows a selection indicator to be calculated, reflecting the overall quality of the initial selection of patients for each Centre.

We defined 4 prognosis levels for this selection indicator, with decreasing probability of CLBR (A=29,6% [22,1-36,8] - B =21,3% [18,0-30,1] - C=13,4% [6,4-20,5] - D=8,1 [3,0-14,2]), and marked differences between Centres.

The range of distribution of the 4 levels highlights the differences in initial selection of patients, especially in extreme values (A=17,2% [6,5-25,0] – B= 48,9% [43,8-52,8] – C=17,3% [11,3-19,9] – D=16,6% [9,8-26,2]).

Centres were ranked in descending order 1 to 12, according to their global CLBR. We calculated what the CLBR of each Center would have been in a standard population, by applying their own success rate in each prognosis class A-B-D-D at the standard distribution of the prognosis classes. Under this approach, the final rank order attributed to all Centers based on their global success rate is completely different from the initial rank order, namely: 1-12-7-8-2-11-9-5-6-3-4-10.

Limitations, reasons for caution: Potential biases might still exist due to missing values, in spite of statistical adjustment.

Wider implications of the findings: This calculation method of the success rate allows to disconnect the role of the initial selection of patient from the expertise of Centres. The segmentation of the treated population into 4 different prognostic classes allows to identify the Centres with specific expertise in the management of the most difficult cases.

Trial registration number: not applicable

P-774 Assessment of operator performance during oocyte retrievals: Residents' learning curve and continuous monitoring of senior physicians.

C. Verhaeghe[1], L. Inchboard[2], R. Corroenne[1], C. Dreux[1], P. Jeanneteau[1], H. El Hachem[3], P. May-Panloup[1], P.E. Bouet[1]

[1]Angers University Hospital, Department of Reproductive Medicine, Angers, France ; [2]Angers University Hospital, Clinical Research Center, Angers, France ; [3]Clemenceau Medical Center, Department of Reproductive Medicine, Beirut, Lebanon

Study question: How does the performance of residents and senior physicians during oocyte retrievals (OR) evolve over time?

Summary answer: A resident needs a mean number of 62 retrievals to reach clinical proficiency, while senior physicians maintain an adequate performance level over time.

What is known already: Only one study looked at the OR learning curve of residents, and reported a large variability between students. Indeed, it found that anywhere between 17 and 50 retrievals were needed to obtain an acceptable performance level. The learning curve cumulative summation test (LC CUSSUM test) allows to define an individualized learning curve and determine the moment when clinical proficiency is attained. After acquisition of the skills, the cumulative summation test (CUSSUM test) allows to monitor the maintenance of the required level over time.

Study design, size, duration: We performed a retrospective study at Angers university hospital between May 2017 and September 2018. 7 Obstetrics and Gynecology residents and 5 senior physicians were included, and all OR performed during that time (n=690) were analyzed.

Participants/materials, setting, methods: During OR, the operator counted the number of follicles punctured in each aspiration tube (At our center, all follicles ≥ 8 mm are punctured during OR). Each tube had a technical sheet containing the name of the operator and the number of follicles. The performance index assessed was the oocyte retrieval rate (ORR), defined as the ratio of oocytes retrieved to follicles punctured.

Main results and the role of chance: 690 OR were included: 315 were performed by residents, 220 by senior physicians, and 139 by both residents and physicians (mixed retrievals). We defined an ORR ≥50% in 60% of retrievals as the threshold of clinical proficiency. 4 residents (57%) (residents 1, 2, 3, and 4) reached the threshold after puncturing 82 67, 53 and 46 ovaries, respectively. The mean number of ovaries punctured in order to reach clinical proficiency was 62, and the mean number of weeks needed was 21. The three remaining residents did not reach the threshold during the observation period: two of them had only been training in the department for 2 months, and the third had a partial training schedule (50%). All the other residents had been training in the department for 6 months. Two senior physicians (40%) remained proficient across the duration of the study, while two physicians (40%) had one statistically "suboptimal" OR, and one physician (20%) had two suboptimal retrievals.

Limitations, reasons for caution: The main limitation of our study was the lack of randomization of the ovaries to be punctured between residents and physicians in mixed retrievals. However, we believe it would be difficult to randomize such cases with the consent of the couples.

Wider implications of the findings: The number of OR needed to achieve clinical proficiency varies between residents. Our study shows that a mean number of 62 retrievals and a full training schedule of 6 months in the department is required in order to reach the acceptable level.

Trial registration number: NA

P-775 Chromosomal abnormalities in males, but not chromosomal polymorphisms, affect the preterm delivery rate in ICSI+PGT cycles

F. Rodriguez Valderrama[1], M. Cruz Palomino[2], J. Pla Victori[3], A. Requena Miranda[2]

[1]Universidad Rey Juan Carlos, PhD student of Health Science, Madrid, Spain ; [2]Instituto Valenciano de Infertilidad, IVIRMA Global, Madrid, Spain ; [3]Instituto Valenciano de Infertilidad, IVIRMA Global, Barcelona, Spain

Study question: Do Chromosomal abnormalities (CA) or chromosomal polymorphisms (CP) in males affect the incidence of congenital alterations or pregnancy outcomes?

Summary answer: CA or CP in males don't affect the congenital alteration rate in ICSI+PGT babies, but preterm delivery rate is higher when CA are present

What is known already: IVF couples often present male/female idiopathic infertility, which could have a genetic origin. CA are known to be a major cause of gametogenesis failure. For these couples, PGT is often offered, which reduces the chance of miscarriage, birth defects, and the probability of live newborns with unbalanced CA.

CP are known as benign variants of chromosomes. Recently, some reports have shown conflicting results on their effect on IVF outcomes. Some studies found no effect, whereas others concluded that CP were associated with adverse effects, such as lower fertilization rate, implantation rate, cleavage rate, clinical pregnancy rate and live birth rate.

Study design, size, duration: A multi-center retrospective cohort analysis of autologous IVF cycles with embryo transfer performed between January 2015 and December 2018. All couples underwent karyotype screening before IVF treatment, and all females had normal karyotypes. Only cycles where euploid embryos were transferred and had at least one live newborn baby were included. Primary outcomes measured were congenital alterations rate and preterm delivery rate.

Participants/materials, setting, methods: Couples were divided in three categories according to the male karyotype: group A males with normal karyotype, Group B males with chromosomal polymorphisms and group C males with abnormal karyotype. Sperm concentration, sperm motility, fertilization rate, abnormal embryo rate, frequency of congenital alterations, low birth weight and preterm delivered were compared between the groups. Data obtained was assessed in terms of clinical outcome and statistically analyzed with ANOVA test and Chi-squared test.

Main results and the role of chance: In total 1798 couples were included in the analysis: 1698 in group A, 44 in group B and 56 in group C. There were significant differences in sperm concentration and non-progressive sperm between Group A and C but not with Group B (41.1 ± 1.1 (A) vs. 34.7 ± 10.0 (B) vs. 26.6 ± 9.6 (C), p=0.004 and 9.6 ± 0.3 (A) vs. 10.4 ± 1.7 (B) vs. 14.4 ± 6.2 (C), p<0.001,respectively).

Fertilization rate and abnormal embryo rate differed significantly between groups (FR: 76.8% (A) vs. 71.8% (B) vs. 68.8 (C), p=0.001 and AER: 46.1% (A) vs. 50.0% (B) vs. 54.8% (C), p=0.043), with group A showing the best results, followed by group B. In the case of pregnancy outcomes, group A showed better results in preterm delivery compared with group C, but not with group B (7.5% (A) vs. 5.3% (B) vs. 15.6% (C), p=0.045). Low birth weight didn't show significant difference between groups, neither did congenital alterations rate (LBWR: 8.0% (A) vs. 8.0% (B) vs. 3.3% (C), p=0.860 and CM: 4.4% (A) vs. 2.2% (B) vs. 5.3% (C), p=0.087).

Limitations, reasons for caution: The main limitation is the retrospective nature of the study, although known and suspected confounders were adjusted. Also, couples with CA are more prone to early pregnancy check-ups in order to diagnose congenital alterations and therefore perform pregnancy interruptions, the frequency of congenital alterations might be higher in this group.

Wider implications of the findings: Our results show that the incidence of congenital alterations is not affected by the presence of CA or CP in the male partner of couples undergoing ICSI+PGT cycles, but the risk of preterm delivery is slightly higher when CA are present.

Trial registration number: N/A

P-776 Obstetric and perinatal outcomes in IVF cycles in which transdermal testosterone has been used during ovarian stimulation

R. Solernou[1], F. Fabregues[1], J. Ferreri[1], E. Vidal[1], M. Solsona[1], S. Peralta[1], A. Goday[1], G. Casals[1], A. Borras[1], D. Manau[1]

[1]Hospital Clínic of Barcelona, Assisted reproduction department, Barcelona, Spain

Study question: Is transdermal testosterone (TT) supplementation in IVF cycles safe in terms of obstetric and perinatal outcomes?

Summary answer: The administration of transdermal testosterone in poor responders (PR) undergoing IVF treatment does not convey a higher risk of obstetric and perinatal complications

What is known already: Many strategies have been tried to improve the results in poor responder patients. Androgen supplementation with transdermal testosterone is the only one that has significantly increased live birth rate (LBR) in these patients. However, the offspring safety has not been analyzed

Study design, size, duration: This is a retrospective cohort study of 126 newborns coming from singleton pregnancies of poor responder patients according Bologna criteria performed between 2015 and 2018

Participants/materials, setting, methods: 126 newborns from singleton pregnancies of PR patients according to Bologna criteria were included within 2015-2018. Study group included 46 newborns from pregnancies in which TT supplementation was administered and a control group of 80 newborns in which TT was not administered. We analyzed birth weight, gestational age at delivery, incidence of preeclampsia, intrauterine growth restriction, gestational diabetes, congenital malformations and genetic disorders. In the study group TT was administered 5 days preceding ovarian stimulation

Main results and the role of chance: There were no differences in both groups in maternal age, BMI, smoke condition or duration of infertility. No significant differences were found between both groups (TT vs no supplementation) in obstetric and perinatal outcomes: birth weight (3210±421g vs 3190±426g; p=0.85), gestational age at delivery (39.4weeks vs 39.2 weeks; p=0.64), incidence of preeclampsia (2.1% vs 6.2%; p=0.36), intrauterine growth restriction (9.5% vs 5.1%; p=0.17), gestational diabetes (17.4% vs; 11.3% p=0.49), congenital malformations and genetic disorders (2.1% vs 2.4% p=0.87)

Limitations, reasons for caution: This a retrospective study with limited number of patients included. Studies are required to evaluate long-term health parameters

Wider implications of the findings: This is the first study to asses obstetric and perinatal outcomes of newborns from an IVF cycle with TT supplementation. Although randomized clinical trials are required, there seems to be no harm to the newborns health.

Trial registration number: not applicable

P-777 Dynamic view of assisted reproduction in Turkey from 1996–2018: Trends and changes in patient characteristics, clinical and laboratory practice

K. Yakin[1], B. Balaban[2], B. Urman[1]

[1]Koc University School of Medicine, Obstetrics and Gynaecology Department, Istanbul, Turkey ;
[2]American Hospital, Assisted Reproduction Unit, Istanbul, Turkey

Study question: What are the trends in patient demographics and practices in assisted reproduction treatment (ART) over the last two decades?

Summary answer: There are substantial changes in female age, indications, ovarian stimulation protocols, ovarian response, utilization of blastocyst culture and single embryo transfer, and multiple pregnancy rates.

What is known already: The last two decades have witnessed considerable changes in patient demographics and improvements in laboratory conditions, culture media and cryopreservation techniques.

Study design, size, duration: A retrospective cohort study of 24819 women who underwent autologous ART treatment in a single private center between 1996 and 2018.

Participants/materials, setting, methods: Data regarding female age, duration of infertility, treatment indication, number of previously failed treatment cycles, ovarian stimulation protocols, number of oocytes retrieved, stage of embryo development at the day of transfer, number of embryos transferred, fresh or frozen-thawed embryo transfer, method for cryopreservation, implantation, pregnancy, and multiple pregnancy rates were extracted by the calendar year of treatment. Interrupted time series and linear regression analyses were used to assess changes in patient characteristics, trends and outcomes.

Main results and the role of chance: Over 23 years during which the data was collected, there was a steady increase in the average age of women undergoing ART from 32.0 to 37.4 years. The duration of infertility showed a downward and the average number of previously failed cycles showed an upward trend. The major indication for ART was male factor infertility until 2001, and then it was gradually replaced by diminished ovarian reserve and unexplained infertility. GnRH antagonist protocols gradually took over GnRH agonist protocols. The mean number of retrieved oocytes decreased from 11.5 to 6.9. The mean number of embryos transferred decreased from 3.9 to 2.4 until 2010, and then to 1.5 following a legislative restriction. Blastocyst stage transfers were started in 1998 and were gradually increased to 50.8% of all transfers by 2018. While multiple pregnancy rates decreased from 31% to 9%, clinical pregnancy rates per embryo transfer were constant between 1997-2018, ranging between 31.6-43.9%. Clinical pregnancy rates in frozen-thawed embryo transfers showed a significant increase after 2015, in parallel with increased utilization of blastocyst vitrification.

Limitations, reasons for caution: This is a retrospective cohort analysis from a single center and does not intend to confirm any causality.

Wider implications of the findings: ART practice in Turkey has evolved in parallel with worldwide trends. While IVF patients are getting older, increased utilization of single embryo transfer at the blastocyst stage and improvements in cryopreservation techniques helped maintain high live birth rates and reduced multiple births.

Trial registration number: Not applicable

P-778 Impact of cell loss after warming of human vitrified day 3 embryos on the obstetrical outcome in single frozen embryo transfers

A. Racca[1], G. Coticchio[2], F. Di Guardo[3], A. Borini[2], P. Drakopoulos[3], S. Mackens[3], H. Tournaye[3], G. Verheyen[3], C. Blockeel[3], L. Van Landuyt, Belgio[3]

[1]UZ Brussel, CRG - Centre Reproductive Medicine, Brussels, Belgium ;
[2]9.baby, Reproductive medicine, Bologna, Italy ;
[3]UZ Brussel, CRG - Centre Reproductive Medicine, Brussel, Belgium

Study question: Does cell loss (CL) after vitrification and warming (V/W) of day 3 embryos have an impact on live birth rate (LBR) and neonatal outcomes?

Summary answer: LBR is significantly higher with intact embryo as compared with an embryo with CL after V/W. Neonatal outcomes are comparable between the two groups.

What is known already: The use of frozen embryo transfer has progressively increased in the last two decades due to the advances in the development of efficiency and safety of cryopreservation techniques, especially in

vitrification. Indeed, vitrification has replaced the slow-freezing technique as an effect of its improved survival rate, fully intact embryo rate and implantation rate as compared with slow-freezing procedures. However, day 3 vitrified embryos with CL after warming, showed lower overnight cleavage rate than fully intact embryos in both methods. In this context, it is interesting to investigate whether the CL may impact pregnancy rate, LBR and neonatal outcomes.

Study design, size, duration: This present retrospective analysis includes all cleavage stage day 3 embryos (n=2334) that were vitrified and warmed between 2011 and 2018. Only single vitrified/warmed embryo transfers were included. Each woman was included only once in the analysis. Pre-implantation genetic screening, oocytes donation and age banking were excluded from the analysis.

Participants/materials, setting, methods: The sample was divided into two groups, namely group A (intact embryo after warming) and group B (<50% blastomere loss after warming). The vitrification method used was closed vitrification using CBS-VIT High Security straws with D

Main results and the role of chance: A total of 2334 embryos were included in the analysis. Group A contained 1954 fully-intact embryos (83.7%), while group B had 380 (16.3%) CL embryos after V/W. In group B, the majority of the embryos had lost one cell (235 embryos, 61.8% of the CL-embryos). Demographic characteristics such as age at cryopreservation, cause of infertility, insemination procedure and semen origin were comparable between the two groups. The positive hCG rate (30% and 23.9%, respectively for intact vs CL group, p=0.018) and LBR (13.7% and 11.6%, respectively for intact vs CL group, p=0.018) per warming cycle were significantly higher in the intact embryos group; however, the LBR per positive hCG was equivalent between intact and damaged embryos (45.6% vs 38.5%, respectively, p=0.2). Newborn measurements (length, weight and head circumference at birth) showed no statistical difference between the two groups. Multivariate logistic regression was performed in order to adjust for potential confounders and it showed that intact vs CL embryos is not predictive of LBR when holding for patients' age and embryo quality.

Limitations, reasons for caution: The major limitation of the present study is its retrospective design. However, this study question would not benefit from a prospective design as it wouldn't be possible to control for embryo damage and deciding to transfer intact or a no-intact embryo would not reflect the real clinical setting.

Wider implications of the findings: This is the first study providing evidence that CL due to V/W of cleavage stage embryos doesn't influence newborn measurements. Vitrification of cleavage stage embryos is associated with lower pregnancy and live birth rates when there is blastomere loss. However, once implantation ensues, LBR is not hindered by cell loss.

Trial registration number: not applicable

P-779 Conception by means of in vitro fertilization (IVF) is not associated with nausea and vomiting of pregnancy

F. Bazargani[1], A. Skalkidou[1], E. Elenis[1]

[1]Uppsala University, Department of Women's Health- Uppsala University Hospital- Uppsala- Sweden, Uppsala, Sweden

Study question: Is there any association between mode of conception or IVF-related variables and nausea and vomiting of pregnancy (NVP)?

Summary answer: Conception by means of IVF is not associated with NVP but the stage of the transferred embryo may affect NVP development.

What is known already: The exact cause of NVP is unknown but risk factors including increased hormonal levels, maternal distress and anxiety disorders, also described in IVF populations, have been reported. There are only a few studies exploring NVP in IVF samples. A population-based study examining the characteristics of women who suffered from a severe form of NVP, it was reported that women with severe NVP had more often conceived through assisted reproduction techniques. So far, the relationship between NVP and IVF or different treatment related parameters in the IVF population in relation to NVP remains unclear.

Study design, size, duration: The study is a longitudinal, matched - cohort, pilot study including 630 pregnant women with singletons without malformations, recruited during the pregnancy ultrasound in gestational week 17 (GW 17). The study was conducted between 2010-2016 at the University Hospital of Uppsala, Sweden.

Participants/materials, setting, methods: The study population comprised 210 women with IVF conceived pregnancies and 420 age and parity matched women with spontaneous pregnancies. All participants self-reported sociodemographic and pregnancy-related information. IVF treatment data were obtained after scrutinization of the medical records. The outcome, NVP at GW 17, was divided into: 1) absence of NVP, 2) NVP not requiring medications and 3) NVP requiring medications. NVP was then studied in relation to exposure and to different IVF treatment-associated variables.

Main results and the role of chance: The mean age of the participants was 33.7 years with 2/3 of the participants being primipara. IVF pregnant women reported more frequently comorbidities (such as hypertension, diabetes, migraine etc) (59.1% vs 49.9%), but less frequently alcohol consumption (38.4% vs 48.7%) compared to women with spontaneous pregnancies. Clinical and sociodemographic characteristics such as education, employment, smoking habits, maternal BMI, depression history, delivery fear and newborn gender, were otherwise similar between the groups. NVP with or without medications was not associated with mode of conception (p=0.889); 11.4% of women who conceived through IVF suffered from NVP requiring medications and 62.4% from unmedicated NVP *vs* 10.8% and 64.3% respectively of women with spontaneous pregnancies. Absence of NVP was reported by 26.2% of IVF and 24.9% of spontaneously pregnant women. However, in a subgroup analysis in the group of women who conceived through IVF, NVP was more frequently seen in the group who received cleavage stage embryos *vs* blastocysts (p=0.019). We could not however find any significant difference in the rate of NVP with or without medications between fresh (69.4%) or frozen/thawed embryo transfers (78.5%), nor between IVF(72.3%) and intracytoplasmic sperm injection(ICSI)(77.4%) treatments. Lastly, there was no significant difference between infertility diagnosis and NVP.

Limitations, reasons for caution: The study had limited power to detect differences in NVP in relation to mode of conception. In addition, there was a missing rate of 30.5% in the reported embryo stage variable. Finally, the rate of blastocyst-transfers during that period was lower than otherwise expected with current statistics.

Wider implications of the findings: It is still unclear whether IVF has an impact on the risk of NVP. However, transfer of a blastocyst may decrease the risk of developing NVP.

Trial registration number: Non- applicable

P-780 Natural cycles in frozen-thawed embryo transfer are associated with lower risks of preeclampsia and large-for-gestational age infants than artificial cycles; A systematic review and meta-analysis

J.A. Moreno[1,2], M.A. Checa[1,3], J.J. Espinós[1,3]

[1]Universitat Autonoma de Barcelona, Gynecology and Obstetrics, barcelona, Spain ; [2]Clinica de la Mujer, Reproductive Medicine, Vina del Mar, Chile ; [3]Fertty, Reproductive Medicine, Barcelona, Spain

Study question: Is Natural cycle frozen embryo transfer (NC-FET) safer than Artificial cycle frozen embryo transfer (AC-FET) for perinatal and maternal outcomes?

Summary answer: Women undergoing NC-FET have a lower risk of hypertensive disorders in pregnancy, preeclampsia and have a newborn large for gestational age than women after AC-FET.

What is known already: Frozen embryo transfer (FET) is associated with a higher risk of hypertensive disorders in pregnancy (HDP), preeclampsia, have a newborn large for gestational age (LGA) and macrosomia compared with fresh embryo transfer (ET), but it is hypothesized that the hormonal endometrium preparation used for the thawed embryo transfer may contribute to the development of placenta-related pregnancy complications.

Study design, size, duration: We conducted a systematic review and meta-analysis of 6 published cohort studies (including 66391 women)

Participants/materials, setting, methods: Literature searches were conducted to retrieve studies which reported on perinatal and maternal outcomes of pregnancies after FET. Databases searched included PubMed/Medline, SCOPUS and The Cochrane library to identify all relevant studies published until October 2019. Six studies matched the inclusion criteria.

Main results and the role of chance: NC-FET is associated with a lower risk of HDP (OR 0.66; 0.53-0.82), preeclampsia (OR 0.51; 0.41-0.64) and LGA

(OR 0.92; 0.87-0.97) compared to AC-FET. There was no significant difference in the risk of macrosomia. Regarding the secondary outcomes, NC-FET had lower odds of preterm birth (OR 0.87; 0.81-0.93), post-term birth (OR 0.41;0.21-0.83), low birth weight (OR 0.84; 0.79-0.89), small for gestational age (OR 0.91; 0.84-0.98), cesarean section (OR 0.75; 0.63-0.89), postpartum hemorrhage (OR 0.36; 0.30-0.42) and placenta accreta (OR 0.17; 0.09-0.32) compared with AC-FET. No statistical differences were noted in the remaining secondary outcomes. The included studies scored well on the Newcastle-Ottawa quality assessment scale.

Limitations, reasons for caution: The review is limited by the quality of the included studies and no randomized controlled trials (RCT) were included. Outcomes such as HDP and macrosomia showed substantial heterogeneity.

Wider implications of the findings: Concerning safety, NC-FET significantly decreases the risk of HDP, preeclampsia, LGA, preterm birth, post-term birth, low birth weight, small for gestational age, cesarean section, postpartum hemorrhage and placenta accreta. Further RCTs that addresses the effect of NC-FET and AC-FET on maternal and perinatal outcomes are warranted.

Trial registration number: not applicable

P-781 Is there a relationship between morphokinetic parameters and perinatal outcome? An analysis of singleton live births after single fresh embryo transfer.

A. Wertheimer[1], S. Onit[1], H. Alyssa[1], B.H. Avi[1], O. Galia[1], S. Ekaterina[1], A. Eran[1], S. Tzippy[1], S. Yoel[1]

[1]Helen Schneider Hospital for Women- Rabin Medical Center-Beilinson Hospital-, IVF and Infertility Unit, Petach-Tiqva, Israel

Study question: Is there a relationship between morphokinetic time-lapse parameters and the perinatal outcome in singleton gestations?

Summary answer: After adjusting for confounding variables, obstetric and perinatal outcomes were not related to any morphokinetic parameter.

What is known already: An association between embryo morphokinetics, implantation and clinical pregnancy rates was studied and reported in numerous publications. However, little is known regarding the association between morphokinetic parameters and the obstetric and perinatal outcomes and complications**.**

Study design, size, duration: A cohort study reviewing fertility and delivery files of all births from successfully treated infertile patients, who underwent ovarian stimulation, IVF embryo culture in time-lapse monitoring incubators and fresh single embryo transfer in a tertiary medical center between June 2013 and April 2019. The study group consisted of 177 single embryo transfers that resulted in 177 live births. Morphokinetic parameters were analyzed in correlation to perinatal complications.

Participants/materials, setting, methods: Embryos were annotated using a time-lapse system after ICSI or insemination. Embryo selection was based on locally established annotation criteria and the KID score provided by the Embryoscope^{tm} (Vitrolife, Denmark). The perinatal complications investigated were: gestational diabetes mellitus (GDM), intra-uterine growth restriction (IUGR), preterm labor (PTL), pre-eclamptic toxemia (PET), revision of uterine cavity, and post-partum hemorrhage (PPH). Logistic regression analysis was utilized to adjust results for potential confounders.

Main results and the role of chance: All deliveries in the study group resulted in live-births. Maternal baseline and treatment characteristics were similar between the groups except for a lower BMI in the IUGR complicated group and a higher BMI in the uterine revision complicated group (21.4±5.9 Kg/m^2 vs. 24.1±3.3 in the non-IUGR group, p=0.024, and 24.1±5.9 vs. 21.1±3.2 in the non-revision group, p=0.043).

Early morphokinetic time-lapse parameters including pronucleus fading, cleavage timings (t2-t8), second cell cycle duration (T3-T2) synchrony (T4-T3) and interval between 8 and 5 cells (T8-T5) were similar between the groups. Late morphokinetic parameters including full compaction at morula stage (tM), start of blastulation (tSB), full blastocyst (tB), and hatching (tHB) were similar between the groups as well, except for a shorter tB in the IUGR complicated group (96.7±5.3 hours vs. 103.2±3.1 in the non-IUGR group, p=0.020). Known implantation data of day 3 and 5 (KID3 and KID5 respectively) analysis revealed higher KID3 score in the IUGR complicated group (4.83±0.39 vs. 4.50±1.0 in the non-IUGR group, p=0.027). On multivariate regression analysis, none of the morphokinetic parameters that were significantly associated with perinatal complications in the univariate analysis were found to be significantly correlated with any of the perinatal complications.

Limitations, reasons for caution: Retrospective design, sample size and the inclusion of only singletons born after single embryo transfer.

Wider implications of the findings: Our findings may be used to reassure women and physicians that different morphokinetic parameters of the embryo transferred, providing the pregnancy continues to the third trimester, do not appear to be associated with increased risks for adverse obstetric and perinatal outcomes.

Trial registration number: not applicable

P-782 Trends in Ovarian Hyper-Stimulation Syndrome (OHSS) hospitalization rates in the United States (U.S.) based on 12,608,757 admissions in women aged 18-43 years: An ongoing concern

K. Rotshenker Olshinka[1], A. Badeghiesh[2], A. Volodarsky-Perel[3], N. Steiner[3], E. Suarthana[4], M.H. Dahan[5]

[1]McGill University- Montréal Quebec- Canada., Department of Obstetrics and Gynecology- Division of Reproductive Endocrinology and Infertility-, Montreal, Canada ;

[2]McGill University- Montréal Quebec- Canada., Department of Obstetrics and Gynecology, Montreal, Canada ;

[3]McGill University- Montréal Quebec- Canada., Department of Obstetrics and Gynecology- Division of Reproductive Endocrinology and Infertility, Montreal, Canada ;

[4]McGill University- Montréal Quebec Canada., Department of Obstetrics and Gynecology, Montreal, Canada ;

[5]McGill University- Montréal Quebec Canada., Department of Obstetrics and Gynecology- Division of Reproductive Endocrinology and Infertility, Montreal, Canada

Study question: Do we see downward trends in OHSS admissions since the development of preventative strategies, based on the National-Inpatient-Survey 2004-2014?

Summary answer: A decrease in OHSS hospitalizations, as well as number admitted-per-fresh IVF cycles, was seen 2004- 2008. However this decrease stopped and has plateaued since 2008.

What is known already: Many techniques have developed over the last 25 years to decrease OHSS risks. These include GNRH-antagonist IVF cycles, GNRH-agonist triggering of oocyte maturation and use of dopamine agonists to decrease VEGF production. Though uncommon, OHSS may sometimes be unpredictable, occurring in low risk women. Concurrently, use of assisted reproduction technology(ART) is increasing putting more women at risk for OHSS. In light of new techniques, It could be hypothesized that rate of OHSS admissions would decrease. However, according to the U.S. National ART Surveillance System (NASS), the rate of OHSS didn't change significantly between 2000-2009, estimated at 106/10,000 IVF cycles yearly.

Study design, size, duration: We conducted a retrospective population-based study utilizing data from the Health Care Cost and Utilization Project-Nationwide Inpatient Sample database (HCUP-NIS) over 11 years- 2004-2014, and based on the number of fresh IVF cycles per year as reported by the NASS during the study period. HCUP-NIS is the largest inpatient database in the U.S. covering over 97% of the U.S. population and represents approximately 20% of all discharges from community hospitals.

Participants/materials, setting, methods: We evaluated OHSS admissions between 2004 and 2014 inclusively. Women age 18-43 were queried for OHSS admissions using ICD-9 code 256.1.This resulted in a database of 12,608,757 admissions, 1900 for OHSS. Data was compared as absolute numbers, percentage of admissions per year in women 18-43 years old and as a percentage of all IVF cycles yearly, reported to the national database. Analysis was done using Mann-Kendall trend test (two-tailed).

Main results and the role of chance: During the study period, there were between 1.2-2/10,000 OHSS hospitalizations in women age 18-43, corresponding with a total of 1900 OHSS hospitalizations out of 12,608,757 database hospitalizations in the age group. The mean number of OHSS admissions per year during 2004-2007 was 261.5 (245-300, SD-25.8), and decreased to 171 subsequently (157- 191, SD-14.2). Evaluating data during the study period, there has been a decrease in both total number of OHSS hospitalizations (p=0.004),

and the frequency of OHSS admissions per 10,000 total women admissions (p=0.035). However, this decline was demonstrated only between 2004 and 2008. Since 2008, the total number of OHSS admissions per year (p=0.734) as well as OHSS admissions-per 10,000 women's admissions (P=0.733) have plateaued, with insignificant changes between 2008-2014. The number of fresh IVF cycles as reported by the NASS have increased from 94,242 to 128,268 cycles, during the study period. When dividing the number of OHSS hospitalizations in the database by the number of fresh IVF cycles, per year, we demonstrate similar trends, a decrease in the number of OHSS hospitalizations per IVF cycle, per year, during the study period (p=0.002) but a plateau from 2008-2014 (p=0.308).
Limitations, reasons for caution: The HCUP-NIS is the largest inpatient sample database in the U.S, but does not include non-community based hospitals, potentially excluding many OHSS admissions. Furthermore, the information was not gathered prospectively and is based on hospital records according to the ICD-9 code, which may mask bias.
Wider implications of the findings: OHSS remains a concern, as frontline ER physicians continued to see similar frequencies of OHSS-visits from 2008-2014. The financial burden of OHSS-hospitalizations persists. Although, techniques have likely resulted in a decrease in OHSS admissions since 2004, this has plateaued, and efforts to further reduce OHSS must continue.
Trial registration number: N/A

P-783 The best choice for embryo transfer in good prognosis patients undergoing freeze-only police: one plus one is better than two

P.A. Monteleone[1,2], P. Peregrino[2,3], J. Miorin[3], A. Gomes[4], H. Martin[2,4], T. Bonetti[5,6]

[1]Centro de Reproducao Humana Monteleone, Clinical director, Sao Paulo / SP, Brazil ;
[2]Universidade de São Paulo, Disciplina de Ginecologia - Departamento de Obstetrícia e Ginecologia, São Paulo, Brazil ;
[3]Centro de Reproducao Humana Monteleone, Clinical, Sao Paulo / SP, Brazil ;
[4]Centro de Reproducao Humana Monteleone, Embriology, Sao Paulo / SP, Brazil ;
[5]Universidade Federal de São Paulo, Gynecology, São Paulo, Brazil ;
[6]Centro de Reproducao Humana Monteleone, Scientific department, Sao Paulo / SP, Brazil

Study question: Which is the best choice for embryo transfer in good prognosis patients undergoing freeze-only police to get best pregnancy success rate and lower adverse effects?
Summary answer: In freeze-only cycles, transferring embryos one-plus-one in subsequent transfers is better than double embryo transfer regards both, higher ongoing pregnancy rates and lower multiple gestation.
What is known already: The freeze-only practice has been increasing recommended in ART. It is supposed to support better synchrony between embryo and endometrium in the absence of ovarian stimulation and is beneficial for patients at ovarian hyperstimulation syndrome (OHSS) risk or undergoing preimplantation genetic testing for aneuploidy. Single embryo transfer (SET) is the best choice to reduce multiple pregnancies and the associated risks, and have been recommended in ART, as well. Then, we hypothesized that the sequential frozen-thawed SET in freeze-only cycles of patients at OHSS risk could result in a more efficient approach compared to transfer of two embryos.
Study design, size, duration: Retrospective cohort study reviewed 5156 cycles performed between 2011 and 2019 in a private ART center. Five hundred and six (n=506) cycles match the inclusion criteria: ICSI using own oocytes and ejaculated/epididymal sperm, no embryo genetic diagnosis, freeze-only police (no fresh embryo transfer) and elective frozen-thawed embryo transfers (eFET) of one or two embryos in a subsequent hormone replacement cycle. eFET was defined as cycles which at least one surplus embryo was available after transfer.
Participants/materials, setting, methods: Patients underwent IVF cycle as routine and were split into two groups: elective Double Embryo Transfer (eDET:n=291) and elective Single Embryo Transfer (eSET:n=209). In the eSET group, 60 women who failed in the 1st eSET, had a 2nd transfer of one embryo. The ongoing pregnancy rates (OPR) after eDET versus eSET+SET were compared. The estimated cumulative ongoing pregnancy rate for eSET+SET group was calculated by [OPR at 1steSET+OPR at 2ndSET * (1-OPR at 1steSET)].
Main results and the role of chance: Groups were homogeneous to demographics characteristics as age (eDET: 34.9±4.2 versus eSET: 35.4±6.9; p=0.155), basal FSH measurement (eDET: 6.3±3.2 versus eSET: 6.3±5.0; p=0.599), dose of gonadotropin administered (eDET: 1869.9±481.4 versus eSET: 1809.4±372.2; p=0.129). Despite of MII oocytes recovered had been higher in eDET (13.3±7.4) versus eSET (15.2±8.5; p=0.008), the number of embryos vitrified and available for transfer (eDET: 8.8±4.5 versus eSET: 9.1±4.5; p=0.381) were similar between groups. After the 1st eFET, the OPR was statistically similar between groups (eDET: 46.9% versus eDET: 44.4%; p=0.596). When we evaluated the estimated cumulative OPR after a 2nd FET in the eSET+SET group, it was significantly higher (63.5%) than eDET (46.9%, p<0.001). Additionally, while the eSET+SET group had 2.2% of multiple gestation, the eDET group had 26.9% of multiples (p<0.001). The choice about the number of embryos to be transferred was performed as a shared decision-making process between patients and doctors, after an explanation of advantages and disadvantages of each situation as routine.
Limitations, reasons for caution: The retrospective characteristic of this study is a limitation. Another point to be considered is that quality of embryos transferred were not assessed in this study. However, all transfers included were elective, which indicate that the best quality embryo was always preferred.
Wider implications of the findings: We demonstrated that the transfer of embryos one by one results in higher cumulative ongoing pregnancy rate compared to a transfer of two embryos in one cycle, and reduce drastically the multiple pregnancy. Thus, we conclude the transfer of one by one is the best choice in freeze-only cycles.
Trial registration number: not applicable

P-784 Residents in training and senior physicians have comparable oocyte retrieval rates, but physicians perform significantly better in complicated cases.

C. Verhaeghe[1], H. El Hachem[2], R. Corroenne[1], C. Dreux[1], P. Jeanneteau[1], L. Inchboard[3], P. May-Panloup[1], P.E. Bouet[1]

[1]Angers University Hospital, Department of Reproductive Medicine, Angers, France ;
[2]Clemenceau Medical Center, Obstetrics & Gynecology- Reproductive Endocrinology & Infertility, Beirut, Lebanon ;
[3]Angers University Hospital, Clinical Research Center, Angers, France

Study question: Is there any difference in oocyte retrieval rates (ORR) between residents in training and senior physicians?
Summary answer: Residents in training and senior physicians have comparable ORR. Operator experience makes a significant difference in cases of endometriosis and polycystic ovarian syndrome (PCOS).
What is known already: Most university hospitals in France do not have a simulation based training program for oocyte retrievals (OR) for residents in training. They usually learn by first assisting senior physicians in the operating room, before gradually performing them, starting with one ovary (usually the more accessible one) (mixed retrievals), then the whole procedure. This approach has proven to be somewhat efficient, but there is a large variability in the learning curve of residents, with one study showing that anywhere between 17 and 50 OR are needed to achieve clinical proficiency.
Study design, size, duration: We performed a retrospective single center study at the Angers university hospital between May 2017 and September 2018. All oocyte retrievals performed during that time (n=690) by all the senior physicians (n=5) and the Obstetrics and Gynecology residents in training (n=7) were included.
Participants/materials, setting, methods: We defined the ORR as the rate of oocytes retrieved to the number of punctured follicles (at our center, all follicles ≥8 mm are punctured). Before the retrieval, each participant counted the total number of follicles to be punctured. The number of follicles punctured per aspiration tube and the name of the operator were written on a sheet that was annexed to the tube.
Main results and the role of chance: Overall, 674 OR were included for the final analysis, 315 performed by residents, 220 by senior physicians, and 139 by both residents and physicians (one side per operator). There was no significant difference in the mean ORR between residents (61.9%) and senior physicians (62%) (p=0.99). Multivariate analysis showed a non-significant difference of 2% in the performance level between the two groups (p=0.52). In cases of endometriosis, there was a significant difference of 12% in favor of senior physicians (p=0.03). Finally, in women with PCOS,

there was a significant difference in the ORR between residents (50%) and senior physicians (56%) (p<0.001), but both groups had suboptimal ORR (defined as <60%).

Limitations, reasons for caution: The main limitation of our study is the retrospective design, and the lack of randomization of which ovary to be punctured between residents and physicians in mixed retrievals.

Wider implications of the findings: Residents in training and senior physicians have overall comparable mean ORR, but senior physicians perform significantly better in cases of endometriosis and PCOS. Therefore, a more targeted training, with the help of simulation training, should be introduced to improve the performance levels in these more challenging cases.

Trial registration number: N/A

P-785 Cardiac diastolic function of 8-9-year-old singletons following fresh or frozen embryo transfer compared to naturally conceived – preliminary results from a cardiac magnetic resonance study

I. Mizrak[1,2], L.L. Asserhøj[1,3], R.B. Jensen[3], M.A.V. Lund[4], G.F. Heldarskarð[1,3], A.S.L. Kjær[1,3], G. Greisen[5], N. Vejlstrup[6], P.L. Madsen[2], A. Pinborg[1]

[1]Rigshospitalet, Fertility Clinic, Copenhagen, Denmark ;
[2]Herlev-Gentofte Hospital, Department of Cardiology, Herlev, Denmark ;
[3]Rigshospitalet, Department of Growth and Reproduction, Copenhagen, Denmark ;
[4]University of Copenhagen, Department of Biomedical Sciences, Copenhagen, Denmark ;
[5]Rigshospitalet, Department of Neonatology, Copenhagen, Denmark ;
[6]Rigshospitalet, Department of Cardiology, Copenhagen, Denmark

Study question: Do singletons conceived after fresh or frozen embryo transfer (FET) have altered cardiac diastolic function compared to naturally conceived children at age 8-9 years?

Summary answer: Children conceived after fresh embryo transfer (Fresh ET) may have impaired left ventricle peak-filling-rate compared to the other two groups.

What is known already: Epigenetic changes secondary to assisted reproductive technology (ART) may alter the cardiovascular system. While singletons conceived after FET are more likely to be large-for-gestational-age, singletons from Fresh ET are at increased risk of being small-for-gestational-age. Studies have suggested that ART children compared with NC children more often have endothelial dysfunction, exaggerated pulmonary hypoxic vasoconstriction, insulin resistance, higher body mass index and arterial blood pressure. In patients known with metabolic syndrome, the latter cardiovascular changes are associated with cardiac diastolic dysfunction. So far, no studies have addressed the effect of Fresh ET and FET on diastolic cardiac function**.**

Study design, size, duration: In all 150 singletons are planned to be recruited in this cohort study. We perform cardiac MRI in 50 children conceived after Fresh ET; 50 children conceived after FET and 50 NC singletons. So far, 124 children have undergone cardiac MRI, and images from 59 children have been analyzed with respect to diastolic function in a blinded manner. The inclusion started in January 2019 and will be completed in March 2020.

Participants/materials, setting, methods: ART singletons were identified through the Danish IVF and Medical Birth registries. NC children matched with respect to sex and birth year served as controls. Cardiac MRI was performed without anesthesia or contrast. Left (LV) and right ventricular (RV) function and volumes, maximum volume of left atrium (LA), LA early-emptying-fraction, LV peak-ejection-rates (PER), peak-filling-rates (PFR) and PER/PFR are reported. Variables were compared by ANOVA or chi-square test (P≤0.05, double-sided) without correction for multiplicity of P.

Main results and the role of chance: Presented results are from preliminary data as inclusion and post-processing work is still ongoing. We have cardiac MRI data on RV and LV systolic function and LV diastolic function from 59 children: 20 children conceived after Fresh ET; 20 children conceived after FET and 19 NC children. The median age of the participants is 9.0 (IQR 8-9) years. Data show no differences in LV and RV ejection fraction, end-diastolic and end-systolic volumes, stroke volumes and left ventricular mass between the three groups. With respect to data on LV diastolic function, no differences were observed in LA volume and LA early emptying fraction; but children conceived after Fresh ET tended to have lower PFR (292± 63 mL/s *vs*. 338±46 mL/s (FET) and 305±78 mL/s (NC); P=0.066; mean±SD) and higher PER/PFR ratio (1.06±0.27 *vs*. 0.91±0.19 (FET) and 0.95±0.17 (NC); P=0.087) compared to the other two groups.

Limitations, reasons for caution: Results are based on preliminary analysis on a cohort. Further analysis of cardiac diastolic function will include peripheral resistance and artery distensibility. Selection bias may be seen as the participation rate was 19.1% in Fresh ET, 21.7% in FET and only 9.1% in NC children.

Wider implications of the findings: The trend towards a decreased LV PFR in the Fresh ET group could be related to the endothelial dysfunction and increased arterial blood pressure previously described after ART. If the absence of diastolic dysfunction in FET children will be confirmed in the full study group, this would be reassuring.

Trial registration number: NCT03719703

P-786 Comparison of physical growth parameters of children conceived by donor oocytes with fresh versus frozen embryo transfer upto 5 years of age :a prospective study

M. Varma[1], S. Singh[2], S. Verma[3], H. Tuli[4], R. Kumar[4], T. Kaur[5]

[1]Sadbhavna Medical & Heart Institute, OBGY, Patiala, India ;
[2]Artemis Health Institute, Reproductive Medicine, Gurugram, India ;
[3]University of California, Life Sciences, San Diego, U.S.A. ;
[4]Sadbhavna Medical & Heart Institute, Neonatology, Patiala, India ;
[5]Sadbhavna Medical & Heart Institute, Anaesthesia, Patiala, India

Study question: Are the weight/length/height/head circumference (mean Z-scores)different in children conceived by frozen embryo transfer(FET) or freshET in a donor oocyte(DO) model, during the first 5 years

Summary answer: Weight of children at 2-5 years was significantly more in FET than fresh ET group with DO after adjusting for maternal age and BMI

What is known already: Prospective studies regarding the potential effect of freezing protocols on childhood growth are limited with comparable / trends of increased weight. FreshET has been compared to FET where ovarian stimulation remains an important variable affecting early events in pregnancy. DO babies have been reported to be spared of macrosomia in FETs. In this study, comparing the growth of children conceived by fresh ET versus FET, in a DO model, with similar laboratory procedures and vitrification protocols, a better insight into the effects of vitrification is observed, as several important confounders are eliminated. There is limited published data regarding the same.

Study design, size, duration: In this prospective cohort study, conducted from 2014-2019 at a tertiary centre, 209 children conceived by DO (delivered after 32 weeks gestation) were followed-up at birth and at one point of time (age 1month – 5 years) Data was available for mothers(n=161), children(n=189); conceived by freshET (n=109),FET(n=80). Both groups had similar ICSI, vitrification/thawing, ET(2/3 cleavage stage) protocols. The IVF program, deliveries, follow-up was conducted at the same institution. Some children were followed-up by post

Participants/materials, setting, methods: Weight/length/height/head circumference(HC) were recorded at birth and later at one point of time as Z-scores (WHO growth standards) to adjust for age at measurement. This was further adjusted for maternal age and BMI. Children were divided into two groups < 2 years and 2-5 years. Singletons were analysed as a sub-set. Two-sample t- test was used to compare means. Multiple regression analysis was used to adjust for potential confounders. Statistical significance was set at *P*<.05(2-tailed)

Main results and the role of chance: Maternal mean age and BMI were comparable in the fresh ET and FET groups at 35.30 ± 5.38 years versus 33.99± 6.65 years(*P*=.13) and 26.70±1.90kg/m2 versus 26.60± 1.99kg/m2(*P*=.72),respectively.

All mothers were non-smokers, 150/161 were nulliparas Incidence of pregnancy complications like preeclampsia, gestational diabetes was similar in both the groups. Oocyte donors were< 30 years with comparable mean BMI(*P*=.34)

The mean Z -scores for birth weight of singletons(n=133) was comparable for the fresh(n=68) and frozen transfers(n=65) after adjusting for maternal age and BMI(*P*=0.06)

In the <2 years cohort, children conceived by fresh ET(n=34) and FET(n=41) and in the 2-5 years group, fresh ET(n=75) and FET(n=39).

In the 2-5 years cohort, mean Z -scores for weight was significantly more for the FET group of all children, compared to the fresh ET group (0.45±1.18 versus -0.09±1.15 ,*P*=.02) Even in the singleton subset, the weight of children in the FET group was more versus fresh ET (0.53±1.18 versus -0.10 ±1.09, *P*=.01). This difference remained significant in both groups even after adjusting for maternal age and BMI(*P*=.004 and *P*=.015,respectively).

Mean Z -scores for weight in the <2year groups, as well as, length/height in all the groups were comparable. HC did not follow any definite statistically significant trend.

Limitations, reasons for caution: This was a single centre study with a limited sample size. After birth, the growth parameters of children were recorded at a single point in time only (requiring the need for Z -scores for comparison)

Wider implications of the findings: Our study, using the DO model, shows significant greater weight of children at 2-5 years conceived by frozen compared to fresh ET. This needs to be confirmed in larger studies with longer follow-ups. The mechanism and clinical relevance of this, also needs to be scientifically explored

Trial registration number: Not Applicable

P-787 Effect of embryo cryopreservation duration on pregnancy-related complications and birthweight after frozen-thawed embryo transfer: a retrospective cohort study

X. Jing-Jing[1], L. Chen[1], C. Li[1], H.F. Huang[1], Y.T. Wu[1]

[1]School of Medicine- Shanghai Jiao Tong University, International Peace Maternity and Child Health Hospital, Shanghai, China

Study question: Whether embryo cryopreservation duration has impact on pregnancy-related complications and neonatal birthweight in women with frozen-thawed embryo transfer (FET)?

Summary answer: Embryo cryopreservation duration does not have negative effects on pregnancy-related complications or birthweight after FET.

What is known already: Several studies have indicated that embryo cryopreservation duration has no effect on the survival rate of the embryo after thawing or the neonatal birthweight in singleton. However, almost all these studies excluded the multiple pregnancies, and no study has focused on the effect of embryo cryopreservation duration on maternal safety in terms of pregnancy-related complications.

Study design, size, duration: A retrospective cohort study including all FET cycles with livebirth deliveries in a university hospital from May 2010 to September 2017 was conducted. These deliveries were grouped according to the cryopreservation duration of the transferred embryo (≤3 months, 4-6 months, 7-12 months, and >12 months).

Participants/materials, setting, methods: Among all 12,158 FET cycles, a total of 3,864 livebirth deliveries comprising 2,995 singletons and 1,739 multiples were included in the analysis. Multinomial and multilevel logistic regression were used to evaluate the associations between embryo cryopreservation duration and pregnancy-related complications or neonatal birthweight among the groups stratified by singletons and multiples. Odds ratios (ORs) and 95% confidence intervals (CIs) were calculated and adjusted for potential confounding factors.

Main results and the role of chance: Compared with women undergoing FET after a cryopreservation duration within 3 months, women undergoing FET after a cryopreservation time longer than 3 months did not show any increased risk of gestational diabetes mellitus, gestational hypertension, preeclampsia, meconium staining of the amniotic fluid, preterm birth or cesarean section deliveries in singletons. For multiples, the risk of meconium staining of the amniotic fluid was found significantly increased for women transferred embryo of over 12 months cryopreservation (adjusted OR=2.22, 95%CI: 1.24-3.94), while the risk of other pregnancy-related complications was comparable among groups. Furthermore, the risk of lower birthweight, macrosomia, small-for-gestational-age, or large-for-gestational-age for either singletons or multiples was not affected by long-term cryopreservation.

Limitations, reasons for caution: Because some patients were concerned about the adverse effects of extremely long-term embryo cryopreservation, the study population on this part was lacking in this study. All embryos transferred in this study were cryopreserved via vitrification, so, our results only applied to women with FET cycles using vitrification rather than slow-freezing.

Wider implications of the findings: This was the first study investigating the safety of transferring long-term cryopreserved embryos in terms of pregnancy-related complications in both singleton and multiple pregnancies. However, further studies with long-term follow-up are still required to assess the possible effects of long-term cryopreservation on child growth and development.

Trial registration number: not applicable

P-788 Incidence of multiple births in relation to current regulations in Turkey regarding the number of embryos transferred

I.N. Duzguner[1], S. Kahraman[1], S. Duzguner[1], Y. Sahin[1], F. Sagır[1], K.B. Yuksel[1], U. Gokturk[1]

[1]Istanbul Memorial Hospital Assisted Reproductive Technologies and Genetics Center, Assisted Reproductive and Genetics, Istanbul, Turkey

Study question: What are the consequences of current regulations in Turkey in relation to incidence of multiple births?

Summary answer: Varying interpretations of current regulations can result in a high risk of multiple births.

What is known already: Before 2010, there was no regulation in Turkey regarding the number of embryos to be transferred. In March 2010, regulations were introduced restricting this number to one, except in particular cases: firstly, up to the maternal age of 35, single embryo transfer (SET) only is allowed for the first two attempts, but double embryo transfer (DET) is allowable for the third or any further cycles. From the age of 35 onwards, a maximum number of two embryos may be transferred in any one cycle. Consequently, many patients have understood this as a right to have 2 embryos transferred.

Study design, size, duration: This retrospective, single center study evaluated single versus multiple births in 5918 fresh and frozen thawed blastocyst transfer cycles and carried out in compliance with current regulations between 2014-2018.

Participants/materials, setting, methods: The study is based on data from İstanbul Memorial Şişli Hospital, ART Center regarding two groups of patients as defined in Turkish regulations. Clinical results of fresh and frozen-thawed single or double blastocyst transfer with 2,3 or 4 previously ART attempts in patients <35 years, SET (n=2562 cycles) and DET (n=662 cycles) and ≥ 35 (35-42) years SET (n=1930 cycles) and DET (n=764 cycles) were analysed.

Main results and the role of chance: As a result of the wording of the current regulations there was a high demand for DET. Furthermore, in these cases multiple birth rates were high at 49.4% (174/352) in the DET group of patients <35 years and 27.6% (82/297) in the DET group of patients ≥ 35 years. There were no statistical difference for live birth rate between blastocyst SET and DET in patients <35 (51.9%- 53.1%; p:0,32) and in patients ≥ 35 (44.4% - 38.4%; p:0,09). Current regulations can act as an encouragement to a demand for DET and should therefore be amended to encourage the use of single blastocyst transfer. The use of single blastocyst transfer should be maximized for women under 35. For women aged 35-42, transfer of a euploid single embryo should be considered as an alternative to DET.

Limitations, reasons for caution: The study was a retrospective analysis.

Wider implications of the findings: Regulations in all countries need carefully evaluation and amendment as necessary to reduce the incidence of multiple births in fresh and frozen-thawed embryo transfer cycles.

Trial registration number: Not applicable

P-789 Importance of long-term follow-up of ART derived babies not only for monitoring physical development, but also to detect latent congenital malformation.

A. Obashi[1], H. Matsumoto[1], S. Mizuno[1], A. Fukuda[1], Y. Morimoto[2]

[1]IVF Osaka Clinic, Department of Obstetrics and Gynecology, Higashi-osaka, Japan ; [2]HORAC grand front osaka clinic, Department of Obstetrics and Gynecology, Osaka, Japan

Study question: It is not clarified yet if ART affects long-term physical development of the resulting babies.

Summary answer: Long-term follow-up of ART babies indicated that babies by ART were not significantly different from the babies without ART, but detected latent congenital anomalies afterward.

What is known already: There is no increase of congenital anomalies in ART neonate compared to natural pregnancies based on the official data of JSOG (Japan Society for Obstetrics and Gynecology). Moreover, physical development of ART derived babies is within 50 percentiles of national average from the data collected by Ministry of Health, Labor and Welfare of Japan (MHLW). However, most of the developmental reports followed the babies until 2 years old, worldwide.

Study design, size, duration: The present investigation is retrospective cohort study. Total of 2641 babies, 1304 male and 1337 female, derived from ART procedures performed between January 2008 and December 2016 were evaluated for analysis. Physical developmental data were evaluated at ages of one and a half (637 babies), 2 years (521 babies), 3 years (360 babies), 5 years (160 babies) and 6 years (62 babies).

Participants/materials, setting, methods: Congenital anomaly rate diagnosed at birth was also compared to the national data provided by the Japan branch of International Clearinghouse for Birth Defects Surveillance and Research (ICBDSR). Physical development was evaluated by weight, height and infant-child development index at ages of one and a half, 2 years, 3 years, 5 years and 6 years by comparing to standard developmental curve of Japanese infant-child by MHLW in each gender.

Main results and the role of chance: Congenital anomaly rate at birth of ART babies was 2.8% which was not different from 2.6% by Japan branch of ICBDSR. Mean with standard deviation of weight and height of male and female babies at birth, ages one and a half, 2, 3, 5 and 6 years were placed within 3rd and 97th percentile on standard curve given by MHLW. Median weight and height of both male and female babies at birth, ages of one and a half, 2, 3, 5 and 6 was plotted between the 25th and 75th percentile on standard curve as well. However, nine ART babies diagnosed normal at birth were newly diagnosed congenital anomaly afterward until age of 5.

Limitations, reasons for caution: Data from a single institution. Data analyzed on ART babies included normal and anomaly babies. Data analyzed only full-term infant. However, Gestational ages and maternal complication during pregnancies were disregarded.

Wider implications of the findings: Long term follow-up of ART babies until 6 years indicated that ART procedures were not detrimental, because their development index stayed within 25-75 percentile on Japanese standard without ART. However, the present study recognized the importance of long-term follow-up due to the existence of newly diagnosed congenital anomalies afterward.

Trial registration number: not applicable

P-790 Implementation of embryo transfer learning using medical simulation tool: comparison of two embryo transfer simulators

M. Ouazana[1], M. Bourdon[1], C. Maignien[1], K. Pocate[2], V. Blanchet[1], J. Gonnot[1], C. Cervantes[1], E. Laviron[1], C. Patrat[2], C. Chapron[1], L. Marcellin[1], P. Santulli[1]

[1]Centre Hospitalier Universitaire CHU Cochin-Bâtiment Port Royal, Department of Gynaecology Obstetrics and Reproductive Medicine Paris, Paris, France ; [2]Centre Hospitalier Universitaire CHU Cochin-Bâtiment Port Royal, Department of Histologie-Embryology and Reproductive Biology- Paris- France., Paris, France

Study question: Are students interested in the use of virtual simulator learning for embryo transfer (ET)?

Summary answer: Students expressed a great interest in ET simulator. Simulator for ET could help to improve the mastery of the equipment and skills for ET procedure.

What is known already: Embryo transfer is a main part for the obtainment of a pregnancy with assisted reproductive technology (ART). It is recommended to form practitioners for the ET technic to optimize pregnancy chance. Virtual reality training is proposed to improve clinician's skills, have a standardized technique and enhance ART outcomes.

Study design, size, duration: An observational study was conducted at the university-based reproductive medicine center of our institution during a medical training concerning infertility and ART in June 2019. Two ET simulators (Simulator A and Simulator B) were tested by trainees, supervised by experienced doctors. Inclusion criteria were (i) all the trainees attending the medical training, (ii) who answered the question survey concerning the two simulators A and B. Exclusion criteria was trainees that did not evaluated both simulators.

Participants/materials, setting, methods: The formation started with a 30 minutes' presentation of the theoretical basis to ET followed by training for ET procedures on the two simulators. Trainees were asked to use both, and the running order was randomly determined. The duration of the training was twenty minutes for each simulator. All student had to practice two type of ET with various difficulty with each simulator. Trainees received an email with a question-survey the night following the training.

Main results and the role of chance: During the study period, 32 trainees which have answered the evaluation for both simulators A and B were included. Used of simulators for ET teaching allows a reassurance for most of the trainees (81.3% in Simulator A and 75.0% in Simulator B group; p=0.55). Both simulators help to improve the mastery of the equipment (p=0.62) and the knowledge of the ET (p=0.19) without significant differences between groups. However, significant differences between simulators have been observed concerning the learning of precision of the ET procedure (p <0.01), the learning about the pathway to introduce the catheter into the cavity (p=0.04), the help for proper placement of the catheter into the uterine cavity (p=0.03) and the reproduction of the embryo into the uterine cavity (p=0.04) in favor of simulator A. Whatever the simulator used, trainees estimated that virtual simulator should be encouraged for learning the practice of ET.

Limitations, reasons for caution: In this preliminary study, we evaluate the interest of students for this type of training, consequently, we have no evaluation of long term benefit on pregnancy chances improvement. Moreover, simulator can't be similar to women's anatomy and isn't suited to reflect on hard cases.

Wider implications of the findings: In order to form and reassure practitioners, simulation learning for ET should be more widespread during gynecologic formation. Nevertheless, optimization of simulations tools for learning is needed.

Trial registration number: NA

P-791 Perinatal outcomes of assisted reproduction compared to natural conception in couples with unexplained subfertility. Follow up of two randomized clinical trials

J. Wessel[1], F. Mol[1], N. Danhof[1], A. Bensdorp[1], R. Tjon-Kon Fat[1], M. Mochtar[1], INeS study Group([1])[j.a.wessel@amsterdamumc.nl], SUPER study group([1])[j.a.wessel@amsterdamumc.nl], M. Van Wely[1]

[1]Amsterdam UMC- University of Amsterdam, Centre for Reproductive Medicine, Amsterdam, The Netherlands

Study question: Does the fertility procedure affect perinatal outcomes of singleton live births compared to natural conceptions in couples with unexplained subfertility?

Summary answer: Compared to natural conception, singletons born after IVF had comparable birth weights, while intrauterine insemination with ovarian stimulation (IUI-OS) resulted in lower birth weights.

What is known already: Children conceived by assisted reproduction have poorer perinatal outcomes such as lower birthweight (LBW) and a higher risk of premature birth (PTB) than naturally conceived children. This might be due to the assisted reproduction, such as laboratory procedures or the ovarian stimulation, or to an intrinsic factor in couples with subfertility. However, most studies compared perinatal outcomes in subfertile couples, carrying the risk of an inherit intrinsic factor, to fertile couples without such an intrinsic factor.

Study design, size, duration: We performed a follow up study of two randomized clinical trials performed in couples with unexplained subfertility, including the naturally conceived singletons. The primary outcome was birthweight. The secondary outcomes were LBW (defined as birthweight <2500g) and PTB (defined as delivery <37 weeks of gestation). We calculated differences in birthweight using regression analyses adjusted for maternal age, BMI, smoking, parity, duration of subfertility, child gender and preeclampsia (PE) during pregnancy.

Participants/materials, setting, methods: To investigate the impact of laboratory procedures on perinatal outcomes, we compared singletons

conceived by IUI-OS or IVF to naturally conceived singletons. To study the impact of ovarian stimulation we stratified the IUI group for type of stimulation (follicle stimulation hormone (IUI-FSH) or clomiphene citrate (IUI-CC)) and the IVF group in modified natural cycle (IVF-MNC) and in standard IVF with single embryo transfer (IVF-SET). We compared all groups to naturally conceived singletons.

Main results and the role of chance: In total there were 553 ongoing pregnancies, which resulted in 493 live birth singletons. Of the 493 singletons, 209 were conceived after IUI-OS (136 with FSH and 73 with CC as ovarian stimulation), 159 after IVF (50 after IVF-MNC and 109 after IVF-SET) and 125 were conceived naturally. Singletons conceived following IUI-OS had lower birthweights than naturally conceived singletons (adjusted difference -127.2gr, 95%CI -249.9 to -4.6). The difference was observed irrespective of whether FSH or CC was used (adjusted difference IUI-FSH -127.5, 95%CI -262.7 to 7.8; IUI-CC -124.7, 95%CI -286.8 to 37.3).

Birthweights from singletons conceived after IVF were comparable to birthweights after natural conception (adjusted difference -5.3, 95%CI -130.5 to 120.0). When corrected for ovarian stimulation no significant difference was found between IVF-MNC and IVF-SET compared to natural conception (adjusted difference IVF-MNC 78.7 95%CI -94.4 to 251.8; IVF-SET -44.4, 95%CI -181.4 to 92.7). We found no evidence of a difference in the secondary outcomes LBW and PTB.

Limitations, reasons for caution: The results are limited by the number of cases.

Wider implications of the findings: In unexplained subfertility, IUI-OS but not IVF might result in slightly compromised perinatal outcomes. Our findings suggest that a part of the previously observed compromised perinatal outcomes are due to an intrinsic effect in infertile couples. Further research in a larger population of singletons is necessary to substantiate our findings.

Trial registration number: NTR939 and NTR 4057

P-792 The impact of in-vitro fertilization treatment on the maternal renin-angiotensin-aldosterone-system in very early pregnancy

R. Wiegel[1], A.H.J. Danser[2], D. Aoulad Fares[1], E.A.P. Steegers[1], J.S.E. Laven[1], S.P. Willemsen[3], V.L. Baker[4], R.P.M. Steegers-Theunissen[1], F. Von Versen-Höynck[5]

[1]Erasmus Medical Center- University Medical Center, Obstetrics and Gynecology, Rotterdam, The Netherlands ;
[2]Erasmus Medical Center- University Medical Center, Internal Medicine, Rotterdam, The Netherlands ;
[3]Erasmus Medical Center- University Medical Center, Biostatistics, Rotterdam, The Netherlands ;
[4]Johns Hopkins University School of Medicine, Reproductive Endocrinology and Infertility, Baltimore, U.S.A. ;
[5]Hannover Medical School, Obstetrics and Gynecology, Hannover, Germany

Study question: What is the impact of in-vitro fertilization (IVF) treatment on associations between corpus luteum (CL) function and the maternal renin-angiotensin-aldosterone-system (RAAS) in early human pregnancy?

Summary answer: Maternal prorenin, renin and aldosterone levels differed significantly between spontaneous conceptions and those after IVF in early pregnancy which may be related to CL function.

What is known already: The RAAS is involved in the maternal cardiovascular and hemodynamic adaptation to pregnancy. Prorenin is synthesized and secreted during maturation of the ovarian follicles by the unique temporary endocrine structure, the CL. The absence of CL is associated with an increased incidence of preeclampsia. We hypothesize that this association can be explained by derangement of the maternal RAAS. The objective of this study is to investigate the potential impact of IVF treatment and CL status on component levels of the maternal RAAS in early pregnancy.

Study design, size, duration: We pooled two prospective cohorts with enrollment before 10 weeks of gestation: 75 pregnancies from the Stanford Pregnancy outcome after infertility (POFI) study and 202 pregnancies from the Rotterdam periconception cohort (Predict) conducted at the Erasmus University Medical Center. Pregnancies were stratified for IVF procedure and CL number, i.e. programmed cycle frozen embryo transfer [FET], n=28 (0CL), natural cycle FET, n=41 (1CL), fresh embryo transfer [ET], n=69 (>1CL) and spontaneous conceptions, n=139 (1CL).

Participants/materials, setting, methods: Prorenin and renin blood levels were measured in the Stanford study at 5 weeks gestational age (GA) and in the Predict study at 9 and 11 weeks GA, with additional aldosterone measurements, all carried out by the laboratory of the Erasmus Medical Center. Fertility treatment, type and dose of gonadotropins and fertility parameters depicted as number of follicles, retrieved oocytes and sum of follicle diameter during oocyte pick-up (OPU) were retrieved from medical records.

Main results and the role of chance: Maternal total renin, prorenin and renin were significantly lower in the absence of the CL at all-time points when compared to 1 CL (at 5 weeks: 1.9-, 2.2- and 1.7-fold lower and at 9 weeks: 2.4-, 2.5- and 2.4-fold lower, respectively). Maternal total renin at 5 weeks and total renin, prorenin, renin and aldosterone at 9 and 11 weeks were significantly higher in the presence of multiple CL when compared to 1CL (at 5 weeks: 1.5- and at 9 weeks: 1.4-, 1.4-, 1.2- and 1.8- fold higher, respectively). Stratified by IVF procedure the maternal total renin, prorenin, renin at all-time points and aldosterone at 11 weeks were significantly different, pregnancies conceived by fresh ET showing the highest RAAS component levels and with programmed cycle FET the lowest. Sum of follicle diameter prior to OPU was positively associated with maternal prorenin levels at 11 weeks GA (β: 0.002 [95%CI: 2.88e-05;0.0047]; p=0.048 after adjustment for gonadotropin type and dose, maternal age and parity). After ovarian stimulation and fresh IVF transfers, Menopur (urinary FSH containing some HCG) showed significantly higher renin and aldosterone levels during late first trimester when compared with Bemfola (recombinant FSH biosimilar), (p=0.009 and p=0.002) respectively.

Limitations, reasons for caution: Due to the observational character of this study residual confounding cannot be ruled out. Furthermore, patients were recruited from two tertiary referral hospitals with potential differences in fertility treatment. According to relatively smaller sample sizes after stratification by IVF procedure and CL number, our findings should be interpreted carefully.

Wider implications of the findings: This data suggests that IVF impacts the association between periconception ovarian biology and maternal RAAS activity. Since RAAS is involved in maternal cardiovascular adaptation to early pregnancy, modulation of RAAS might contribute to pregnancy complications. Future research should investigate the impact of IVF on ovarian biology and CL during pregnancy.

Trial registration number: NL6684

P-793 Validation of the competency and benchmark values of the Vienna Consensus for the ART laboratory performance indicators

G.H. Trew[1], C. Henry[2], S.M. Nelson[3]

[1]The Fertility PartnerShip, Faculty of Medicine, London, United Kingdom ;
[2]The Fertility Partnership, Information and Technical Division, Oxford, United Kingdom ;
[3]University of Glasgow, School of Medicine, Glasgow, United Kingdom

Study question: To assess whether the Vienna Consensus values regarding competency and validation for performance, reference and key performance indicators are appropriate for the proposed reference population.

Summary answer: The competency values can be achieved but the values for good blastocyst development are dependent on consistency of embryo grading, rather than culture conditions.

What is known already: The Vienna Consensus proposed competency and aspirational benchmark values for a range of performance indicator, reference indicator and key performance indicators for the laboratory. These were derived based on surveys, scientific evidence and personal clinical experience with the minimum and expected and target value based on 50 and 75 percentile values, respectively. With further discussion of each proposed indicator until consensus was reached. However, whether these values are appropriate or attainable is unknown and the group encouraged national and international bodies to gather data that can be used for the derivation of KPI standard values.

Study design, size, duration: Retrospective cohort study of 6,339 fresh treatment cycles and 4,670 frozen embryo transfers in women <40 years old; using their own fresh oocytes; ejaculated spermatozoa (fresh or frozen); no PGD/PGS (PGT); and having routine IVF or ICSI. All cycles were conducted within the UK between 1 January 2018 and 31 December 2019.

Participants/materials, setting, methods: Women undergoing assisted conception at the eight UK clinics of The Fertility Partnership who met the inclusion criteria suggested by the Vienna Consensus for reference value

derivation . Data was recorded in real-time for clinical and laboratory characteristics using IDEAS with data retrospectively analysed and visualised using Qlik.

Main results and the role of chance: Of the 6339 fresh cycles, the mean age was 33.9 years, with a mean of 12 oocytes retrieved with an overall pregnancy rate of 41.3% per embryo transfer, with a multiple pregnancy rate of 9.3%, while for the 4,670 frozen cycles the mean age was 34.1 years with a clinical pregnancy rate of 45% and multiple rate of 11.4%. Of the 72,586 oocytes retrieved 58.6% of cycles were fertilised by ICSI. The observed mean and (suggested competency Indicators noted in brackets) for all oocytes retrieved for follicles >10mm was 80.9% (80-95%), and 79.2% (75-90%) were MII. For the Performance Indicators; IVF polyspermy was 5.5% (<6%), 1PN IVF 3.64% (<5%), IPN ICSI 2.69% (<3%) and good blastocyst 24.56% (≥30%). For KPIs the ICSI damage rate was 6.7% (<10%), ICSI fertilisation rate 66.6% (≥65%), IVF normal fertilisation rate 61.2% (≥60%), IVF failed fertilisation rate 3.2% (<5%), cleavage rate 93% (≥95%), day 3 development rate 64.7% (≥45%), blast development rate 59.3% (≥40%), successful biopsy 98% (≥90%), and implantation rate for blastocyst 39.9% (≥ 35%) while for the 10.8% of women who had a cleavage stage transfer the implantation rate was 19.7% (≥25%).

Limitations, reasons for caution: Different laboratory protocols were used across the eight units improving the generalisability of the findings. A quality control assessment of the reproducibility of classification of a good quality blastocyst indicated substantial variability. Patients with cleavage stage embryo transfer were of poor prognosis, driving a move to blastocyst transfer for all.

Wider implications of the findings: We found that in the proposed reference population suggested within the Vienna Consensus that the competency values as defined as the mean value observed are appropriate and can be used for routine quality management of the ART laboratory.

Trial registration number: Not applicable

P-794 Chromosomal abnormalities after ICSI in relation to sperm parameters: results in 1114 fetuses and 1391 neonates from a single-center

F. Belva[1], M. Bonduelle[1], A. Buysse[1], A. Van den Bogaert[1], F. Hes[1], M. Roelants[2], G. Verheyen[3], H. Tournaye[3], K. Keymolen[1]

[1]UZ Brussel, Medical Genetics, Jette- Brussels, Belgium ;
[2]KU Leuven, Department of Public Health and Primary Care, Leuven, Belgium ;
[3]UZ Brussel, Center for Reproductive Medicine, Jette- Brussels, Belgium

Study question: Is there a relationship between karyotype abnormalities in fetuses and children conceived by intracytoplasmic sperm injection (ICSI) and their father's semen parameters?

Summary answer: *De novo* chromosomal abnormality rate in pre-and postnatal karyotypes of ICSI offspring was higher than in the general population and related to fathers' sperm parameters.

What is known already: Several studies have reported a higher rate of *de novo* chromosomal anomalies in ICSI fetuses but recent data from large cohorts are limited. Overall, reported prevalences of non-inherited karyotype aberrations are increased in fetuses conceived after ICSI and vary between 1.6% and 4.2%. Only few studies focus on the relation between karyotype anomalies in ICSI offspring and semen parameters of their fathers. Furthermore, an increased incidence of abnormal karyotypes in ICSI neonates has been described, but the rates vary widely across studies.

Study design, size, duration: We report on karyotype results from prenatal testing by means of chorionic villus sampling and amniocentesis and results from postnatal blood sampling from offspring conceived by ICSI in a single-center. Ongoing pregnancies resulting from an oocyte retrieval between January 2004 and December 2012 and after transfer of fresh ICSI embryos obtained after ejaculated or non-ejaculated sperm were included. Pregnancies following frozen embryo transfer, oocyte or sperm donation, IVF, PGT and IVM were excluded.

Participants/materials, setting, methods: From the 4816 eligible ICSI pregnancies, information on pregnancy outcome was available for 4267 pregnancies. Prenatal testing was performed in 22.3%, resulting in a diagnosis in 1114 fetuses. A postnatal karyotype was obtained in 29.4% of the pregnancies resulting in a total of 1391 neonates sampled. The prevalence of chromosomal anomalies according to maternal age and semen quality was analyzed by logistic regression. For definitions of normal semen quality, the WHO reference values were adopted.

Main results and the role of chance: An abnormal fetal karyotype was found in 41 fetuses (29 singletons, 12 multiples) (3.7%; 95%CI: 2.7-4.9%): 36 anomalies were *de novo* (3.2%; 95%CI 2.3-4.4), either numerical (n=25), sex (n=6) or structural (n=5) and 5 anomalies were inherited. Logistic regression analysis did not show a significant association between maternal age and having a *de novo* chromosomal abnormality (OR 1.05; 95%CI 0.96-1.15). In all but one case, fetuses with an abnormal karyotype were conceived after ICSI using ejaculated sperm.

Abnormal karyotypes were observed in 14 (1.0%; 95%CI: 0.6-1.7) out of 1391 postnatal samples of children born after ICSI who were not tested prenatally: 12 were *de novo* anomalies and 2 were inherited balanced karyotypes. The 14 abnormal karyotypes were all found in children born after ICSI using ejaculated sperm.

The odds of a *de novo* karyotype aberration increased with maternal age when combining pre- and postnatal data (OR 1.11; 95%CI 1.04-1.19). A higher rate of *de novo* chromosomal abnormalities was found in fetuses and children of couples with men having low (AOR 2.10; 95%CI 1.14-3.78) and extremely low sperm concentration (AOR 1.9; 95%CI 1.05-3.45) and a non-significant higher rate was found in men with below-reference sperm counts (AOR 1.70; 95%CI 0.95-3.06).

Limitations, reasons for caution: We cannot exclude that the observation of an increased prevalence of karyotype anomalies in ICSI offspring is due to enhanced surveillance after ART given the lack of a control group. Although we did not find more chromosomal anomalies after non-ejaculated sperm, the small numbers do not allow firm conclusions.

Wider implications of the findings: The observed increased risk of a *de novo* karyotype anomaly after ICSI in couples with poor sperm warrants continued counseling towards prenatal testing. The widespread use of innovative non-invasive prenatal testing will result in larger datasets, adding to a balanced estimation of the prevalence of karyotype anomalies in ICSI offspring.

Trial registration number: not applicable

P-795 Patient age does not influence all decisions during an IVF cycle according to HFEA data

C. JACQUES[1], J. Chambost[1], C.A. Pena[1], M. Kotrotsou[2], C. Hickman[3]

[1]Apricity, AI Team, Paris, France ;
[2]Apricity, Medical Team, London, United Kingdom ;
[3]Apricity, AI Team, London, United Kingdom

Study question: One of the most important factors of success for an IVF cycle is the patient's age, does it influence all steps of a cycle?

Summary answer: According to literature, age is one of the key factors in the success of IVF, but age should not influence all decisions during a cycle.

What is known already: Different factors can influence the outcome of an IVF. Several studies observed a relation between the life birth rate (LBR) and factors such as BMI, smoking, number of eggs collected, cause of infertility, etc. According to most studies, the factor having the most influence is the patient's age. In fact, we tend to quote chance of pregnancy based on age. In fact, in most studies to predict SR from a patient's profile with machine learning (ML) algorithm, the common feature is the age (Hassan, 2018, «A Machine Learning Approach for Prediction of Pregnancy Outcome Following IVF Treatment »).

Study design, size, duration: This is a retrospective study on publicly available HFEA data from 2000 to 2016 and from 2010 to 2016. Only fresh cycles with patients' own gametes were selected and divided in age cohorts.

Several moments of a cycle were studied: egg collection, cleavage/blastocyst culture, embryo transfer (single or multiple) and finally the life birth rate in relation to the patient's profile (age, infertility cause, etc.).

Participants/materials, setting, methods: About 300000 cycles from 2010-2016 (DB_2010) and about 200000 (DB_2000) additional cycles from 2000 to 2016 were used for this study and divided into age cohorts: 43% of 18-34 year-old (y.o.), 22% of 35-37 y.o., 15% of 38-39 y.o., 14% of 40-42 y.o., 4% of 43-44 y.o. and 2% of 45-50 y.o.

Multivariate statistical analyses were conducted on those data and 6 algorithms of Machine Learning such as Random Forest were learnt.

Main results and the role of chance: According to DB_2010, although the optimum number of eggs to get the maximum LBR differs by age (18 eggs collected under 35 y.o. whereas over 35 y.o., LBR increases with the number of

eggs collected), there is a strong correlation between the number of fresh eggs collected and the number of embryos created (y=0.49x, R2=0.98) regardless of the age of the patients.

Regarding day of transfer, irrespective of patient age, blastocyst transfer offers better SR than cleavage transfer. According to DB_2000, delaying embryo transfer increased LBR in a similar way from day 1 to 5 across all age groups (LBR +20% under 37 y.o. and +10% over 37 y.o.).

Age should not be considered within a single/multiple embryo transfer (SET/MET). MET provided no benefit for young patients (Odds Ratio, OR, 1.0±0.02CI) and only marginal for older patients (OR around 1.4). This benefit should be considered with the risk of multiple LB (1.4 avg. number of LB under 35 y.o. decreased to 1.1 over 45 y.o.).

In addition to overall analysis, the DB_2010 allows you to customize results. The Fertility Predictor (https://www.apricity.life/fertility-predictor) based on 6 ML models predicts the SR according to the patient's profile, age, infertility cause, etc.

Limitations, reasons for caution: This is a retrospective study based on HFEA data, hence has inherent bias. Although the data (approximately 300000 cycles) may reflect the general population in the UK, there is more data for the younger cohorts. That's why, for better results, more data is needed.

Wider implications of the findings: Using AI in studies implies the use of a large dataset to reduce bias and improve generalization of the model, and the need to create a collaborative infrastructure which allows to increase the size of training datasets.

Trial registration number: NA

P-796 Different placental vascularisation after ART?

C. Vrouwenraets[1], R. Van Golde[1], S. Al-Nasiry[1], A. Van Montfoort[1]

[1]MUMC+, Obstetrics and Gynaecology, Maastricht, The Netherlands

Study question: Is early placental vascularisation related to birthweight in naturally and ART conceived -pregnancies?

Summary answer: This study provides an indication that early placental vascularisation is different in ART-pregnancies , but this is not related to a difference in birthweight.

What is known already: It is well known that ART-children show a higher risk of adverse neonatal outcomes, such as low birthweight, compared to naturally conceived children. The underlying aetiology is still unknown, but we expect that placental vascularisation plays a major role. We hypothesize that; 1) there is an association between birthweight and placental vascularization in general and; 2) ART placental vascularisation is lower and results in a lower birthweight compared to naturally conceived pregnancies.

Study design, size, duration: This prospective pilot study was performed at the MUMC+, department of Obstetrics and Gynaecology. At 12, 16 and 20 weeks of gestation a placental ultrasound was performed measuring the placental vascularization index (VI) using 3D Power Doppler and VOCAL. Birthweight and gestational age at time of delivery were collected after delivery.

Participants/materials, setting, methods: Women aged above 18 years, who conceived naturally (NC) or via IVF with or without ICSI (ART) were included. Multiple pregnancies were excluded.

Main results and the role of chance: In total 112 subjects were included, 57 in the ART-group and 65 in the NC group. The median VI at 12 weeks of gestation was 0.51% [IQR 0.2-2.8] in the NC group and 0.17% [IQR] 0.01-1.1] in the ART group (*P*=0.492). At 16 and 20 weeks respectively the median VI was 0.25% [0.1-1.5] (NC) vs 0.42% [0.1-1.0] (ART)(*P*=0.078) and 0.4% [0.2-1.2] (NC) vs 0.12% [0.03-0.4] (ART)(*P*=0.052). No association was found between placental VI and fetal birthweight at 12 (*P*=0.46), 16 (*P*=0.58) and 20 (*P*=0.33) weeks of gestation.

Limitations, reasons for caution: The number of participants in this pilot study is limited. Secondly, the control group of NC pregnancies is recruited in a tertiary hospital, resulting in an increased number of high risk pregnancies , possibly underestimating the results.

Wider implications of the findings: The results of this pilot study suggest that placental vascularisation might differ between ART pregnancies and NC-pregnancies. Currently a prospective well-powered cohort study on this topic is carried out, in which previous limitations regarding the control group are taken into account.

Trial registration number: x

P-797 1 million cycles: what can we learn from the UK national registry (HFEA) dataset?

C. Hickman[1], C. Jacques[2], C.A. Pena[3], M. Kotrotsou[4], J. Chambost[5]

[1]Apricity, Embryology, London, United Kingdom ;
[2]Apricity, Data Analysis, Paris, France ;
[3]Apricity, Data, Paris, United Kingdom ;
[4]Apricity, Clinical, London, United Kingdom ;
[5]Apricity, Artificial Intelligence, Paris, France

Study question: What can the HFEA data registry teach the fertility sector that will improve fertility care?

Summary answer: Although trends can be identified in the HFEA registry, the type, diversity and accuracy of data collected limits incorporation of learned knowledge into clinical practice.

What is known already: The HFEA registry records all IVF cycles performed at British fertility clinics. It is recognised as amongst the best national registries worldwide and has been the source of numerous publications attempting to find patterns that may improve practice. For instance: identifying the optimal number of eggs to be collected in order to maximise the chance of pregnancy for each patient age group; comparison in outcome for different types of stimulation; or a comparison of outcome for cleavage versus blastocyst transfer; creation of fertility predictors to help manage patient's expectations; amongst many other questions we have on optimal clinical care.

Study design, size, duration: HFEA registry is a large, national, multicentre dataset allowing for cohort analysis based on patient age, number of previous cycles, type of treatment, type of infertility, cleavage/blastocyst transfer, number of embryos transferred, type of stimulation. Outcomes include number of eggs collected, number of embryos created and utilised, clinical pregnancy, live birth. There was no access to data on embryo quality, embryo imagery, degree of mosaicism, ultrasound imagery, extended patient demographic or clinical diagnostic data.

Participants/materials, setting, methods: The HFEA registry comprises 235,614 cycles from 1995 to 1999, 492,387cycles from 2000-2009, and 495,628 cycles from 2010 to 2016 were assessed. Data trends were assessed to evaluate the quality and accuracy of the data. Data from 2010 to 2016 was consequently selected for further analysis to answer clinical practice questions using multivariate analysis. This subset had an age distribution of 43,22,15,14,4,2% for the following age groups respectively: 18-34,35-37,38-39,40-42,43-44,45-50 years.

Main results and the role of chance: Live birth rate(LBR) following fresh ET is affected by the number of mature eggs collected. In patients <35 and 35-37years, range of optimal number of eggs collected was 13-19 and 14-21 respectively, with a significant reduction in LBR at lower (understimulation) and higher egg numbers (overstimulation). At increasing age, the plateau was never reached, suggesting that the more eggs the better. However, there were insufficient patients in cohort groups at increased egg numbers and increased age. With increasing age, proportion of patients categorized with unexplained infertility tripled (8%vs30%, age <35yvs45-50); male factor infertility halved(36%vs14%). Within female infertility, proportion of patients with ovulatory disorder doubled(22%vs46%), whilst tubal infertility halved(31%vs16%). These trends are likely due to inaccuracies in data entry and/or reduction in diagnostics with increasing patient age. More than half the increase in LBR in IVF in the UK may be attributed to blastocyst culture, although there was a period of learning from 2000 to 2006 where success rates for blastpcyst culture increased with time before plateauing. The benefits of increasing LBR with multipleET compared to singleET did not increase with patient age, and was not observed in patients under 35, so that age should not be considered within an eSET policy.

Limitations, reasons for caution: Despite the large dataset, when looking at specific cohorts, there were insufficient datapoints to conclude on best clinical practice. Missing data types also limited conclusions (i.e. embryo quality, OHSS, clinical/laboratory practices, patient data).

Wider implications of the findings: Due to limitations of the current structure of the HFEA registry, fertility predictor studies and calculators based on this data cannot achieve true personalised medicine. In the era of healthcare digitisation, the fertility sector should rethink how to share better quality data to fuel structured international prospective cohort studies.

Trial registration number: NA

P-798 Triple risk of severe maternal morbidity in women with twin pregnancy obtained by oocyte donation

D. Korb[1], S. Thomas[1], S. Aurélien[2], L.R. Camille[3], S. Pietro[4], G. François[3], D.T. Catherine[5]

[5]Université de Paris- Centre for Epidemiology and Statistics Sorbonne Paris Cité CRESS- Obstetrical Perinatal and Pediatric Epidemiology Research Team- EPOPé- INSERM- INRA- Paris- France1.Université de Paris- Centre for Epidemiology and Statistics Sorbo, ,

Study question: Is there a difference in the risk of serious maternal complications in twin pregnancies according to the mode of conception, while differentiating infertility treatments categorization?
Summary answer: The risk of serious maternal complications was increased by 50% for twin pregnancies after IVF with autologous oocyte and almost tripled after oocyte donation.
What is known already: IVF has been recognized as a risk factor of serious maternal complications in general populations of parturients and in singleton pregnancies. In twin pregnancies, this association is less documented, with contradictory results. Moreover, these findings were limited by imprecise categorization of the mode of conception and the lack of specific analyses for exploring the causal underlying mechanisms implicated.
Study design, size, duration: In this secondary analysis of the JUMODA cohort, a national prospective population-based study of twin deliveries conducted from 2014 to 2015 in 176 French hospitals, we included all women with twin pregnancies ≥22 weeks of gestation with known mode of conception (n=8823).
Participants/materials, setting, methods: We included women with known mode of conception (n= 8748). Mode of conception was studied in 5 classes: spontaneous conception (reference group), non IVF fertility treatment (NIFT), IVF with autologous oocyte (IVF-AO), ICSI with autologous oocyte (ICSI-AO) and oocyte donation (OD). We assessed the association between mode of conception and severe acute maternal morbidity (SAMM) (composite criterion) with multivariate logistic regression. Role of intermediate factors was analyzed by structural equation modelling (SEM).
Main results and the role of chance: Among the 8748 women of the study population, 5890 (67.3%) conceived spontaneously, 854 (9.8%) had NIFT, 1307 (14.9%) IVF-AO, 368 (4.2%) ICSI-AO and 329 (3.8%) OD. Overall, 538 (6.1%) developed SAMM. Overall, 538/8748 (6.1%) women developed SAMM. Women with non-spontaneous twin pregnancy had a higher risk of SAMM than those with spontaneous twin pregnancy, after adjustment for confounders (227/2858 (7.9%) compared to 311/5890 (5.3%), aOR 1.3, 95% CI [1.1,1.6]). The risk of SAMM was higher among women with IVF-AO (108/1307; 8.3%) and OD (46/329; 14.0%) compared with the reference group (respectively aOR 1.5, 95% CI [1.1,1.9] and aOR 2.7, 95% CI [1.8,4.1]), and higher after OD than after IVF-AO (aOR 1.7, 95% CI [1.1-2.6]). Conversely, the risk of SAMM in women with NIFT (53/854; 6.2%) and ICSI-AO (20/368; 5.4%) did not differ from that of the reference group (311/5890; 5.3%) (respectively aOR 1.1, 95% CI [0.8,1.5] and aOR 0.9, 95% CI [0.6,1.5]).These risk augmentations were poorly explained by the intermediate factors tested (non-severe preeclampsia, placenta praevia and planned mode of delivery).
Limitations, reasons for caution: Beyond the confounders and intermediate factors considered in our analysis, precise causes of infertility and specificities of infertility treatments may explain the differences we found in the risk of SAMM by mode of conception. However these data were not available and could not be taken into account.
Wider implications of the findings: Knowledge of the differential risk of SAMM in women with twin pregnancies according to the mode of conception may inform the discussion of clinicians and women and help optimizing the obstetrical care for women in subgroups of mode of conception at higher risk.
Trial registration number: not applicable

P-799 Failure Mode and Effects Analysis of current IVF cryostorage processes in a large HFEA licensed clinic

R. Gregoire[1], R. Lunt[1], A. Drakeley[1]

[1]Liverpool Women's Hospital, The Hewitt Fertility Centre, LIVERPOOL, United Kingdom

Study question: What is the scale of risk associated with IVF cryostorage in a UK, Human Fertilisation and Embryology Authority (HFEA) licensed clinic?
Summary answer: Despite high standards in laboratory practice and technology, 6 High, 50 medium and 14 low risks were identified.
What is known already: The occurrence of clinical incidents in IVF cryostorage (including misplaced/unidentifiable samples, exposure to variations in temperature, and tank failure) frequently highlight the need for improved risk management and improved technologies for cryopreservation and cryostorage of gametes and embryos. There is therefore a need to conduct a comprehensive Failure Mode and Effects Analysis (FMEA): a proactive method aimed at identifying real or potential incidents in order to develop strategies to mitigate the risks with cryopreservation in IVF.
Study design, size, duration: FMEA analysis consisted of mapping the cryostorage process, from cryopreserving and cryostorage to subsequent warming - a process not currently tracked by the RFID witnessing system used by the clinic. Possible sources of error were identified, and scored with a Risk Priority Number (RPN), a product of likelihood, severity and detection of incidence associated with each risk, as previously described by Rienzi et al., 2015.
Participants/materials, setting, methods: In January 2020, an FMEA analysis was carried out in a busy IVF HFEA licensed clinic with 36 years' experience, to evaluate possible cryostorage procedural risks. Four members of the multidisciplinary IVF team including clinical, embryology and andrology specialists, completed the FMEA based on 20 years of previous clinical experience performing over 30 000 fresh and frozen IVF cycles under HFEA regulation, and risk assessed cryostorage procedures against current laboratory practice and available technologies.
Main results and the role of chance: The team identified 6 current cryostorage process phases, 56 associated process steps and 70 failure modes in current cryostorage processes, among which 50 risks were given a medium RPN score (RPN15-49) and 6 risks were scored as severe RPN (RPN>50). Failure modes identified included cryopreserved samples exposed to variable temperatures during handling; label removed from straw during cryostorage; incorrect or ineligible labelling; sample misplaced in cryostorage; difficulty in maintaining an accurate inventory; vitrified samples removed from the cryostorage environment; failure to fulfil patient cryostorage consent wishes; alarm failure; wrong sample removed from storage; tank maintenance and failure; tank contamination, and potential for staff injury. RPN scores ranged from 4 to 75 for the risks identified.
Limitations, reasons for caution: FMEA framework processes were based on the clinic's current laboratory practice. Potential errors were identified from HFEA incident reports and PUBMED literature review. Incidence likelihood was scored based on personal experience. These risk levels may not be representative of clinics operating outside HFEA regulation, and/or not utilising RFID witnessing technology.
Wider implications of the findings: FMEA is effective in supporting clinics to identify process risks and to consider alternative processes for safer practice. This FMEA demonstrates that there continues to be risks associated with IVF cryostorage processes in HFEA licensed clinics, and alternative strategies should be considered to further mitigate or eliminate these risks.
Trial registration number: Not applicable

P-800 Assisted reproductive technology and abnormal placental cord insertion: a review of adverse perinatal outcomes in over 4700 placentas

H. Leftwich[1], M. Burns[1], A. Kastrinakis[1], K. Leung[1], S. Khedr[2], S. Chauhan[1], J. Yeh[1]

[1]University of Massachusetts, Obstetrics and Gynecology, Worcester, U.S.A. ; [2]University of Massachusetts, Pathology, Worcester, U.S.A.

Study question: Do pregnancies conceived by assisted reproductive technology have higher rates of poor perinatal outcomes regardless of the location of the placental cord insertion (PCI)?
Summary answer: Pregnancies conceived by assisted reproductive technology are associated with higher rates of stillbirth in cases of abnormal PCI and cesarean delivery in normal PCI cases.
What is known already: Abnormal placental cord insertion, specifically velamentous insertion, has been associated with an increase in preterm delivery, low birth weight, neonatal intensive care admissions and emergent cesarean delivery. Both marginal and velamentous are abnormal placental cord insertions and affect less than ten percent of deliveries. Assisted reproductive technology (ART) has been associated with some similar placental-mediated pregnancy complications. It is unclear whether ART has an additional impact on the rates of adverse pregnancy outcomes in this cohort of patients.
Study design, size, duration: We performed an IRB approved retrospective chart review of 4718 singleton and twin placentas sent to pathology at the University of Massachusetts between January 2011-December 2019. Women were excluded if they delivered outside our institution or had a delivery before 24 weeks gestation.
Participants/materials, setting, methods: Chart review was performed and documented in a password protected electronic database, REDCap. Placental pathology reports were reviewed and evidence of abnormal placental cord insertion, either velamentous or marginal, were recorded. Demographics and adverse perinatal outcomes were recorded. Chi-square test was used for categorical and student T-test for continuous variables. Logistic regression was used to control for potential confounders. P less than 0.05 was used for statistical significance.
Main results and the role of chance: Of the 4718 pregnancies that were reviewed, 194 were conceived via ART. There were 483 cases of abnormal placental cord insertions. Our cohort contained 616 cases of twin gestations, and 4102 singletons. Pregnancies conceived via ART were more likely older mothers in both the abnormal and normal PCI groups. After controlling for the number of fetuses, pregnancies conceived by ART with placentas with normal placental cord insertion (PCI), had a 47 percent increase in odds of cesarean delivery (OR 1.47 [1.04-2.08], p=0.03). For those with abnormal PCI, ART was associated with an increase in odds of stillbirth (OR 5.31 [1.52-18.57], p=0.01). No other adverse outcomes were different between ART versus spontaneous conception in either normal or abnormal PCI.
Our findings show higher rates of stillbirth in cases with abnormal PCI compounded by conception utilizing ART as compared to controls. While other outcomes such as Apgar <7 at 1 minute, preterm birth or small for gestational age infants were not different among our groups, this may be due to small incidence of such adverse outcomes. Our findings suggest a closer follow up may be warranted if abnormal PCI is diagnosed on prenatal ultrasound in patients who conceived using ART.**Limitations, reasons for caution:** Limitations of our study include the retrospective nature, which does introduce bias, as not all placentas are sent to pathology at our institution. Additionally, each of our adverse outcomes are rare occurrences, which may explain the lack of difference in each outcome.
Wider implications of the findings: While there is remains some controversy regarding the risk for poor perinatal outcomes regarding abnormal placental cord insertion, our study suggests more intense monitoring, such as antenatal testing, may be appropriate when abnormal PCI is detected on prenatal ultrasound in those conceived with ART. Future studies are warranted.
Trial registration number: not applicable

POSTER VIEWING SESSION
STEM CELLS

P-801 Endometrial regeneration with establishment of improved culture methods for endometrial epithelial cells: co-culture with feeder cells.

R. Yokomizo[1,2,3], Y. Fujiki[1], H. Kishi[2], H. Sago[3], A. Okamoto[2]
[1]National Center for Child Health and Development, Department of Reproductive Biology- Center for Regenerative Medicine, Tokyo, Japan ; [2]The Jikei University School of Medicine, Department of Obstetrics and Gynecology, Tokyo, Japan ; [3]National Center for Child Health and Development, Center for Maternal-Fetal-Neonatal and Reproductive Medicine, Tokyo, Japan

Study question: Endometrial epithelial cells have limited expansion potential and it should be overcome to make regenerative medicine as a therapeutic strategy for refractory thin endometrium.
Summary answer: We successfully cultured endometrial epithelial cells until passage 5 for two and a half months using human embryonic stem cell-derived feeder cells.
What is known already: Various therapeutic approaches including hormone replacement to overcome thin endometrium, however, they remain a challenge in reproductive medicine with only slight enhancements attained with the currently available treatment. Regenerative medicines based on cellular approaches have the potential to provide new therapeutic methods, however, endometrial epithelial cells have limited expansion potential and it should be overcome to make regenerative medicine as an available therapeutic strategy.
Study design, size, duration: Endometrial samples from four healthy women undergoing benign gynecological surgery without any endometrial pathology and/or exposure for exogenous hormone therapy at a university hospital were included and analyzed for *in vitro* experiments. The protocol of the present study was approved by Institutional Review Board of the National Center for Child Health and Development of Japan (approval number: 2289) and The Jikei University School of Medicine (approval number: 28-083(8326)).
Participants/materials, setting, methods: We prepared primary human endometrial epithelial cells and endometrial stromal fibroblasts from the endometrial samples by enzymatic digestion, then isolated and cultured endometrial epithelial cells with growth media on feeder cells including mouse embryonic fibroblasts, endometrial stromal fibroblasts, and human embryonic stem cell-derived feeder cells to explore the conditions applicable for regenerative medicine. We performed cell proliferation assay and investigated cellular morphology and characteristics with immunohistochemistry.
Main results and the role of chance: Co-cultivation of the endometrial epithelial cells with the feeder cells was significantly efficient compared with cultivation in the absence of the feeder cells in viewpoints of cell growth; we could not culture the endometrial epithelial cells without the feeder cells beyond passage 1 as previously reported. Among the feeder cells, mouse embryonic fibroblasts resulted in the best feeder activity for proliferation of the endometrial epithelial cells. Likewise, endometrial stromal fibroblasts showed the equivalent potential with mouse embryonic fibroblasts; we could passage the endometrial epithelial cells on these feeder cells up to passage 5 for two and a half months. Aiming to establish the culture method with easily available human cell resources, we examined the potential of human embryonic stem cell-derived feeder cells. We found that the endometrial epithelial cells were cultured on the human embryonic stem cell-derived feeder cells up to passage 5 for two and half months, which might be regarded as an alternative culture method. Furthermore, we explored protein expression of an epithelial cell-specific marker, pan-cytokeratin, and found that expression of pan-cytokeratin was preserved in the endometrial epithelial cells with serial cultivation on the feeder cells.
Limitations, reasons for caution: We need to address further a clinical model for human application.
Wider implications of the findings: Autologous transplantation of *in vitro* cultured endometrium can be a potential option for treating women with thin endometrium. Furthermore, findings from this research can lead to establishment of *in vitro* three-dimensional endometrium model and it can also be utilized to elucidate underlying mechanisms of embryo implantation.
Trial registration number: not applicable

P-802 Epithelial-mesenchymal plasticity in neonatal spermatogonial stem cell revealed by RNA-Seq and single cell ATAC-Seq

H.C. Suen[1], J. Liao[1], C.S.A. Luk[1], W.T. Lee[1], J.K.W. Ng[1], T.L. Lee[1]
[1]The Chinese University of Hong Kong, School of Biomedical Sciences, Hong Kong, Hong Kong

Study question: Whether epithelial-mesenchymal transition (EMT) occurs in spermatogonial stem cells (SSCs) and the role of EMT in SSC self-renewal and development remain unknown.
Summary answer: SSCs demonstrated epithelial-mesenchymal plasticity, as we observed EMT-like process in SSC and recapitulated EMT in vitro, and showed that EMT is involved in SSC migration.
What is known already: EMT is a biological process which epithelial cells lose cell-cell adhesion and gain cell-matrix adhesion to become mesenchymal cells. EMT participates in embryonic development, involving in processes such as organ formation and gastrulation. The reverse of EMT is mesenchymal-epithelial transition (MET), which is crucial in stem cell self-renewal. SSCs are male germline stem cells for spermatogenesis. SSC subtypes display distinct epithelial-like or mesenchymal-like gene expression signature. During postnatal development, SSCs migrate from the center of testicular cord to the basement membrane, leading to the establishment of SSC pool. Nonetheless, the cellular mechanisms involved in SSC migration remain elusive.
Study design, size, duration: We hypothesize that, EMT facilitates cell migration of SSC, while MET maintains the undifferentiated stem cell population. To recapitulate the EMT process in SSCs in vitro, we devised a novel SSC culture method through controlling extracellular matrix substrate. We then defined the transcriptional and epigenetic program by RNA-Seq and single cell ATAC-Seq (scATAC-seq). Lastly, we performed an in vitro assay by applying small molecules to evaluate the effects of candidate regulators towards cell migration.
Participants/materials, setting, methods: Oct4+/Kit- SSCs were isolated from PND6 mouse testes for culture. SSCs were cultured on Matrigel of different concentration, which high (5-20 μg/cm2) and low concentration (0.1-0.5 μg/cm2) of Matrigel promoted formation of flat-shaped colonies (fSSCs) and domed-shaped colonies (dSSCs) respectively. dSSCs and fSSCs were characterized by cellular and molecular assays (FACS, RT-PCR, invasion assay, etc). dSSCs and fSSCs were also subjected to bulk RNA-Seq, bulk ATAC-Seq and scATAC-Seq for transcriptome and chromatin accessibility analysis.
Main results and the role of chance: In Oct4+/Kit- SSC culture, differentiation-primed subpopulation (Oct4-GFP-high) showed higher expression of genes related to ECM components and organization, implying ECM regulates SSC cell fate and maintenance. To investigate how ECM regulates SSCs at physical and molecular level, SSCs were cultured on different concentration of Matrigel, which promoted formation of two morphologically distinct cell populations, fSSCs and dSSCs. Gene expression analysis revealed dSSCs resemble an epithelial-like phenotype, characterized by higher epithelial marker (CDH1, Occludin) and self-renewal gene expression. In contrast, fSSCs is more mesenchymal-like and showed higher EMT-inducing TFs (TWIST, SNAIL, ZEB) and mesenchymal marker (Vimentin, N-cadherin, MMPs) expression. Concordantly, fSSCs displayed a significantly higher invasion rate.
To define the epigenetic program executed by SSCs undergoing EMT, we first performed bulk ATAC-Seq and confirmed the EMT-associated genes underwent increased chromatin openness. We then performed scATAC-Seq to reconstruct the regulatory dynamics of EMT transition and further identified epithelial, mesenchymal clusters and a cluster of partial EMT. The result not only recapitulated known EMT factors (Tgfb1, Zeb1) but also identified several potential regulators such as Sp1, Mef2d and Vdr. Lastly, we further demonstrated TGF-β signaling pathway plays in EMT of SSC in vitro by applying TGFBR1 inhibitor, which substantially inhibited SSC migration.
Limitations, reasons for caution: In this study, we have demonstrated EMT process in SSC in vitro. However, the link between this phenomenon and in vivo postnatal SSC development is yet to be completely elucidated. Therefore, the role of EMT in vivo warrants further investigation.
Wider implications of the findings: This study implied that EMT, or EMT-like process, can occur in SSC and modulate its migratory ability. Our results shed light on the novel molecular mechanisms underlying postnatal spermatogonial development and give insight into the clinical application of SSC transplantation to restore fertility after cancer treatment at adolescence.
Trial registration number: not applicable

P-803 Histone modifications facilitate the specification of human primordial germ cells from induced pluripotent stem cells

S. Yang[1], S. Peng[2], S. Ding[3], H. Xu[1], Y. Cao[1], Y. Huang[1]

[1]Shenzhen University General Hospital- Shenzhen University Clinical Medical Academy, Department of Obstetrics and Gynecology, Shengzhen, China ; [2]Central South University, the Key Laboratory of Carcinogenesis of The Chinese Ministry of Health and Cancer Research Institute, Changsha, China ; [3]The University of Hong Kong-Shenzhen Hospital, The Center of Reproduction Medicine, Shenzhen, China

Study question: Can histone modifications facilitate the induction of human primordial germ cells (PGCs) from induced pluripotent stem cells (iPSCs) *in vitro?*
Summary answer: Histone deacetylase inhibitors (HDACi) panobinostat promoted the differentiation of human PGCs from iPSCs *in vitro.* The induced PGCs showed high levels of histone acetylation status.
What is known already: Histone modifications modulate DNA accessibility and chromatin structure, and further affect gene expression and cell differentiation. It has also been confirmed that human iPSCs can differentiate into PGCs. But we did not know the histone status of differentiated PGCs from iPSCs *in vitro*, and the relationship of histone deacetylation and the induced differentiation of PGCs from iPSCs *in vitro*.
Study design, size, duration: VASA-GFP iPSCs were used for induction differentiation experiments. The induction efficiency of PGCs from VASA-GFP iPSCs were compared between two groups, which one is induction medium adding the HDACi (panobinostat) at day 4 and other is no adding HDACi. During inducted differentiation, the histone status was analysed at day 5 and day 8.
Participants/materials, setting, methods: The HDACi panobinostat is added after pre-induction for deacetylation at day 5. The final concentration was 8 nM. These cells were cultured three days with HDACi panobinostat and PGC medium for downstream experiments. We analyzed the histone acetylation dynamics in human PGCs at day 5 and day 8 by ChIP-sequencing and the efficiency of induced differentiation to ask whether the histone deacetylation accelerated the differentiation of human PGCs from iPSCs.
Main results and the role of chance: Our results showed in our experiments, we added histone deacetylase inhibitors panobinostat during the induction differentiation of PGCs from human iPSCs. Our results showed the human PGCs derived from iPSCs displayed high levels of histone acetylation marks in H3K9ac and H3K27ac, and also showed, in HDACi panobinostat group, VASA-GFP positive cells were 23.5 ± 4.65%, 48.1±5.65% on day 5 and day 8 induction, but in no HDACi panobinostat group, VASA-GFP positive cells were 18.6 ± 3.15%, 41.4 ± 3.48% on day 5 and day 8 induction, indicating histone modifications facilitated the specification of human primordial germ cells from pluripotent stem cells during induction differentiation *in vitro.*
Limitations, reasons for caution: In this study, the global epigenetic reprogramming process during induction differentiation of PGCs from iPSCs *in vitro* remains to be determined.
Wider implications of the findings: This provides a new and high-efficiency way for PGC induction differentiation from iPSCs *in vitro*.
Trial registration number: 'not applicable

P-804 Feasibility of parental genome cloning

P. Xie[1], A. Trout[1], R. Setton[1], Z. Rosenwaks[1], G. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: We tested the feasibility of generating biparental conceptuses through the fusion of haploid male and female pseudo-blastomeres.
Summary answer: Biparental complementation was achievable through fusing a single 2-cell–stage male pseudo-blastomere with the female counterpart; this post-syngamy reconstruction achieved full preimplantation development.
What is known already: Male haploid embryos can be generated through sperm injection of enucleated oocytes, while the maternal counterpart can be achieved by activating metaphase II oocytes by artificially inducing calcium oscillations. These haploid embryos can be used to clone scarce gametes for reproductive uses in both genders as well as for heterozygosity identification and eventual heritable genomic editing at the pre-syngamy level. Dispermic and digenic embryos can be obtained through nuclear transfer; however, these embryos do not achieve normal preimplantation development because of gender-related imprinting.
Study design, size, duration: A single cohort of mouse metaphase II oocytes was divided into groups: 1) generating male pseudo-blastomeres by inseminating

enucleated oocytes, 2) activating oocytes to yield female pseudo-blastomeres, and 3) generating control ICSI conceptuses. Biparental reconstruction was performed by subzonal pseudo-blastomere replacement of haploid male and female embryos at the 2-cell stage. Constructs were cultured for 96h to obtain full preimplantation development and compared with control. Cleavage rates were compared using t-test with 0.05 considered significant.

Participants/materials, setting, methods: To generate male pseudo-blastomeres, metaphase II oocytes from B6D2F1 mice were treated with cytochalasin B, enucleated by herniating spindle region under Oosight™ visualization, injected with a spermatozoon from same strain and cultured up to 2-cell stage. Female counterparts were generated by parthenogenesis using calcium ionophore and allowed to reach first division. At 2-cell stage, a female pseudo-blastomere was replaced by a male counterpart and fused by Sendai virus. Control embryos were generated by piezo-actuated ICSI.

Main results and the role of chance: A total of 60 oocytes were enucleated, and 57 ooplasts were obtained. Out of 57 ooplasts injected with sperm heads, 43 survived (74%), and all developed a single male pronucleus 4-6h post-ICSI. After culturing for approximately 20h, 40 androgenic embryos entered first zygotic division (93%). For the female counterparts, 52 out of 60 oocytes (86.7%) extruded the second polar body and formed a single female pronucleus. After approximately 20h, 50 2-cell haploid female embryos were obtained. Forty reciprocal pseudo-blastomere transfers were performed with a fusion rate of 90%. The cleavage rates of reconstructed conceptuses into 2-cell embryos (77.8%) and 4-cell embryos (69.4%) were comparable to the control group at 86.7% and 83.3%, respectively. However, morula compaction (50.0%) and blastocyst development (44.4%) of reconstructed conceptuses were significantly lower than the control ICSI conceptuses, with 83.3% morula compaction and 83.3% blastocyst formation rates ($P < 0.001$ and $P < 0.01$, respectively). Full preimplantation development was achieved in only 44.4% of the constructs; the remainder exhibited abnormal rotational holoblastic cleavage with a high level of fragmentation.

Limitations, reasons for caution: Although both paternal and maternal gamete cloning was achievable, the embryo development potential appears to deteriorate prior to embryo compaction. While ooplasmic heteroplasmy was prevented, reconstructed embryos may have premature loss of imprinting and abnormal syngamy resulting in aneuploidy.

Wider implications of the findings: This technique offers the possibility of propagating male and female genomes for reproductive or diagnostic applications. These cloned gametes can be utilized synchronously to reconstitute biparental conceptuses. Sibling blastomeres could be propagated, cryopreserved, or genetically screened and processed for eventual genomic editing.

Trial registration number: not applicable

P-805 Investigating the potential use of autologous platelet-rich plasma (PRP) intra-ovarian infusion treatment for ovarian rejuvenation in menopausal and peri-menopausal women: a prospective pilot study

K. Pantos[1], M. Simopoulou[2], A. Pantou[1], S. Grigoriadis[2], P. Tsioulou[2], E. Maziotis[2], N. Nitsos[1], A. Rapani[2], P. Giannelou[2], G. Kokkali[1], M. Koutsilieris[2], K. Sfakianoudis[1]

[1]Genesis, Medical, Chalandri- Athens, Greece ;
[2]National and Kapodistrian University of Athens- School of Medicine, Physiology, Athens, Greece

Study question: Could autologous PRP intra-ovarian infusion restore ovarian function promoting menstrual cycle and hormonal profile regulation and enable reproductive potential in menopausal and peri-menopausal women?

Summary answer: Intra-ovarian PRP infusion may restore ovarian function enabling folliculogenesis, and may promote menstrual cycle regulation enabling a reproductive dynamic for menopausal and peri-menopausal women.

What is known already: Women of advanced age presenting with menopausal symptoms may opt for hormone replacement (HR). However, HR is presenting with limitations. In order to address infertility, oocyte donation is employed in the context of ART. Nowadays, women of advanced age investigate alternative options in their quest to ensure a pregnancy employing their own oocytes. Recently published studies demonstrate that PRP intra-ovarian infusion may restore ovarian function in this population. However, provided data lucks robustness. This is the first pilot study aiming to provide sufficient data regarding PRP application for ovarian rejuvenation in menopausal and peri-menopausal women.

Study design, size, duration: This prospective pilot study was carried out between 1 February, 2017 and 31 January, 2019 at the Centre of Human Reproduction, Genesis Athens Clinic, Athens, Greece. Participants were included in the study following oral and written consent. Study's participants were divided in two cohorts according to the menopausal symptoms reported namely, peri-menopausal and menopausal groups. Thirty women were included in each group. In total, 60 participants were recruited to participate in the study.

Participants/materials, setting, methods: Participants were ≥40 years old presenting with menstrual cycle irregularities (peri-menopausal) or amenorrhea for at least 12 months (menopausal). Prior to PRP treatment, basic investigation, including Antral Follicle Count (AFC), Anti-Mullerian Hormone (AMH), gonadotropin and estradiol assessment, was performed. Subsequently, participants were subjected to PRP infusion. The follow-up period was three months. Regarding both of groups, the primary outcomes were: progressive reduction of Follicle Stimulating Hormone (FSH) levels and menstrual cycle restoration.

Main results and the role of chance: Regarding the peri-menopausal group, 24 women (80%) achieved menstrual cycle regulation. Mean age was 43.25±1.42 years. All 24 patients presented with at least three consecutive regular menstrual cycles following PRP. A progressive reduction was observed regarding FSH levels, reaching lowest levels in the third menstrual cycle following PRP (18.51±2.62 vs 15.28±4.03, p-value=0.021). From the first menstrual cycle following PRP, an increase was observed regarding AMH levels (0.96±0.28 vs 1.42±0.16, p-value<0.001), estradiol levels (29.67±3.82 vs 39.50±2.06, p-value<0.001) and AFC number (1.54±0.51 vs 2.79 ± 0.78, p-value<0.001). Four patients achieved natural conceptions. Regarding the menopausal group, 13 women (43.3%) achieved menstrual cycle restoration. The mean age was 48.85±1.57 years. All 13 patients presented with at least three consecutive regular menstrual cycles following PRP. The mean time for menstrual cycle recovery was 40.92±7.57 days. A progressive reduction was observed regarding FSH levels, reaching the lowest levels in the third menstrual cycle following PRP compare to baseline (80.27±5.03 vs 30.55±2.50, p-value<0.001). From the first menstrual cycle following PRP, an increase was observed in regards to AMH levels (0.13±0.03 vs 0.32±0.08, p-value<0.001), estradiol levels (14.01 ± 2.59 vs 22.19±5.63, p-value<0.001) and AFC number (0 vs 1.31± 0.48, p-value<0.001). One patient achieved natural conception.

Limitations, reasons for caution: The absence of control groups, mainly attributed to the observational nature of this pilot study, consists of the most significant limitation of the study. Furthermore, the small sample size could serve as an additional limitation. The relatively small follow-up period could serve as another reason for caution.

Wider implications of the findings: Autologous intra-ovarian PRP infusion may restore ovarian function, folliculogenesis reactivation, recovery of menstrual cycle, and enhancement of the hormonal profile regarding peri-menopausal and menopausal women. This may provide the basis for enabling a reproductive dynamic. Future studies are required to provide robust evidence in regards to PRP efficiency and safety.

Trial registration number: Not applicable

P-806 Similar population of small CD133+ stem cells from recurrent ovarian and testicular cancer expressing some markers of germline (DDX4, PRDM14) and pluripotency (SSEA4)

I. Virant - Klun[1], V. Salamun[1], N. Kenda - Suster[1], S. Novakovic[2], P. Skerl[2], S. Smrkolj[1]

[1]University Medical Centre Ljubljana, Department of Obstetrics and Gynaecology, Ljubljana, Slovenia ;
[2]Institute of Oncology Ljubljana, Molecular Diagnostics, Ljubljana, Slovenia

Study question: Are there stem cells that persist from the embryonic period of life (indifferent gonads) and are associated with both ovarian and testicular cancer ?

Summary answer: There is a population of CD133+ stem cells expressing some markers of germline and pluripotency which are associated with both ovarian and testicular cancer.

What is known already: Numerous publications indicate that ovarian cancer is associated with stem cells that are involved in cancer, metastasis, and chemoresistance, but these cells express different phenotypes/markers; there is no

generally accepted population of ovarian cancer-related stem cells. Testicular cancer has been less studied in terms of cancer-related stem cells. Spermatogonia are well-researched and of clinical importance (e.g., freezing of spermatogonia for fertility preservation), but testicular cancer is more attributed to their pre-stage – unknown gonocytes. Therefore, the purpose of this study was to identify stem cells that are common to both ovarian and testicular cancer and express germline and pluripotency-related markers.

Study design, size, duration: During three years, ascites was retrieved from 10 patients with recurrent serous ovarian cancer and testicular tissue from 4 patients with bilateral seminoma testicular cancer. Cell culture was established from each sample and CD133+ cells were sorted by magnetic-activated cell sorting (MACS). Sorted cells were proliferated (FSH+valproic acid), analyzed for genes/markers of germinal lineage (DDX4, PRDM14) and pluripotency (SSEA4), and differentiated into other types of cells to compare cells from ovarian and testicular cancer.

Participants/materials, setting, methods: Ascites was obtained under sterile conditions, centrifuged and cultured in RPMI medium supplemented with insulin, EG, bFGF, FBS, and penicillin/streptomycin. Testicular tissue was enzymatically degraded with collagenase and cultured in supplemented DMEM-F12 medium. After MACS-sorting (Miltenyi), CD133+ cells were proliferated (FSH+valproic acid), analyzed with qPCR and immunocytochemistry, and differentiated into adipogenic, osteogenic and neural-like lineages; adipogenic cells were confirmed by Oil Red O, osteogenic cells with Von Kossa staining, and neural-like cells with S100 staining.

Main results and the role of chance: In both ovarian and testicular cancer, there was a similar population of small (diameters of up to 5 .µm) and yellow shining CD133+ cells after MACS. In both types of cell cultures, these cells were more abundant than in normal, non-malignant ovarian and testicular tissue. Ascites cells expressed *CD133* and *DDX4* genes at a lower level than testicular cancer cells (6.14±1.1 and 9,55±2.15 vs. 20.85±5.40 and 763.99±186.05) at a comparable cell count; they did not express the primordial germ cell-related *PRDM14* gene, while the testicular cells did. Both, ascites and testicular cancer cells expressed CD133, DDX4, PRDM14, and SSEA4 markers after immunocytochemistry. After MACS, all cells were dormant but proliferated strongly after 2-3 months of exposure to FSH+valproic acid. The proportion of cells was differentiated into adipose, osteogenic, and neural-like cells in appropriate differentiation media. It can be concluded that there is a similar CD133+ stem cell population in both ovarian and testicular cancer cell cultures expressing stem cell and germline markers, and can differentiate into other types of cells. Nevertheless, there are also differences at the molecular level. These small cells are suggested as stem cells – gonocytes/VSELs that persist in gonadal tissues from the embryonic period of life.

Limitations, reasons for caution: Further characterization of discovered cells is required, including transplantation into SCID mice for testing the formation of tumors.

Wider implications of the findings: This new knowledge may lead to a better understanding and treatment of ovarian/testicular cancer in the future.

Trial registration number: Republic of Slovenia Medical Ethical Committee approval 154/07/10

P-807 Ovarian Autologous Platelet rich plasma therapy in ovarian insufficiency: An alternative for donor oocyte

R. Sahay[1], S. Shukla[1]

[1]India IVF Clinic, Infertility, Delhi, India

Study question: Does intraovarian infusion of autologous platelet rich plasma increases the egg/embryo quality ?

Summary answer: Intraovarian infusion of autologous platelet rich plasma represents a new effective and safe alternative method for infertile patients with low ovarian reserve .

What is known already: The major function of platelets is to prevent acute blood loss and repair vascular walls and adjacent tissues , they also activate and aggregate to release granules containing growth factors, such as Transforming Growth Factor -β, Platelet Derived Growth Factor , Insulin like growth factor , Vascular Endothelial Growth Factor, Epidermal Growth Factor and Fibroblast Growth Factor -2 , which stimulate the inflammatory cascade and healing process. It is fractionated plasma from autologous blood and contains concentrated platelets. It is nowadays widely applied in various clinical scenarios, in orthopedics, ophthalmology, oromaxillary and wound healing to improve the tissue regeneration.

Study design, size, duration: Case series study ,

Seven patients were recruited ,

Duration is of six months (August 2019-January 2020)

Participants/materials, setting, methods: One IVF cycle canceled for poor follicular recruitment , Anti mullerian hormone < 1 ng/ml , Follicle stimulating hormone >16mIU/mL . At tertiary level IVF centre after taking written consent 15 ml of venous blood was drawn from Arthrex Double syringe system , centrifuged by ACP centrifuge system for 10 min. The supernatant pellet 3ml was infused bilaterally intraovarian by single lumen needle under transvaginal ultrasound guidance with multiple punctures under anesthesia.

Main results and the role of chance: In this study, seven patients had extraordinarily poor ovarian response and the ovaries were non-responsive to conventional controlled ovarian stimulation, resulting in cycle cancellation, need for donor eggs, low possibility of pregnancy and heavily emotional distress.

After application of intraovarian autologous platelet rich plasma , the ovarian response was satisfactory (FSH level decreased by 40% , AMH level increased by 10% , serum estradiol levels increased by 35% ,healthy oocytes were retrieved and blastocyst were made) in five of the patients, and in rest two we are planning repeat cycles as the response was inadequate . They all showed features of restoration of menstruation and symptomatic changes in their body.

Our findings suggest that it is able to increase the ovarian function and help the patients make embryo from there own eggs .

Since PRP is prepared from autologous blood, theoretically there are minimal risks for disease transmission, immunogenic reactions. No infection or injury was observed.

As the diagnosis of IVF failure is always tentative, clinical efficacy and reproductive outcome of Platelet rich Plasma in this indication is difficult to assess and predict.

Limitations, reasons for caution: Various extensive research have been done regarding optimal treatment for controlled ovarian stimulation . However, till date no such approach is there which gives guaranteed results .

Wider implications of the findings: The findings provide evidence for future randomized, controlled trials with large sample size in this field.

Additional research is needed to clarify (and enhance) which PRP components are responsible for altered ovarian function, and to identify predictive characteristics for patients most likely to benefit from this intervention.

Trial registration number: not applicable

P-808 Somatic cell nuclear transfer of different diploid cells into an enucleated oocyte aimed at nuclear haploidization

A. Trout[1], P. Xie[1], R. Setton[1], Z. Rosenwaks[1], G.D. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: We evaluated the efficiency of oocyte-mediated haploidization with different types of donor nuclei and observed their complete preimplantation development.

Summary answer: Despite cumulus cells having a superb haploidization rate, embryo development rates were comparable between all donor cell types.

What is known already: Success with human reproductive technology is universally limited by oocyte aging, characterized by higher aneuploidy. Numerous attempts have been made to generate oocytes through the haploidization of a somatic nucleus. A large array of cell types, at different cell-cycle stages, have been proposed as candidate donor cells. Studies in primate models found fibroblasts to be superior donors than cumulus cells, while others found mouse embryonic stem cells to be more effective than differentiated cells. Nonetheless, in the most recent study, cumulus cells have been used to analyze correct chromosome number and the developmental potential of artificially derived oocytes.

Study design, size, duration: Metaphase II oocytes from B6D2F1 mice were split into 4 groups: 1) to generate ooplasts for somatic cell haploidization of corona/cumulus cells, 2) embryonic stem cells, 3) fibroblasts, and 4) to generate ICSI conceptuses serving as control. Successfully haploidized oocytes were then observed for meiotic spindle development and then ICSI inseminated. Rates of successful haploidization, fertilization, and blastocyst development were compared among the different donor somatic cells. The chi-squared test was used to compare results.

Participants/materials, setting, methods: To generate ooplasts for haploidization, MII oocytes were exposed to cytochalasin B and enucleated by herniating spindle complexes under Oosight™ visualization. Afterwards, a single cell, cumulus, mES, or fibroblast was inserted into the perivitelline space of the ooplast, and fused using Sendai virus. Successful oocyte fusion and somatic cell reprogramming was verified by spindle development and extrusion of a polar body prior to injection by piezo-ICSI. Intact oocytes, solely injected by piezo-ICSI, served as control.
Main results and the role of chance: Of 338 enucleated oocytes, cumulus cells were transferred in 232, while mESCs were transferred into 49, and fibroblasts into 57, ooplasts. Following spindle development and pseudo polar body extrusion, oocytes injected with cumulus cells were found to have a significantly higher rate of haploidization (55%, $P<0.00001$), while mESC and fibroblasts had rates of 31% and 17%, respectively. The rate of fertilization, measured by the presence of two clear pronuclei and one distinct second polar body, at 4-6 hours post-insemination, was comparable among the cumulus (32%), mESC (42%), and fibroblast (29%) cohorts. However, the rate of fertilization for the control group (73%) was significantly greater than each of the donor cell groups ($P< 0.00001$). In the experimental groups, after fertilization, blastocyst development for cumulus cells (21%) was also comparable to mESCs (9%) and fibroblasts (17%). Despite no significant differences among each experimental category, when compared to the control (87%), blastocyst development was present but significantly compromised ($P<0.0001$).
Limitations, reasons for caution: This is a preliminary study on the efficiency of female genome haploidization. While this study only assessed preimplantation development, the next step would be to enhance the efficiency of embryo development and obtain live pups.
Wider implications of the findings: Once this technique is optimized, and successful post-implantation development is confirmed, it may serve to generate genotyped gametes. Implementation of somatic cell haploidization may be able to alleviate age-related female infertility by generating competent oocytes in women with premature ovarian insufficiency.
Trial registration number: N/A

P-809 Revealing the aging effect in menstrual blood-derived stem cells using CD146+ phenotype

W.T. Lee[1], J. Liao[1], C.S. Luk[1], H.C. Suen[1], J.K.W. Ng[1], T.T.H. Chan[1], M.Y. Cheung[1], M.P. Zhao[2], D.Y.L. Chan[2], W.Y. Chan[1], T.Y. Leung[2], K.L. Chow[3], Q. Lian[4], T.C. Li[2], T.L. Lee[1]

[2]The Chinese University of Hong Kong, Department of Obstetrics and Gynaecology, Hong Kong, Hong Kong ;
[3]The Hong Kong University of Science and Technology, Department of Chemical and Biological Engineering, Hong Kong, Hong Kong ;
[4]The University of Hong Kong, Li Ka Shing Faculty of Medicine, Hong Kong, Hong Kong

Study question: Can we restore the quality of menstrual blood-derived stem cells (MenSCs) from women of advanced maternal age (AMA) for autologous cell-based therapies?
Summary answer: Selection of CD146$^+$ MenSCs could be feasible to establish personal MenSC banks with high therapeutic potential for women of AMA.
What is known already: In recent years, MenSC has become a promising strategy in regenerative and therapeutic application. It includes ovarian-related diseases, endometriosis and Asherman's syndrome (AS). MenSCs are abundant, easily and non-invasively isolated. They have high proliferative capacity and multilineage differentiation potency. Previous studies revealed that they express most mesenchymal stem cell (MSC) specific markers. Therefore, they are considered as a source of MSCs. It is well-established that there was an age-related decline in the number of CD146$^+$ in bone marrow-derived MSCs which contributed to lower therapeutic potential. However, the effects of aging on biological characteristics and gene expression of MenSC remain unclear.
Study design, size, duration: Menstrual blood blood from young (age ≤ 26 years) and elderly (age > 35 years) donors were freshly collected. Both *in vivo* and *in vitro* MenSCs were extracted for investigating the aging effects.
Participants/materials, setting, methods: Menstrual blood mononuclear cells (MMCs) were isolated using Ficoll-Hypaque density-gradient centrifugation. MMCs were directly analyzed by standard cell surface marker (CD90, CD105 and CD146) using fluorescence-activated cell sorting (FACS). Meanwhile, MenSCs collected from the two age groups were cultured for further evaluation including morphology, adenosine triphosphate (ATP) content and immunophenotypes.
Main results and the role of chance: Subpopulation of individual immunophenotype (CD90$^+$/CD105$^+$/CD146$^+$) in *in vivo* MMC population differs among donors as the number of cells detached from endometrium varies in each collection. Meanwhile, we revealed that the percentage of MenSCs declined dramatically in *in vivo* MMC population when the storage time of menstrual blood increased. Therefore, fresh samples were essential in order to collect larger number of *in vivo* MenSCs. There was no obvious aging effect on the number of *in vivo* MMCs and subpopulations of individual immunophenotypes. Surprisingly, we discovered that the number of CD146$^+$ MenSCs in *in vivo* MenSC population from young donors was greater than that of elderly donors by approximately 1.5-fold. Furthermore, *in vitro* MenSCs from elderly donors showed lower ATP content and expressions of MSC markers.
Limitations, reasons for caution: The number of donors in the elderly group was limited, a larger sample size is required for a confident conclusion.
Wider implications of the findings: Our study provides promising information for the potential of using CD146$^+$ phenotype to predict the age of MenSCs and the efficacy of autologous MSCs for treating elderly patients.
Trial registration number: not applicable

P-810 Future stem cell therapies in fertility preservation of prepuberal children with cancer or genetic syndromes. Improvements in the characterization of human Spermatogonial Stem Cells.

Study question: Is possible to improve the *in vitro* expansion and to determine the ploidy of Spermatogonial Stem Cells (SSCs) of Klinefelter Syndrome (KS) prepuberal patients?
Summary answer: We achieved an *in vitro* expansion improvement of SSCs with PRP and we determine the correct ploidy of SSCs in KS patients by DNA FISH.
What is known already: Oncologic prepuberal children after cancer treatments and prepuberal children with genetic syndromes, such as Klinefelter Syndrome, can suffer fertility problems in adulthood. The aim of this experimental fertility program is to preserve testicular tissue (with SSCs) to expand *in vitro* these stem cells for future autologous transplantation of the tissue or expanded SSCs in the adulthood. On one hand, still is needed a good SSCs expansion protocol for future spermatogenesis restoration in these patients. On the other hand, a correct ploidy determination (mosaic/pure) in SSCs of prepuberal SK patients is needed.
Study design, size, duration: We collected and processed testicular biopsies of both adults and children (oncologic and KS). Each biopsy is divided into 3 fragments: for histological study, for clinical use and for research.

Participants/materials, setting, methods: Testicular biopsy fragment for histological studies, we performed immunofluorescence to determine expression of germ cells (VASA) and SSCs (MAGEA4) markers.

Testicular biopsy fragment for clinical use is preserved in a specific cryopreservation medium with quality controls.

Testicular biopsy for research is processed and SSCs put into culture (+/-PRP) for 28 days. We analyzed SSC markers (GPR125, CD9, CD49f, CD90, HLA-I, SSEA4) by flow cytometry. We analyzed the ploidy in KS biopsies by DNA FISH.

Main results and the role of chance: We have collected and processed 60 adult testicular biopsies from azoospermic patients as a control, 9 of KS prepuberal patients and 2 of oncologic prepuberal patients.

We have observed that the majority of adult patients, all oncologic prepuberal patients and 20% of Klinefelter Syndrome prepuberal patients express both VASA and MAGEA4 markers by immunofluorescence. In these 20% of KS prepuberal patients that we found previously SSCs then we determined the ploidy (mosaic/pure) by DNA FISH assay. It has been described that GPR125 markers as a putative markers for SSCs in humans. We observed that in our *in vitro* expansion cultures of adult SSCs in the presence of 5% Platelet enriched plasma (PRP) there are more GPR125 + cells (3,3%) in comparison with the control medium (1,5%) condition after 28 days in culture. After these preliminary data in adult SSCs, we will use this novel culture condition for improvement of *in vitro* expansion of prepuberal SSCs.

Limitations, reasons for caution: Due to the limited and difficulty in the obtaining of material used in this study, we used few samples of prepuberal testis.

Wider implications of the findings: We have determined the presence of SSCs in oncologic prepuberal patients (100%) and in SK prepuberal patients (20%). We determined the ploidy (mosaic/pure) of KS SSCs.

The PRP improved the *in vitro* expansion of SSCs in culture during 28 days for future use in auto-transplants to restore patient fertility.

Trial registration number: none

P-811 Fertility preservation in pre-pubertal boys with cancer: cryopreserving immature testicular tissue and developing a three-dimensional scaffolding system to encourage in vitro spermatogenesis

S. Tang[1], J. Celine[1], C. Kevin[1]

[1]University of Oxford, Women's and reproductive health, OXford, United Kingdom

Study question: What are the impacts of three cryopreservation methods on bovine immature testicular tissue (ITT) and can a three-dimensional (3D) scaffolding system encourage *in vitro* spermatogenesis using frozen/thawed tissue?

Summary answer: Speed-controlled slow freezing is favorable for cryopreserving ITT, and spermatogonial stem cell (SSC) colonies can be successfully maintained in a 3D culture system.

What is known already: Annually, around 2000 new cases of childhood cancer are diagnosed in the UK. However, when treated with aggressive chemo- or radio-therapy, prepubertal boys are often rendered infertile. The production of functional sperm from SSCs in the testis is initiated at puberty, thus the cryopreservation of ITT is the only option for pre-pubertal boys at present. In the testis, SSCs are located inside a 3D structure (the seminiferous tubules), and direct cell-to-cell interactions play a critical role in both their proliferation and development.

Study design, size, duration: Three cryopreservation methods (automated slow-freezing, isopropyl alcohol (IPA) uncontrolled slow-freezing, and vitrification) were used to cryopreserve ITT. After thawing, we then investigated apoptosis, gene expression, and the morphology of each sample of ITT. We also isolated SSCs and transferred them into a 3D culture system for further culture.

Participants/materials, setting, methods: Bovine ITTs (n=6) were frozen using three cryopreservation methods. After thawing, ITTs were evaluated by RT-qPCR for germ-cell markers (*PLZF, Oct4, Nanog, Sox2, C-kit* and *Grfa-1*), and apoptosis-related markers (*CREM, KLF4, THY-1, UCHL Stra8* and *HSP70-2*). SSCs were isolated by a two-step enzymatic digestion and Percoll density gradient. Immunocytochemistry, using specific markers (PGP 9.5, PLZF), was then used to detect SSCs, while TUNEL assays were used to determine the extent of apoptosis in testicular cells.

Main results and the role of chance: No significant differences were evident in terms of the expression levels of either germ-cell markers (*PLZF, Oct4,Nanog, Sox2, C-kit,* and *Grfa-1*), or markers of apoptosis (*CREM, KLF4, THY-1, UCHL Stra8,* and *HSP70-2*) when comparing the three methods of cryopreservation. Following the two-step enzymatic digestion of testicular tissue from an immature bovine model, cell viability was 68.87%. SSCs isolated from calf testes exhibited 65% and 59% positivity for PGP9.5 in cells selected from 30% and 40% Percoll gradients, respectively, therefore indicating good rates of SSC recovery. Three days after digestion, TUNEL assays further showed that the apoptosis rates of these SSCs were 21.1% and 14.6% in cells selected by 30% and 40% Percoll density gradients, respectively. Finally, SSCs isolated using a 30% Percoll density gradient showed a significantly higher rate of proliferation ($p<0.05$) than cells isolated from a 40% Percoll gradient. Isolated cells that had been seeded onto Matrigel were successfully able to form SSC colonies, as verified by the positive expression of SSC markers (*PGP 9.5, PLZF*) and the germ-cell marker *Oct4*. The SSC colonies could be maintained in the 3D culture system for up to three weeks.

Limitations, reasons for caution: An increased number of tissues should be tested in order to confirm our findings. Further validation methods are now needed to investigate the function and health of ITT. The time period used for the cryopreservation of ITT could also be a potential source of bias.

Wider implications of the findings: Vitrification represents a potential method with which to cryopreserve ITT since it avoids the need for expensive laboratory equipment.

Trial registration number: not applicable

P-812 The development of a stem cell-based assay for quality control testing in IVF

N. Adjirackor[1], T. Beckitt[2], K. Fowler[1], S. Harvey[1]

[1]Canterbury Christ Church University, School of Human and Life Sciences, Canterbury, United Kingdom ;

[2]Genea Biomedx, Research and Development, Sydney, Australia

Study question: Can embryonic carcinoma cells be used to replace or reduce the use of mouse embryo assays (MEA) in *in vitro* fertilisation (IVF) quality assessment?

Summary answer: Findings from 2D and 3D P19 assays demonstrated the potential of embryonic carcinoma cells to respond to minor changes in culture conditions.

What is known already: The MEA is a toxicological bioassay commonly used to assess the quality of media used in IVF laboratories. Despite its popularity, there are issues with the assay including insensitivity to sub-optimal conditions, ethical concerns about the use of animals, and variation in end-point interpretation between operators. Previous attempts to develop alternative methods have failed because cell and embryo survival have been too high, hence effects that would be toxic to embryos are not detected. There have also been concerns relating to the associated costs and the lack of reproducibility associated with advanced or extended versions of the MEA.

Study design, size, duration: P19 embryonic carcinoma cells (ECACC 95102107) were primed to form 2D (monolayer) or 3D (embryoid bodies) structures in 96-well plates. When induced by DMSO or retinoic acid, P19 cells differentiate into germ layers, and therefore provide a suitable model for embryonic development. Following treatment with test substances, cell viability was determined by Alamar Blue, CellTiter-Glo and RealTime-Glo cell viability assays (Promega), and fluorescence and luminescence outputs were determined using FLUOstar Omega microplate reader.

Participants/materials, setting, methods: Cells were treated with test substances including media containing different concentrations of pyruvate and calcium lactate, two forms of glutamine, and increasing concentrations of base salts. Findings were verified by comparison to treatment with negative (αMEM) and positive (DMSO) controls. In 2D assays, cell viability was determined by fluorescence from resazurin reduction and in 3D assays, by luminescence from Luciferin and NanoLuc reduction. Statistical analyses were performed using ANOVA and Tukey HSD post-hoc tests.

Main results and the role of chance: Both 2D and 3D assays responded to varying effects of energy substrate availability, mono and dipeptide glutamine and increasing osmolality. There were insignificant differences between cellular response to increasing pyruvate and calcium lactate in the 2D assay (pyruvate $F = 0.131$; $df = 6$; $p = 0.717$, calcium lactate $F = 2.803$; $df = 6$; $p = 0.063$), but significant differences in the 3D assay (pyruvate $F = 510.5$;

df = 4; *p* = <0.001, calcium lactate *F* = 1606.71; *df* = 7; *p* = <0.001), indicating increased sensitivity with luminescence-based viability assays in comparison to fluorescence-based assays. Treatment with media containing L-glutamine and alanyl glutamine demonstrated insignificant differences in ammonium build-up between the two forms of glutamine (2D assay *p* = <0.001; 3D assay *p* = <0.001). Findings also showed that cells were sensitive to reduced and increased osmolality, although cell death did not increase with increasing osmolality but rather, complete cell death occurred when media osmolality exceeded 402 mOsmol/kg. Cells were treated with commercially available fertilisation, cleavage and blastocyst media, and comparison to blastocyst development in mice showed equal or increased sensitivity of P19 cells to sequential media, in comparison to MEA findings.

Limitations, reasons for caution: Cellular response to test substances must be directly compared to MEA findings in order to determine the true sensitivity of these cell-based assays. P19 response to commercially available fertilisation, cleavage and blastocyst media are the only set of results that have been directly compared to the MEA.

Wider implications of the findings: This study demonstrates the sensitivity of embryonic carcinoma cells to changing culture conditions, specifically changes in energy substrate levels. The P19 assay could therefore provide a robust, reproducible and cost-effective alternative to MEAs for quality assessment in IVF.

Trial registration number: not applicable

P-813 Extracellular vesicles from endometrial-derived MSCs as coadjuvants for embryo culture mediums: omics and systems biology studies

[7]Jesús Usón Minimally Invasive Surgery Centre, Scientific Direction, Cáceres, Spain

Study question: Which is the influence at "system-level" of proteome and miRNAome of extracellular vesicles from endometrial-derived Mesenchymal Stem Cells (EV-endMSCs) on the developing embryo?

Summary answer: Proteins and miRNAs from EV-endMSCs differentially act on embryo cells. Proteins may be involved in immune events and tissue remodelling; miRNAs may regulate cell cycle.

What is known already: It is well known that extracellular vesicles (EVs) have a pivotal role in cell-cell communication. When released by stem cells, EVs act as principal mediators of their potent paracrine effect. Moreover, EVs participate in reproductive processes, spanning from gametogenesis to embryo development. It has been recently demonstrated that EVs from endometrial-derived Mesenchymal Stem Cells (EV-endMSCs) are involved in: I) embryo implantation, II) proliferation of embryonic cells, III) improvement of embryo developmental competence in aged murine models. Nowadays, the molecular mechanisms underlying these findings are still under investigation, especially under a "system biology" point of view.

Study design, size, duration: Endometrial MSCs were isolated from menstrual blood of healthy pre-menopausal women (n=4) and *in vitro* expanded under controlled conditions. EV-endMSCs were collected from cell culture supernatants every 72 hours and concentrated/purified for subsequent analyses.

Participants/materials, setting, methods: Cells and EVs were characterised by flow cytometry for stemness and exosomal markers. Protein extracts were analysed by high-throughput multiplexed quantitative proteomics approach. Total RNAs were isolated and underwent next generation sequencing. Target genes of the mapped miRNAs were identified using miRNet database (https://www.mirnet.ca/). The Reactome analysis tool (https://reactome.org/) was used for enrichment analysis of proteins and miRNAs targets.

Main results and the role of chance: Flow cytometry demonstrated the presence of stemness markers in endometrial MSCs and exosomal surface markers (CD9 and CD63) in EVs.

For proteomic results, a Reactome overrepresentation analysis was performed on a total of 616 proteins (number of peptides ≥ 2, FDR ≥ 0.01). These proteins were also listed under the Gene Ontology category *Extracellular exosome* (GO:0070062). Conversely, miRNAome results were focused on the 6978 target genes of mapped miRNAs (tags per million ≥ 25). In this analysis, only the most relevant pathways (p ≤ 0.05, FDR ≤ 0.01) were considered.

EV-endMSCs proteins appeared to be involved in two major events: *Extracellular matrix organization* (R-HSA-1474244) and *Immune System* (R-HSA-168256). Interestingly, proteins were involved in pathways like adaptive/innate immune system; antigen presentation; neutrophil degranulation; cytokine, interferons and interleukins signalling; platelet activation, signalling, aggregation, and degranulation.

In the case of miRNA target genes, they were found to be involved in the major categories *Cell Cycle* (R-HSA-1640170) and *Gene expression* (R-HSA-74160), actively participating to pathways related to G1 and M phases, cell cycle checkpoints, chromatin organization, pre-mRNA processing, mRNA Splicing, and Translation Initiation. Interestingly, miRNA target genes of EV-endMSCs were also related to the events *Cellular responses to external stimuli* (R-HSA-8953897) and *Apoptosis* (R-HSA-109581).

Limitations, reasons for caution: Although the functional effect of EV-endMSCs has been previously studied in murine embryos, this study was aimed to obtain system biology results. *In vitro* studies including EV-endMSCs-embryos co-culture, followed by immunohistochemistry and qPCR should be performed to confirm the presence of endMSCs proteins and miRNA target genes in embryo cells.

Wider implications of the findings: We hypothesize that EV-endMSCs miRNA cargo may regulate the pre-implantation balance between cell division during embryo cleavage and apoptosis of aneuploid cells in mosaic embryos. Proteins may regulate maternal immune-tolerance and support trophoblast invasion during implantation.

The addition of EV-endMSCs as coadjuvants for embryo culture may increase ART success rate.

Trial registration number: not applicable

P-814 Progress toward manufacturing oocytes

R. Setton[1], A. Trout[1], P. Xie[1], Z. Rosenwaks[1], G. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: Can the observation of meiotic-like spindles during somatic cell haploidization provide better artificial oocytes with superior embryonic developmental competence?

Summary answer: Monitoring the appearance of putative meiotic spindles prior to insemination during somatic cell haploidization predicts haploidization and fertilization but not pre-implantation development of reconstructed embryos.

What is known already: Somatic cell haploidization is an in vitro gametogenesis technique that attempts to artificially induce a diploid somatic cell into halving its chromosomal content once incorporated into an enucleated MII oocyte. These newly manufactured oocytes can be fertilized to induce the extrusion of a pseudo-polar body (PB). In studies to date, the most relevant factor for the successful generation of oocytes through haploidization is the ability to choose the right cell at the right cell cycle stage and form a proper meiotic-like spindle prior to the extrusion of a pseudo polar body at the time of insemination.

Study design, size, duration: In our mammalian model, MII oocytes were gathered from superovulated B6D2F1 mice. Meiotic spindles were identified and removed under polarizing light microscope visualization. Nuclear transfer was performed using either a cumulus cell (CC), an embryonic stem cell (ESC), or an endometrial cell (EMC) and fused with enucleated oocytes using Sendai virus. Three hours after nuclear fusion, reconstructed oocytes were

assessed for the detection of a meiotic-like spindle by polarizing light microscopy.
Participants/materials, setting, methods: Oocytes were divided into those that demonstrated a clear meiotic-like spindle and those that did not. Reconstructed oocytes were then fertilized with mouse spermatozoa from the same strain via piezo-actuated intracytoplasmic sperm injection (ICSI). Preimplantation development was compared using a t-test assessing for rates of pseudo-PB extrusion, normal fertilization, and for progression to 2-cell, 4-cell, morula, and blastocyst stages. Each group was also compared to control ICSI conceptuses.
Main results and the role of chance: Of 397 oocytes that were enucleated, 372 (93.7%) survived and underwent transfer with CCs (n=253), ESCs (n=63), or EMCs (n=56). CC nuclei had meiotic-like spindle development at a rate of 59.1% (150/253), ESCs 31.7% (20/63) and EMCs 3.6% (2/56, P<0.0001). Only CC constructs (n=202) underwent ICSI and 111 survived (55%). Haploidization was confirmed by pseudo-PB extrusion in 48.3% (29/60) of reconstructed oocytes with spindles compared to 11/51 (21.6%) that did not (*P*<0.01). Oocytes with spindles yielded superior fertilization (19/60, 31.7%) then those without (5/51, 9.8%, *P*<0.05), but lower than control (88.0%, P<0.0001). When comparing cleavage of fertilized oocytes, 94.7% (18/19) of oocytes with spindles versus 80.0% (4/5) of those without reached 2-cell stage, comparable to control at 83.3%. However, 2-cell stage arrest was prevalent regardless of spindle detection: only 47.4% (9/19) with and 40.0% (2/5) without spindles reached 4-cell stage, a lower rate compared to controls (83.3%, *P*<0.001). Those embryos underwent blastocyst development at a rate of 77.8% (7/9) for those with meiotic-like spindles at insemination and 50.0% (1/2) for those without. All blastocysts (n=8) have been transferred to pseudopregnant mice but did not yield any implantation (0%) in comparison to control (76%).
Limitations, reasons for caution: Somatic cell haploidization remains challenging with unpredictable results. The main limitation is represented by the cell cycle stage of the donor somatic cell nucleus. While visualization of the spindle seemed to predict higher pseudo-PB extrusion and normal fertilization rates, it did not enhance complete pre-implantation development.
Wider implications of the findings: This preliminary data offers satisfactory fertilization and but with compromised embryo growth. The achievement of post-implantation development would set the stage for this technique as an option to generate oocytes for women with exhausted ovarian reserve or primary ovarian insufficiency.
Trial registration number: Not applicable

P-815 Three-dimensional culture of mouse embryonic stem cells maintained on a biological scaffold through direct spherification

S. Lawrence[1], M. Haddad[1], P. Xie[1], Z. Rosenwaks[1], G.D. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: Does direct spherification provide an alternative method to generate a suitable three-dimensional culture system for stem cells?
Summary answer: Direct spherification provided a sustainable three-dimensional scaffold for growth of embryonic stem cells and allowed their differentiation into early male germ cells.
What is known already: Stem cell research commonly relies on the utilization of a 2D monolayer cell culture partially due to its low cost and high reproducibility. However, 2D cell cultures do not allow the study of 3D intercellular relationships, thus providing an inaccurate replication of *in vivo* environments. 3D culture systems, such as spheroid systems, have been proposed to reproduce the biological microenvironment, particularly when replicating *in vivo* spermatogenesis. Direct spherification, a technique commonly used in molecular gastronomy, provides a cost-effective method to generate a tailored 3D scaffold while allowing fluid exchange across the membrane.
Study design, size, duration: Spheres were made from a base spherification solution of water and sodium alginate. In the first group, mESCs were injected into the spheres; in the second group, a mESC suspension was directly encapsulated (DE). mESC spheres were maintained in a basal medium bath. To coax differentiation, mESC spheres were bathed in epiblast-like cell (EpiLC) medium containing activin A, bFGF, and KSR. EpiLC markers were used to confirm cells at the pre-meiotic germ cell stage.
Participants/materials, setting, methods: MESCs were initially cultured on a 6-well dish and injected into spheres or DE. Each sphere was bathed in mESC or EpiLC medium and incubated at 37°C and 5% CO_2. The diameter of each sphere ranged from 30 to 45 mm, containing approximately $1.2x10^6$ cells per sphere. Viability was tested through cell morphology and reattachment onto inactivated mouse embryonic fibroblasts (MEFs). Differentiation was assessed by using OCT4 and Nanog as markers.
Main results and the role of chance: The morphology of the cellular contents within the spheres showed the survival and growth of mESC colonies with both methods. Spheres injected with mESCs showed a lower concentration of cells compared to the DE approach. Embryoid body formation was first observed in the DE group at day 4, indicating a higher efficiency of this approach. To test the reattachment capability of the mESCs, spheres were mechanically breached to release mESCs, resuspended in fresh basal medium, and plated onto MEF for further propagation. Colony growth and confluency of reattached mESCs were comparable to untreated monolayer mESC culture. Confident with the sustainability and efficiency of DE, we attempted differentiation by bathing the spheres in EpiLC medium. After 3 days of culturing, the spheres were breached and showed a positive OCT4 expression and decreased Nanog expression, indicating successful progression to EpiLCs.
Limitations, reasons for caution: Despite successful sustenance and propagation of mESCs using direct spherification, reproducibility of differentiation and efficiency rates still need to be confirmed. The ability to support differentiation in the post-meiotic stages will provide final proof of reliability of this approach.
Wider implications of the findings: Culturing mESCs inside spheres through direct spherification may provide an alternative method to study intercellular relationships and differentiation in a 3D structure. Incorporation of extracellular matrix proteins during spherification may provide a more physiologically relevant structure for attaining *in vitro* gametogenesis.
Trial registration number: not applicable

P-816 Zygotic cytoplasts of woman of advanced maternal age are competent enough to support normal embryo development when carry young karyoplasts

P. Mazur[1], L. Diachenko[1], V. Veselovskyy[2], Y. Masliy[2], M. Borysov[2], D. Mykytenko[3], V. Zukin[4]

[1]Darwin Life Nadiya, Embryology, Kyiv, Ukraine ;
[2]Clinic of Reproductive Medicine 'NADIYA', Gynaecology, Kyiv, Ukraine ;
[3]Darwin Life Nadiya, Genetics, Kyiv, Ukraine ;
[4]Clinic of Reproductive Medicine 'NADIYA', Administration, Kyiv, Ukraine

Study question: What is the reason of lowering blastulation rates and euploidy rates in women of advanced maternal age (AMA)?
Summary answer: It's plausible that high rates of aneuploidies and low rates of blastulation in women of AMA are associated with the oocyte karyoplast and not cytoplasm.
What is known already: Women of AMA have decreased blastulation and euploidy rates with no regard to their ovarian reserve. It's believed that their oocyte's cytoplasm is responsible for raising of aneuploidies, although, the excact mechanism is unclear. Some of the researchers propose that mitochondria play the crucial role in aging of woman's oocytes.
Study design, size, duration: The study period was from September 2015 to March 2019. Patients were informed and consent to possible risks and the experimental protocol was approved by ethics committee of local association of reproductive medicine. Inclusion criteria were: (1) no less than two failed previous IVF attempts, (2) low blastulation rates or recurrent embryo arrest, (3) low number or absence of euploid embryos, (4) age ≥ 37 years.
Participants/materials, setting, methods: 17 infertile patients (mean age was 41.5±2.5 years) participated in this study. Mean age of oocyte donors was 27.7±3.3 years. Intracytoplasmic sperm injection had been performed in all cases. Pronuclear transplantation (PNT) was assisted by HVJ-E cell fusion kit and reverse reconstitutions (RPNT) were done, if possible. Embryos obtained after reconstitutions were cultured until blastocyst stage in time-lapse incubator, were biopsied for further PGT-A analysis and then were vitrified.
Main results and the role of chance: In PNT group 83 zygotes were obtained and resulted in 25 biopsied blastocysts (30%); 3 of which (one per

patient) were euploid (12%). One try of elective single embryo transfer (eSET) of thawed embryo was done for each of three patients. Positive hCG level (> 100 mIU/mL) and following heartbeating were confirmed only for one patient (42 y.o.).
In RPNT group, where zygotic cytoplasts of women of AMA were used for carrying donor karyoplasts, 58 zygotes were obtained and resulted in 20 biopsied blastocysts (40%); 14 of which were euploid (70%, $p < .05$).
Results in RPNT group are similar to common oocyte donation cycles.
Limitations, reasons for caution: The study was conducted in one center only and the results should be confirmed by other investigators. Also two eSETs (one per patient) of RPNT embryos were done with no implantation, so the real implantation potential of such embryos remains unknown.
Wider implications of the findings: Although the study is limited to obtained zygotes, number of euploid embryos and ongoing pregnancies after applying PNT was low, thereby infertile women of AMA should be advised not to undergone such procedure in order to increase the number of euploid embryos or pregnancy rates.
Trial registration number: None

P-817 An Australian experience of operating IVF clinics during the COVID-19 pandemic

D. Bui[1], S. Dalati[1], S. McArthur[2], N. Hesketh[1], K. Fisk[1], F. Olivier[1]

[1]*Genea, Embryology, Sydney, Australia*
[2]*Genea, Executive, Sydney, Australia*

Study question: How a major Australian IVF clinic managed risk patients and staff to allow a reduction in and subsequent ramping up of assisted reproductive treatments during the COVID-19 pandemic?
Summary answer: Genea implemented a split team working model to enable patients to safely access and staff to safely provide IVF treatment and care during the pandemic.
What is known already: The outbreak of COVID-19 resulted in the declaration of a pandemic by the Australian Government on 27 February 2020 and was followed on March 11, 2020 by the World health Organisation (WHO). These declarations resulted in restrictions being placed on elective surgeries in Australia, including fertility treatment. International response to COVID-19 had at this stage varied from a complete shutdown to a business as usual approach to fertility treatment. Due to a rapid response, Australia managed to significantly slow the spread of the virus, allowing for the staged resumption and increase of elective surgeries, including IVF services.
Study design, size, duration: A review of a work model that enabled social distancing following Australian Government guidance of one person per square metre to reduce the risk of transmission. Half the embryology team was onsite to complete clinical work and perform procedures, with the other half working from home (WFH). Patient facing procedures and discussions were allocated to the WFH team, minimising exposure time of embryologists to patients and to each other.
Participants/materials, setting, methods: Embryologists were rotated one week onsite and one-week WFH, with all patient communication shifted to WFH embryologists. Patient communication was facilitated by utilising Geri time-lapse incubator and Geri Connect. All embryologists were equipped with mobile computer workstations to optimise workflow and communication between embryologists onsite and WFH. Onsite embryologists were required to be temperature tested prior to entering the clinic and laboratory. All clinical embryology was centralised to the group's main clinical facility in Sydney.
Main results and the role of chance: The split team model enabled embryologists to social distance effectively and reduce the risk of virus transmission. Limiting patient facing discussion at the time of clinical procedures reduced the face to face time between embryologists and patients. Implementation of WFH protocols, which included all patient embryology updates, laboratory to laboratory and nurse to embryology communications by telephone and face to face via apps such as Microsoft Teams relieved the onsite embryologists of regular administration work. The onsite embryology team were able to focus solely on delivery of clinical procedures whilst ensuring appropriate levels of patient care were maintained. The adaptability of embryologists was critical to the success of this model due to the rapidly evolving COVID-19 situation. Weekly review meetings were set up to communicate with all embryologists and to discuss and implement best practises as they were identified. WFH protocols were continuously reviewed and refined to improve patient outcomes and service efficiencies. The utilisation of remote access software for time-lapse incubators is central to allowing a split team model to function efficiently.
The split team model also reduced the risk of the whole embryology team being potentially infected with COVID-19 and therefore requiring isolation, effectively shutting down the IVF clinic.
Limitations, reasons for caution: The final analysis of the split team model is limited by the ongoing nature of the COVDI19 pandemic and a final understanding of the benefits and negatives of the split team model are still to be finalised.
Wider implications of the findings: IVF clinics have had to restructure their day to day tasks to continue to provide care to their patients safely during COVID-19. The split team model is one example of how an Australian clinic has been able to safely continue to provide its services to its patients during the pandemic.

P-818 Vertical transmission of the SARS-CoV-2: an extensive review of the literature

A. Soligo[1], I. Barcelos[2], I. Andrade de Araujo Penna[3], Z. Bernardes Costa[4], W. de Paula Martins[5]

[1]*Universidade de Campinas UNICAMP Brazil/ Assisted reproduction Private clinic, Gynecology and Obstetrics, São Paulo, Brazil*
[2]*Universidade Estadual Oeste Paraná, Gynecology and Obstetrics, Curitiba, Brazil*
[3]*Universidade Federal Fluminense., Gynecology and Obstetrics, Rio de Janeiro, Brazil*
[4]*Universidade Federal de Goiás, Gynecology and Obstetrics, Goiânia, Brazil*
[5]*Faculdade de Medicina de Ribeirão Preto - USP, Gynecology and Obstetrics, Ribeirão Preto, Brazil*

Study question: Is there any evidence on vertical transmission of the SARS-CoV-2?
Summary answer: There is a low probability of vertical transmission.
What is known already: The SARS-CoV-2 coronavirus pandemic has caused an immediate mobilization of the biomedical community with the goal of defining routes of transmission, especially concerning the maternal-fetal condition. In that sense, pregnant women have become a matter of concern due to their susceptibility to respiratory infections, as occurred with MERS and SARS, previously. The route of the viral infection is determined by the affinity of the virus to specific receptors, and the presence of the virus described in the placenta alerts to the possibility of vertical transmission.
Study design, size, duration: A systematic and non-systematic reviews and large observational studies (N > 100) assessing the risk of vertical transmission and perinatal outcomes.

The last electronic search was performed on Apr.30.2020, resulting in total of 1,245 records: We excluded 564 duplicates, and 681 records were screened based on title/abstract resulting in the exclusion of 597 records, as they were not related to vertical transmission of COVID-19. We evaluated the full text of 84 records.
Participants/materials, setting, methods: Not applicable
Main results and the role of chance: Among the systematized reviews eligible to compose our study, a total of 238 pregnancies and 174 deliveries were evaluated, of which the only one suspected vertical transmission case reported above was found, the other 5 cases that we described as suspect included low impact observational studies.

The first case in China, presents a methodology bias, which does not guarantee the occurrence of vertical transmission. In the second one, the diagnosis of possible vertical transmission was made by IgM positivity two hours after delivery, but swab PCR tests was negative. The third, in Iran, the virus in the amniotic fluid was identified by PCR during the cesarean section, but there was no positivity in the nasopharynx samples. This suggests the possibility of perioperative contamination. The fourth reported case, in Peru, showed positivity for the virus by PCR in the sample collected after 16 hours and in the control 48 hours after. Finally, two cases in Italy, where the swab was also not performed shortly after birth and the authors themselves suggest the possibility of postpartum transmission.
Limitations, reasons for caution: Due to the small number of cases included in the analyzed studies, as they are mostly non-randomized retrospectives and without clear selection criteria.

Another weakness of this study is the impossibility of stratifying by gestational age, type of test performed, intertest variation, post-birth maternal confinement and time of neonate examination.
Wider implications of the findings: it is not possible to confirm or refute the existence of any case of vertical transmission of COVID-19 until the date of article selection. Further studies with an appropriate methodological design are needed to establish whether the vertical transmission is an acceptable route and recommend specific protocols.

P-819 The dramatic impact of COVID-19 on a busy ART clinic

S. Ahuja[1], E. Fincham[1], M. Taranissi[1]

[1]Assisted Reproduction and Gynaecology Centre ARGC, Reproductive Medicine, London, United Kingdom

Study question: What was the impact of the COVID-19 pandemic on a busy central London ART clinic ?
Summary answer: The COVID-19 pandemic has had a multidimensional impact on all the clinical and functional aspects of the ART clinic.
What is known already: The COVID-19 was declared a pandemic on the 11th march 2020 by WHO. ESHRE, ASRM, BFS and ARCS published guidelines between 14th and 18th March advising clinics to suspend the start of all new fertility treatments, consider cancelling embryo transfers, and suspend elective and non-essential work. HFEA issued general direction 14 on 23rd march, on the same day as lockdown was commenced in UK, to limit treatment to gamete and embryo freezing for those likely to become prematurely infertile ie; oncology patients. They also stipulated that all ongoing treatments should be completed by 15th April.
Study design, size, duration: The impact of the COVID-19 pandemic on the working pattern of the clinic, the clinical management of the patients and the impact on staff, at the time that the fertility societies published guidelines globally, and UK lockdown was introduced, in March 2020, is presented.
Participants/materials, setting, methods: Clinic protocols were modified in line with national guidance on reducing the spread of COVID-19 infection. All patients who were already in the process of fertility treatment or at the preparation stage were advised individually regarding their options informing them about unknown impact on the pregnancy. In addition, due to the suspension of all new fertility treatments, there was a significant impact on all disciplines of staff.
Main results and the role of chance: Clinic pathways were changed to incorporate social distancing, intensified disinfection schedules, the use of PPE and introduction of virtual clinics.

In mid March 2020, there were 46 women aiming for a transfer (31 fresh, 15 frozen). All woman due to have a transfer were counselled regarding their options: cycle cancellation, embryo freezing or proceeding with an embryo transfer. Only 1/46 (2.1%) women due to have an embryo transfer cancelled the cycle due to the lockdown and travel restrictions. There were 26 women expected to start treatment cycles the following week and all their treatments were deferred. In addition, there were about 100 pregnancies (majority as a result of ART) being monitored due to their previous fertility/obstetric history. About 30 % of our staff went on sick leave due to symptoms of COVID-19 in themselves or their family members. A large proportion of the staff were furloughed. A small core team was retained to manage the existing patients.

Inspite of the disastrous effects of the pandemic globally, some positive outcomes included the seamless introduction of virtual clinics, streamlining of SOP's, more efficient working patterns with a smaller core team with personalised care for the remaining patients in this very difficult situation.
Limitations, reasons for caution: The pandemic has been evolving everyday with changes in the advice regarding social isolation, quarantine, testing protocols, the government policies, etc on a regular basis in line with the the available evidence. The above findings highlight the response of our clinic at the time of the epidemic in UK.
Wider implications of the findings: Social distancing measures are likely to continue with virtual clinics, distant teaching/consent, here to stay for the foreseeable future. There is likely to be a surge of patients as soon as treatments are restarted and strict strategies will need to be in place and strictly followed.

P-820 Low seroprevalence of SARS Cov2 IgG antibodies in a fertility setting population in Romania

C. Manolea[1], M. Bechir[2], I.A. Rugescu[3]

[1]Carol Davila University of Medicine, IVF Department - Columna Medical Center, Bucharest, Romania
[2]Regina Maria Hospital, Assisted reproduction, Bucharest, Romania
[3]National Transplant Agency, Reproductive Cells, Bucharest, Romania

Study question: Which is the seroprevalence of antibodies directed against SARS Cov2 in a fertility setting population (staff and patients) in Romania?
Summary answer: Only 2% of the people tested demonstrated the presence of IgG antibodies against the novel Coronavirus
What is known already: With a population of slightly over 19 million and 17.700 Covid-19 tests per million people, Romania is amongst the "medium hit" countries, ranking place 37 among 215 countries as regards the number of confirmed infections. As a national particularity, 1 in 7 confirmed cases is a health care worker (HCW).

The lockdown established on the 16th of March was eased starting the 15th of May providing the possibility of restarting the provision of fertility care.

Infertile patients are usually healthy 18 to 45-year-olds, forming a young and active population potentially at risk for developing asymptomatic forms of CoVid-19.
Study design, size, duration: An observational study of a cohort of asymptomatic people – staff and patients of a private fertility unit – consisting of serological testing for SARS Cov2 antibodies (IgM and IgG) undertaken between 11-19th of May 2020.
Participants/materials, setting, methods: We conducted the seroprevalence survey in 100 people (25 HCW and 75 infertile patients) working and respectively attending our private assisted reproduction facility in Bucharest.

The screened persons were aged 25-48 years, living in Bucharest and had a negative epidemiological triage. They have been tested for Ig presence of SARS Cov-2 Ig M and IgG antibodies using an in Vitro chemiluminescence immunoassay (CLIA).
Main results and the role of chance: Out of the 25 HCW tested by CLIA, 1 nurse had a positive result for the presence of SARS-Cov-2 Ig G which means a 4% crude seroprevalence amongst the tested HCW in our clinic.

Regarding the 75 fertility-seeking patients, serological sampling revealed only 1 woman with positive Ig G, so a 1.33% crude seroprevalence of SARSCov2 protective antibodies.

None of the persons undergoing serological testing showed evidence of positive Ig M.
Limitations, reasons for caution: The major limitation lies in the small number of cases, but this is inherent with the short time frame from reopening to the date of abstract submission. It is still a glimpse of a real-life situation in a selected population confined to HCW and patients in a fertility setting
Wider implications of the findings: The seroprevalence of anti-SARS-Cov2 IgGs in this study is consistent with the reported low immunization in the general population. For infertile patients, this could mean that maintaining preventive measures would enhance the safety of restarting treatments.

Knowledge on immunization of fertility HCW could inform decision making in activity organization.

P-821 Patients perspectives on the sudden discontinuation and imminent restart of their fertility treatment due to the COVID-19 pandemic

F. Vanden Meerschaut[1], I. Stuyver[1], K. Tilleman[1], D. Stoop[1]

[1]Ghent University Hospital, Department for Reproductive Medicine, Gent, Belgium

Study question: What are the views and attitudes of fertility patients towards treatment discontinuation and the modalities of treatment resumption during the COVID-19 pandemic?

Summary answer: Patients support the decision to discontinue fertility treatments during lockdown. However, they encourage restart of treatment under strict safety conditions as soon as possible.

What is known already: The COVID-19 pandemic brought unprecedented challenges to healthcare systems worldwide as many countries or cities were put into lockdown with cancellation or postponement of all non-urgent medical care. Consequently, but also precautionary to avoid COVID-19 exposure during (early) pregnancy, leading scientific fertility societies advised for the abrupt discontinuation of most fertility treatments. It has been well established, well before the current pandemic, that fertility treatments lead to significant psychological burden. In that view, the prospect of considerable delays in conception inevitably impacts the patients' wellbeing.

Study design, size, duration: An online anonymous questionnaire, to explore the patient perspectives on the abrupt discontinuation and imminent restart of their fertility treatment, was developed and sent to 1377 patients. A second and third reminder, both after one week, still need to be send. The questionnaire consists of 30 questions and the following answering options: discrete quantitative and nominal categorical variables, scoring questions (Likert scale 1 to 10) and free text fields.

Participants/materials, setting, methods: This study included patients from a university-based fertility center who visited the clinic between January and April 2020. Eligible patients were supposed to start treatment or were undergoing a fertility treatment at the moment of sudden discontinuation of non-urgent hospital activities due to the COVID-19 pandemic.

Main results and the role of chance: Preliminary response rate is 16.1% (n = 222/1377). On a Likert scale of 1 (do not agree) to 10 (fully agree), the mean score for understanding the decision to stop fertility treatment was 7.7 (SD 2.43), whereas when asking if they would have preferred to complete their treatment the score was 6.9 (SD 3.06). The mean score expressing sadness related to the discontinuation of treatment was 7.3 (SD 2.86) (1 = no sadness to 10 = very sad). 24.8% of the respondents believed this delay will have a negative impact on future success rates. When asking if fertility treatment should be prioritized compared with other (non-urgent) medical treatments, the mean score was 6.4 (SD 2.24) (1 = non-priority to 10 = highest priority). Top-5 criteria to prioritize patients for resuming treatment were: female age (83.3%), amount of time being in treatment (55.0%), diagnosis (45.5%), rank of treatment cycle (38.3%) and medical history (32.9%). Respondents were pro safety measures to diminish SARS-CoV-2 transmission during treatment and preferred the following alternative communication tools: telephone call (7.0, SD 2.36), video call (6.3, SD 2.71) and written instructions (6.1, SD 2.61) (1 = do not prefer to 10 = mostly prefer).

Limitations, reasons for caution: Questionnaires cannot fully capture emotional responses or feelings. Although the preliminary response rate is already significant, the results cannot be extrapolated to other centers since the impact of COVID-19 and local healthcare organization might be substantially different.

Wider implications of the findings: Patients suffer from discontinuation of treatment due to the COVID-19 pandemic and are eager to restart treatment in safe conditions. In case a second wave of COVID-19 would require future shutdowns, fertility treatments should be considered as priority medical care, at least for certain groups of patients.

Trial registration number: NCT04396210

Funding source: Not Applicable

P-822 Status quo and interfering factors of posttraumatic stress disorder symptoms screening in gravidas underwent assisted reproductive technology in the COVID-19 epicenter Wuhan city

M. Wang[1], L. Yang[1], L. Jin[1]

[1]Tongji Hospital- Tongji Medical College- Huazhong University of Science and Technology, Reproductive Medicine Center, Wuhan, China

Study question: Does COVID-19 epidemic cause posttraumatic stress disorder (PTSD) symptoms in gravidas who underwent assisted reproductive technology (ART) in epicenter Wuhan city?

Summary answer: COVID-19 epidemic may increase the risk of PTSD symptoms among gravidas underwent ART in Wuhan city.

What is known already: COVID-19 epidemic has caused hundreds of thousands of deaths worldwide, and Wuhan city was once the epicenter in China. Post-traumatic stress disorder is the most common psychological dysfunction caused by exposure to traumatic events. The health conditions of gravidas underwent ART in Wuhan city during the COVID-19 epidemic deserve attention of reproductive medicine doctors.

Study design, size, duration: A total of 3326 pregnant women who met the inclusion criteria in Reproductive Medicine Center of Tongji Hospital-Tongji Medical College, Huazhong University of Science and Technology.were included. Random sampling was conducted according to the random number table, and 800 questionnaires were given out by our research assistants through the Internet. Participants were asked to accomplish four questionnaires, including PTSD Checklist-Civilian version, Mishel's Uncertainty in Illness Scale-Adult, Simplified Coping Style Questionnaire and Perceived Social Support Scale.

Participants/materials, setting, methods: The PTSD symptom scores of gravidas with different characteristics were compared using non-parametric rank sum test (Mann-Whitney test and Krukal-Wallis test). Multiple linear regression was used to analyze the influence of different characteristics of gravidas on PTSD symptom score. A structural equation model was established to analyze the path analysis of PTSD symptoms with disease uncertainty, social support and coping style.

Main results and the role of chance: A total of 488 gravidas who visited Reproductive Medicine Center of Tongji Hospital-Tongji Medical College, Huazhong University of Science and Technology during April 2019 to January 2020 were included in this study. 12.3% of them were considered to be high-risk of PTSD during COVID-19 epidemic. The result of multiple linear regression showed that a history of chronic disease and the frequency of checking the epidemic situation were positively related with PTSD symptom scores, but pregnancy complications, sleep quality, whether relatives were isolated, fear of infection, confidence in current prevention methods, and bleeding or abdominal pain during the closure period were negatively related with PTSD symptom scores. In addition, uncertainty in illness had a positive effect on PTSD directly or through coping styles, while perceived social support affect PTSD negatively completely through coping styles.

Limitations, reasons for caution: Firstly, coping style was the only intermediary variable analyzed in this study. Secondly, due to the epidemic situation, we failed to carry out psychiatric examination for patients with positive PTSD symptoms. Finally, the live birth rate and neonatal complications in PTSD symptoms gravidas are needed follow-up investigation.

Wider implications of the findings: Medical workers should pay more attention to mental health of gravidas underwent ART during the epidemic of COVID-19. PTSD symptoms may be relieved by reducing the uncertainty in illness, giving sufficient social support and strengthening positive coping styles.

Trial registration number: not applicable

P-823 COVID-19 among assisted reproduction patients in Spain. What should we do to stop the spread of infection

G. Barrenetxea Ziarrusta[1], I. Romero[1], R. Celis[2], A. Abio[3], M. Bilbao[4], J.I. Arambarri[5], J. Barrenetxea[6]

[1]REPRODUCCION BILBAO, Gynecolgy & Assisted Reproduction, BILBAO, Spain
[2]Reproduccion Bilbao, Gynecology & Assister Reproduction, Bilbao, Spain
[3]Reproduccion Bilbao, Gynecology & Assisted Reproduction, Bilbao, Spain
[4]Reproduccion Bilbao, Gynecology & asisted Reproduction, Bilbao, Spain
[5]Reproduccion Bilbao, Gynecology & Obstetrics, Bilbao, Spain
[6]Osakidetza, Gynecology and Obstetrics, Bilbao, Spain

Study question: Once assisted reproduction (AR) treatments are reinitiated, is it enough to screen patients and staff by clinical means or should we assess them more thoroughly?

Summary answer: From a public health perspective, detection and quick isolation of asymptomatic patients is of paramount importance to discontinue the spread of the disease.

What is known already: Up to 18th of May 2020, almost 5,000,000 cases with COVID-19 were diagnosed and more than 300,000 death cases were recorded.

It has been stated by ESHRE and other organizations that any risk of viral contamination from SARS-CoV-2 to gamete and embryos in the IVF laboratory is likely to be minimal and pregnant women should not be considered at higher risk for developing severe infection,

Detection of asymptomatic patients, who can spread the disease, is of paramount importance.

Presently, RT-PCR for RNA detection is the only acknowledged method to rapidly and accurately detect COVID-19 infection in humans.

Study design, size, duration: The study was carried out from May 4th to 18th (after restart of clinical activity at AR centers).

Observational study involving 194 infertility patients and 19 staff members of an AR center. Data are reported as percentages. A chi-squared test was used for comparisons of qualitative variables (significance set at p<0,05).

The study was approved by Institutional Review Board . All the procedures were in accordance with the Helsinki Declaration of 1964 and later amendments.

Participants/materials, setting, methods: First, a clinical and epidemiological survey was completed by both, patients and staff members.

Second, those patients scheduled for an ovarian puncture for egg retrieval and/or embryo transfer were assessed by a double diagnostic test: a RT-PCR to detect SARS-CoV-2 RNA from nasopharyngeal aspirate and serologic test to determine the presence of, either, IgG or IgM against the virus. The double test was also performed on the partners of the patients.

Main results and the role of chance: Sixty-eight and 19 RT-PCR and serologic immunoglobulins determinations were performed among patients and staff members respectively.

Among patients, 30,4% were confined at home during lockdown, 27,8% were teleworking, 25,8% were working at the office, whereas 16 % were on sick leave (from diseases different of COVID-19).

Five patients reported previous symptoms like fever, cough, diarrhea, muscle aches, in the past two weeks. However, only 2 out of these patients had been previously offered to perform any diagnostic test. No symptomatic patient had positive RT-PCR or serologic results at our setting. Among 189 asymptomatic patients, 2 (1,1%) had positive serologic determination of IgG and/or IgM. No patient had a positive RT-PCR determination.

Even though 12 (6,2%) of the patients reported that a relative had been diagnosed of COVID-19 only one of them (8,3%) had had any diagnostic test performed prior to attending at our center.

There was a positive RT-PCR case among staff members (5,6%). It was an asymptomatic case with positive determination of IgG and IgM. The test was repeated after an asymptomatic period of 3 weeks and the virus was not cleared. The patient remains asymptomatic. A new test is to be performed in 3 weeks-time.

Limitations, reasons for caution: The results in our series show a low percentage of positive RT-PCR and a low presence of antibodies against SARS-CoV-2.

Although this figure may be due to the lockdown itself, it may show that the assessed patients do not represent properly general population.

Wider implications of the findings: Even though the low percentage of positive cases, we should take into account that asymptomatic patients may be infected by the SARS-CoV-2 and, thus, may spread the infection.

The only positive cases in our series were asymptomatic, highlighting the importance of performing the PCR and serologic tests.

Trial registration number: non-applicable

P-824 Psychological themes with restarting fertility treatment in the era of Covid-19: A tertiary centre

A. Pericleous-Smith[1], M. Mascarenhas[1], H. Bhandari[1]

[1]Leeds Teaching Hospitals, Leeds Fertility, Leeds, United Kingdom

Study question: What are the psychological experiences of men and women on learning that fertility treatments are being restarted after they were suspended in view of Covid-19?

Summary answer: Whilst most expressed positive emotions on learning of the restart of fertility treatment, a substantial proportion expressed ambivalence or a wish to defer fertility treatment

What is known already: Infertility and the unpredictability of the outcome of fertility treatment are known psychological stressors. The Covid-19 pandemic has led to an unprecedented suspension of fertility treatment across Europe. The suspension of fertility treatment and the uncertainty as to when this suspension might be lifted has created an additional psychological burden on men and women seeking fertility assistance. There has been much recent research and attention in the lay-press on this psychological impact – especially on those whose biological clock is 'ticking'. Fertility treatment suspension is gradually being lifted in some European countries, depending on local control of the pandemic.

Study design, size, duration: Remote counselling sessions of 60 minutes duration with both individuals and couples were carried out between 1st May 2020, on the day the UK government and the HFEA announced that fertility clinics can resume fertility treatment. Data available until the 20th May 2020 from 48 counselling sessions (including 31 individual and 17 couple counselling sessions) is summarised here with further data to be available at the time of presentation.

Participants/materials, setting, methods: Thirty-five participants were married, six unmarried, but in stable relationships and seven single women. Counselling offers a safe place for patients to explore any uncertainties and manage expectations. Sessions were undertaken remotely via telephone (n = 34; 71%) or video (n = 14; 29%) consultation. Each session included open questions of the government's announcement and participants shared their experiences, perceptions and concerns of clinics re-opening including any communication they had received from their clinic.

Main results and the role of chance: The 48 participants were aged between 18 and 48 years (average age 34.11 years). Some (31%) participants reported the announcement as good news, 69% expressed uncertainties, ambivalences and concerns and one participant reported suicidal ideation.

Some patients believed treatment would resume on 11th May 2020 (date from when clinics could apply to resume treatment). Clarification was provided, which resulted in patients' perceptions of time frames ranging from "with next cycle", "in 4-6 weeks", to "seven months".

The majority (n = 27; 56%) reported having attempted to contact the clinic. Patients felt coping strategies, stress and anxiety could be better managed if they had (i) contact from the clinic and (ii) clearer time frame to resume their individual treatment.

Those with pre-existing relationships with clinic staff expressed concerns over relational dynamics with the use of personal protective equipment and partners unable to be present for appointments.

Several raised anxieties in relation to safety of pregnancy and impact of second pandemic wave on their treatment. Some reported changes in financial circumstances affecting their ability to proceed with treatment.

A few reported waiting "to see" how clinics and the pandemic "pan out" with three couples planning to delay by at least 1 year.

Limitations, reasons for caution: The sample size is limited, and the profile of patients who choose to have counselling might not be the same as the overall population of patients seeking fertility treatment. Therefore, our findings should be taken as descriptive and may not be suitable for extrapolation to the outpatient clinic setting.

Wider implications of the findings: Most patients had positive thoughts and emotions on hearing the news that fertility treatments could recommence. Clinics should take note that patients felt that contact initiated by the clinic rather than patients regarding restarting treatment and providing better time scales might help to manage their stress and anxiety.

P-825 Impact of COVID19 pandemic on fertility treatment : a Tunisian Experience

H. ELLOUMI[1], M. Ben khelifa[1], S. Mnallah[1], M. Khrouf[2], K. Terras[2], M.H. Ben aribia[1], F. Zhioua[2], M. Benkhalifa[1], K. Mahmoud[2]

[1]fertility center FERTILLIA- Tunis- Tunisia., Laboratory of reproductive biology, tunis, Tunisia

[2]fertility center FERTILLIA- Tunis- Tunisia., Gynecology departement of the fertility center FERTILLIA, tunis, Tunisia

Study question: Here we aim to investigate the impact of the current covid-19 pandemic on patients who underwent reproductive treatment compared to COVID19 pre-pandemic period

Summary answer: The current COVID19 pandemic has a slight negative effect on outcome fertility treatments

What is known already: During the COVID19 pandemic, strict measures have been adopted by tunisian governement, and as a result we have observed a slow progression of the disease. So, we have observed radical changes in health care practices. Reproductive Medicine Societies have advised people not to undergo infertility treatment . The lockdown of ART centers was detrimental for society as a whole, and infertility patients in particular. In our ART clinic, the laboratory provided limited service for the emergency procedures, and for patients in active treatment cycles.

Study design, size, duration: Retrospective descriptive study evaluating activity during COVID19 pandemic (Group A) and pre-pandemic period (Group B) in an ART clinic. In this period (March and April 2020), we had remaining activity concerning the following acts : intrauterine insemination (IUI), In vitro fertilisation (IVF) and frozen-thawed embryo transfer (FET). We screened all patients for exposure and risk factors for COVID19 before being authorized to join ART unit. Treatment of Patients who failed screening, was cancelled.

Participants/materials, setting, methods: About IVF cycles, the freeze-all strategy was proposed to all couples, but some couples insisted on fresh embryo transfer. All transfers were made on day 3 post-pickup. In all cases, the couple signed a consent form. An online survey was sent to our current patients to estimate psychological COVID19 pandemic effect and outcomes of infertility treatment. All statistical analyses were performed using SPSS software. A significant difference was accepted when the p value was <0.05.

Main results and the role of chance: A total number of listed acts were performed during pandemic and prepandemic period respectively: IUI cycles: 27 vs 49 ; IVF cycles:202 vs 450 and FET cycles: 60 vs 120. Four couples could not have access to our ART center because they failed screening for exposure and risk factors for COVID19. We called all patients who had treatment during COVID19 pandemic in our center, two and four weeks later, and no patients became sick from COVID19. The online survey indicate that 80% of respondents found that pandemic situations have an important emotional impact with 50% rating it to be equivalent to loss of chance to conceive. Concerning IUI cycles, no signifiant difference was observed of CPR between the two groups (A:13% ; B:12.5% ; p<0.05). Using an intention to analyse IVF cycles data, 56% of couples only accepted a freeze all strategy. We identified significant diffrence concerning Clinical pregnancy rate, and miscarriage rate in groups A and B were (28.5% vs 32.9 % ; 29% vs 24%) respectively (p<0.05). Parameters of the ovarian stimulation were comparable between the two groups. Concerning FET cycles no signifiant difference was observed in terms of CPR and MR between the two groups .

Limitations, reasons for caution: This retrospective data set included a variety of treatment and protocols used in two periods with different characteristics. In addition, the rates observed concerned all the patients treated, the comparison of rates between treatments, should be subject to further investigation

Wider implications of the findings: Given the severity of the COVID19 pandemic, the physical and emotional impact of this unprecedented threat cannot be underestimated in our fertility patients.

Study question: What were the perceptions of infertility patients and the factors contributing to their psychological distress, following suspension of fertility treatments during the COVID-19 pandemic?

Summary answer: Higher self-mastery and greater perceived social support were associated with lower distress. Feeling helpless was associated with higher distress. Background characteristics had no significant contribution.

What is known already: Infertility diagnosis and treatment frequently result in significant psychological distress. Personal resources play an important protective role in times of crisis, helping to reduce levels of distress. This is the first study, to the best of our knowledge, to describe the psychological impact of global suspension of fertility treatments and provide a window to patient's state of mind in this particular complex time.

Study design, size, duration: Cross-sectional questionnaire study including patients in a tertiary hospital, whose fertility treatment was suspended following the COVID-19 pandemic. The survey has been delivered to 297 patients within 12 days at the beginning of April 2020

Participants/materials, setting, methods: The self-administered questionnaire included items addressing: 1. Patient's demographic characteristics, 2. Anxiety related to COVID-19 infection risk and level of social support (COVID-19 anxiety score and social support score were calculated), 3. Patient's perception of the new guidelines and description of subsequently related emotions, and 4. Two validated scales assessing levels of emotional distress (MHI-5) and Self-mastery. Multivariate analysis was conducted to assess factors alleviating or exacerbating emotional distress during the COVID-19 pandemic.

Main results and the role of chance: One hundred sixty-eight patients completed the survey for a response rate of 57%. Study variables in the regression model explained 38.6% of the variance in psychological distress experienced by patients during treatment suspension. None of the background characteristics (e.g. age, marital status, economic level, duration of treatments, and parity) had a significant contribution. Higher self-mastery and greater perceived social support were associated with lower distress (p<0.01). Feeling helpless following the suspension of treatments was associated with higher distress (P<0.01). Seventy two percent of patients wished to resume treatment at the time of survey despite the ministry of health's decision.

Limitations, reasons for caution: This pandemic, its length and implications are unknown, therefore, the ability to draw conclusions about the psychological consequences of the crisis is limited at this point of time. The study was conducted in one IVF unit which may influence its generalizability, however, the high response rate of 56.6%, enabled heterogeneity.

Wider implications of the findings: Study findings suggest that attention should be paid to strengthening and empowering patients' personal resources together with directly confronting and containing feelings of helplessness. In line with the ESHRE guidelines, especially at time of high levels of distress, it is imperative for caregivers to offer emotional support.
